Foreword

Drs. Steele, Hull, Hyman, Maykel, Read, and Whitlow and their respective chapter authors are to be congratulated on the successful completion of the fourth edition of *The ASCRS Textbook of Colon and Rectal Surgery*. This edition is greatly enhanced with new authors for each chapter reflecting international experts in the treatment of colorectal disease, expansion of online videos, and a continued emphasis on algorithms and evidence-based recommendations. This edition also serves as the first step in expansion to an online modular platform, facilitating dynamic updates of content.

The ASCRS Textbook of Colon and Rectal Surgery is unique. The concept of a definitive text for state-of-the-art information for all health professional learners and practitioners, including residents in training in colon and rectal surgery as well as fully trained surgeons in practice, was conceived, implemented, and supported by the American Society of Colon and Rectal Surgeons in 2007. It was the recognition of an idea initially conceived by Bruce Wolf, co-implemented by Jim Fleshman, and fully supported by the ASCRS Executive Council. All chapters have been extensively referenced, authoritatively written and illustrated, and have included ASCRS clinical practice guidelines. The success of the first edition led to second and third editions in 2011 and 2016. With the rapid expansion of knowledge, technology, and techniques, each edition has been meticulously and thoroughly updated to reflect state-of-the-art, evidence-based practice. The editors have been continuously refreshed just like the content to keep the book fresh and contemporary. With the fourth edition, the torch has been picked up and carried by each group of editors since the inception.

The textbook remains fully supported and endorsed by the American Society of Colon and Rectal Surgeons: the work is a product of and for the Society, owned by our society with all proceeds flowing back to the Education Fund of the society to continue to support a long-term commitment of the organization to the lifelong education not just of colon and rectal surgery trainees but all clinicians.

Preface

One given definition of the word *textbook* is "a book used as *a standard* work for the study of a particular subject." Our collective goal for the fourth edition of *The ASCRS Textbook of Colon and Rectal Surgery* was to make this volume *the standard* for the study of colon and rectal surgery, providing a valuable resource for surgeons and health care providers at all stages of their career caring for patients with colorectal disease. This edition provides all newly written chapters, organized around the "pillars" of colorectal disease: perioperative (including endoscopy); anorectal disease; benign disease (including inflammatory bowel disease); malignancy; pelvic floor disorders; and a "miscellaneous" section that covers aspects both inside and beyond the operating room.

Colon and rectal surgery is in a golden age; our special skills and expertise are highly valued by patients and colleagues alike. Colon and rectal training programs continue to thrive, attracting the very best and brightest surgery residents – they are the rock stars of their generation! We hope this textbook will also expose the many critical gaps in our knowledge base and inspire the next generation to answer them through thoughtful and high-level scientific inquiry.

Finally, we would like to thank our Developmental Editor Elektra McDermott for her extraordinary efforts and thoroughness in overseeing and ensuring its timely completion, along with each chapter author and coauthor(s) for their devotion to this task and to the mission of the ASCRS. We are deeply indebted to our teachers and mentors, who have been our heroes and generously shared their knowledge, experience, and enthusiasm over the years. We devote this edition to our trainees, whose energy, intellectual curiosity, and commitment to excellence drive us every day to be better. Pass it forward!

Contents

Part I Perioperative/Endoscopy

1 **Anatomy and Embryology of the Colon, Rectum, and Anus** 3
Joseph C. Carmichael and Steven Mills

2 **Colonic Physiology** 29
Glenn T. Ault and Jennifer S. Beaty

3 **Anorectal Physiology** 41
Pasithorn A. Suwanabol and Scott E. Regenbogen

4 **Endoscopy** 51
Matthew D. Zelhart and Brian R. Kann

5 **Endoscopic Management of Polyps and Endolumenal Surgery** 79
William Forrest Johnston and Emre Gorgun

6 **Preoperative Evaluation in Colorectal Patients** 95
Ron G. Landmann and Todd D. Francone

7 **Optimizing Outcomes with Enhanced Recovery** 121
Julie Thacker and Nancy Morin

8 **General Postoperative Complications** 141
Daniel I. Chu and David J. Maron

9 **Anastomotic Construction** 157
H. David Vargas and David A. Margolin

10 **Anastomotic Complications** 189
Charles M. Friel and Cindy J. Kin

Part II Anorectal Disease

11 **Hemorrhoids** 209
Jennifer S. Davids and Timothy J. Ridolfi

12 **Anal Fissure and Anal Stenosis** 231
V. Liana Tsikitis and Slawomir Marecik

13 **Cryptoglandular Abscess and Fistula** 249
Eric K. Johnson and Greta Bernier

14 **Rectourethral and Complex Fistulas: Evaluation and Management** 271
Jan Rakinic and W. Brian Perry

15 **Rectovaginal Fistula** 281
Brooke H. Gurland and Jon D. Vogel

16 Pilonidal Disease and Hidradenitis Suppurativa 293
Anuradha R. Bhama and Bradley R. Davis

17 Dermatology and Pruritus Ani 311
Konstantin Umanskiy and Evangelos Messaris

18 Sexually Transmitted Infections of the Colon and Rectum 323
Michelle Cowan and Andrew T. Schlussel

19 Anal Intraepithelial Neoplasia 343
Wolfgang B. Gaertner and Mukta K. Krane

Part III Malignant Disease

20 Anal Cancer 357
Dana R. Sands and Najjia N. Mahmoud

21 Presacral Tumors 375
Scott R. Kelley and Eric J. Dozois

22 Sporadic and Inherited Colorectal Cancer: How Epidemiology and Molecular Biology Guide Screening and Treatment 397
Sean C. Glasgow and Karin M. Hardiman

23 Management of Malignant Polyps 413
Dennis Yang and Mark H. Whiteford

24 Colorectal Cancer: Preoperative Evaluation and Staging 429
Amanda V. Hayman and Carol-Ann Vasilevsky

25 Colon Cancer Surgical Treatment: Principles of Colectomy 451
Evie H. Carchman and Matthew F. Kalady

26 Rectal Cancer: Neoadjuvant Therapy 463
Steven R. Hunt and Matthew G. Mutch

27 Rectal Cancer: Local Excision 479
John R. T. Monson and Rebecca Hoedema

28 Rectal Cancer: Nonoperative Management 491
Julio Garcia-Aguilar and Rodrigo Oliva Perez

29 Proctectomy for Rectal Cancer 509
John Migaly and Eric G. Weiss

30 Colorectal Cancer: Postoperative Adjuvant Therapy and Surveillance 529
David A. Kleiman and David W. Larson

31 Colorectal Cancer: Management of Distant Metastases 547
Traci L. Hedrick

32 Locally Recurrent Rectal Cancer 561
Michael J. Solomon

33 Appendiceal Neoplasms 577
Sanda A. Tan and Luca Stocchi

34 Gastrointestinal Stromal Tumors, Neuroendocrine Tumors, and Lymphoma 587
Karim Alavi and Marylise Boutros

35 Cytoreductive Surgery and Hyperthermic Intraperitoneal Chemotherapy 605
Michael A. Valente and Brendan John Moran

36 Colorectal Cancer: Minimally Invasive Surgery 619
Antonino Spinelli

37 Minimally Invasive Complete Mesocolic Excision with Extended Lymphadenectomy for Colon Cancer 643
Patricia Sylla

Part IV Benign Colorectal Disease

38 Colonic Diverticular Disease 665
Jason F. Hall and Willem A. Bemelman

39 Large Bowel Obstruction 681
Daniel L. Feingold and Fergal J. Fleming

40 Lower GI Hemorrhage 699
Mehraneh D. Jafari and Joshua I. S. Bleier

41 Endometriosis 715
Heidi Chua and Michael J. Snyder

42 Benign Colorectal Disease Trauma of the Colon and Rectum 729
Reza Askari, Ali Salim, and Matthew Martin

43 Inflammatory Bowel Disease: Pathobiology 743
Benjamin D. Shogan and Pokala Ravi Kiran

44 IBD Diagnosis and Evaluation 751
Mantaj S. Brar and Helen MacRae

45 Medical Management of Ulcerative Colitis 765
Amy L. Lightner and Scott A. Strong

46 Medical Therapy for Crohn's Disease 781
Radhika K. Smith and Stefan D. Holubar

47 Anorectal Crohn's Disease 799
Emily Steinhagen and Andrea Chao Bafford

48 Crohn's Disease: Surgical Management 813
Lisa M. Cannon and Alessandro Fichera

49 Ulcerative Colitis: Surgical Management 835
Karen N. Zaghiyan and Phillip R. Fleshner

50 Complications of the Pelvic Pouch 851
Jean H. Ashburn and David W. Dietz

51 Infectious Colitis 865
Craig A. Reickert and Maher A. Abbas

52 *Clostridium difficile* Infection 879
Ian M. Paquette and David B. Stewart

53 Radiation, Microscopic, and Ischemic Colitis 893
Jamie A. Cannon and Gregory D. Kennedy

54 Intestinal Stomas 907
Michael F. McGee and Peter A. Cataldo

55 Abdominal Wall Reconstruction and Parastomal Hernia Repair 947
Clayton C. Petro, Ajita Prabhu, and Michael J. Rosen

Part V Pelvic Floor Disorders

56 Functional Disorders After Colorectal Surgery/IBS 963
Hiroko Kunitake and Kyle Staller

57 Common Tests for the Pelvic Floor 979
Amy J. Thorsen and Leslie Roth

58 Evaluation of Constipation and Treatment of Abdominal Component 995
Kelly A. Garrett and James W. Ogilvie Jr

59 Treatment of Difficult/Obstructive Defecation 1007
Massarat Zutshi and Lucia Camara Castro Oliveira

60 Rectal Prolapse 1019
Margarita Murphy and Sarah A. Vogler

61 Fecal Incontinence: Evaluation and Treatment 1035
Giovanna da Silva and Anders Mellgren

62 Low Anterior Resection Syndrome (LARS) 1047
Liliana Bordeianou and Craig A. Messick

63 Sexual Function After Colorectal Surgery in Women 1055
Deborah S. Keller and Jenny Alex Ky-Miyasaka

64 Male Genitourinary Dysfunction as a Consequence of Colorectal Surgery 1067
Nathalie Mantilla and Shane McNevin

65 Middle and Anterior Pelvic Compartment: Issues for the Colorectal Surgeon 1077
Danielle Patterson, Susan L. Gearhart, and Elisa Birnbaum

Part VI Miscellaneous

66 Pediatric Colorectal Disorders 1089
Erin A. Teeple and Kenneth S. Azarow

67 Considerations for Geriatric Patients Undergoing Colorectal Surgery 1105
Nicole M. Saur and Kirsten Bass Wilkins

68 Healthcare Economics 1117
Walter R. Peters and Teresa deBeche-Adams

69 Ethical Considerations (Conflict of Interest, Surgical Innovation, and End of Life) 1127
W. Donald Buie and Anthony R. MacLean

70 Welcome to Litigation 1139
Dennis K. Ames

71 Quality 1161
Elizabeth C. Wick and David A. Etzioni

72 Practice Management 1171
Jennifer D. Rea and Jeffrey L. Cohen

Index 1189

Part I

Perioperative/Endoscopy

Anatomy and Embryology of the Colon, Rectum, and Anus

1

Joseph C. Carmichael and Steven Mills

Key Concepts

- The dentate line represents a true division between embryonic endoderm and ectoderm.
- The location of the anterior peritoneal reflection is highly variable and can be significantly altered by disease such as rectal prolapse.
- The right and left ischioanal space communicate posteriorly through the deep postanal space between the levator ani muscle and anococcygeal ligament.
- The junction between the midgut (superior mesenteric artery) and the hindgut (inferior mesenteric artery) leads to a potential watershed area in the area of the splenic flexure.
- There is a normal, three-stage process by which the intestinal tract rotates during development beginning with herniation of the midgut followed by return of the midgut to the abdominal cavity and ending with its fixation.

Anatomy of the Anal Canal and Pelvic Floor

Textbooks of anatomy would define the "anatomic" anal canal as beginning at the dentate (pectinate) line and extending to the anal verge. This definition is one defined truly by the embryology and mucosal histology. However, the "surgical" anal canal, as first defined by Milligan and Morgan [1], extends from the anorectal ring to the anal verge. The surgical definition of the anal canal takes into account the surrounding musculature that is critical to consider during the conduct of operations from low anterior resection to anal fistulotomy. The surgical anal canal is formed by the internal anal sphincter, external anal sphincter, and puborectalis (Fig. 1.1) and is easily identified on digital examination, ultrasound imaging [2], and magnetic resonance imaging (MRI) [3].

On average, the surgical anal canal is estimated to be longer in males than in females. Intraoperative measurements of the posterior anal canal have estimated the surgical anal canal to be 4.4 cm in men compared with 4.0 cm in women [4]. In addition, the anal canal was shown to be a unique muscular unit in that its length did not change with age. However, when using MRI, the anatomy of the anal canal has been characterized differently. MR imaging did not show a difference in the length of the posterior anal canal in men and women but did show that the anterior and posterior external anal sphincter length (not including puborectalis) was significantly shorter in women [5].

The anal canal forms proximally where the rectum passes through the pelvic hiatus and joins with the puborectalis muscle. Starting at this location, the muscular anal canal can be thought of as a "tube within a tube." The inner tube is the visceral smooth muscle of the internal anal sphincter and longitudinal layer that is innervated by the autonomic nervous system. The outer muscular tube consists of somatic muscles including the components of the puborectalis and external anal sphincter [6]. It is the outer muscular tube that provides conscious control over continence and is strengthened during Kegel exercises. The external anal sphincter extends distal to the internal anal sphincter, and the anal canal terminates at the anal verge where the superficial and subcutaneous portions of the external anal sphincter join the dermis.

Anal Canal Epithelium

The proximal anal canal has a pink appearance and is lined by the columnar epithelium of the rectal mucosa. Six to 12 mm proximal to the dentate line, the anal transition zone (ATZ) begins. The ATZ appears purple in color and represents an area of gradual transition of columnar epithelium to squamous epithelium. In a parallel to cervical anatomy, the

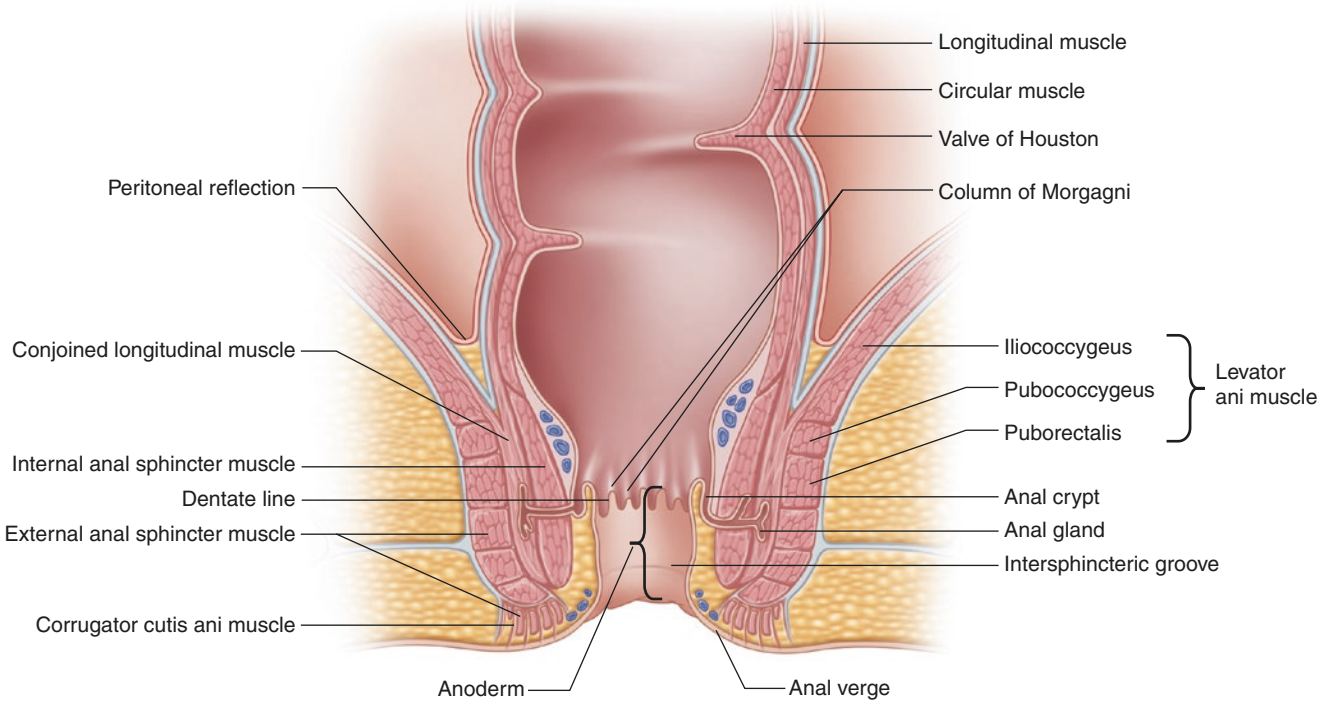

Fig. 1.1 Anal canal

ATZ is the area in which the majority of human papillomavirus-related dysplastic lesions are found in the anal canal [7]. The columns of Morgagni are noted in this area where redundant columns of tissue are noted with anal crypts at their base. This forms the rippled dentate line (or pectinate line) which can be most easily identified by locating the anal crypts at the base of the anal columns (columns of Morgagni). Anal crypts are connected to underlying anal glands which are the presumed source of sepsis in the majority of anorectal abscesses and fistula. On average, there are six anal glands surrounding the anal canal (range, 3–12) [6, 8, 9], and they tend to be more concentrated in the posterior quadrants. More than one gland may open into the same crypt, and some crypts may not be connected to anal glands. The anal gland ducts proceed inferior and lateral from the anal canal and enter the submucosa where two-thirds enter the internal anal sphincter and half terminate in the intersphincteric plane [8]. It is theorized that obstruction of these ducts leads to anal abscess and fistula [6]. Knowledge of the anatomy also explains why the internal opening of a "cryptoglandular" anal fistula should typically be at the dentate line.

Distal to the dentate line, the anoderm begins and extends for approximately 1.5 cm. According to Milligan and Morgan, anoderm or "anal canal skin… has the structure of skin, but there are no hairs and sweat glands and it consists of modified squamous transitional epithelium" [10]. In other words, anoderm has squamous histology and is devoid of hair, sebaceous glands, and sweat glands. At the anal verge, the anal canal lining becomes thickened and pigmented and contains hair follicles – this represents normal skin.

The dentate line represents a true division between embryonic endoderm and ectoderm. Proximal to the dentate line, the innervation is via the sympathetic and parasympathetic systems, with venous, arterial, and lymphatic drainage associated with the hypogastric vessels. Distal to the dentate line, the innervation is via somatic nerves with blood supply and drainage from the inferior hemorrhoidal system.

Internal Anal Sphincter

The internal anal sphincter (IAS) is the downward continuation of the circular smooth muscle of the rectum and terminates with a rounded edge approximately 1 cm proximal to the distal aspect of the external anal sphincter. 3D imaging studies of this muscle demonstrate the overall volume does not vary according to gender, but the distribution is different with women tending to have a thicker medial/distal internal anal sphincter [11]. Overall, the IAS was found to be approximately 2 mm in thickness and 35 mm in length. The authors note that on any study, it is difficult to identify the proximal portion of the IAS as it is a continuation of the wall of the lower rectum.

Conjoined Longitudinal Muscle

The anatomy and function of the perianal connective tissue is often overlooked but plays a significant role in normal anorectal function. Measuring approximately 0.5 mm to 2.0 mm in thickness, the conjoined longitudinal muscle (or conjoined longitudinal coat) lies in between the internal and external anal sphincters. It begins at the anorectal ring as an extension of the longitudinal rectal muscle fibers and descends caudally joined by fibers of the puborectalis muscle [12]. At its most caudal aspect, some of the conjoined longitudinal muscle fibers (referred to as *corrugator cutis ani muscle*) traverse the distal external anal sphincter and insert into the perianal skin, and some enter the fat of the ischiorectal fossa. Fibers of the conjoined longitudinal muscle also pass obliquely and caudally through the internal anal sphincter to interlace in a network within the subepithelial space. These subepithelial smooth muscle fibers were originally described by Treitz in 1853 [13] and have been referred to as Treitz's muscle. They have also been referred to as *corrugator cutis ani*, *musculus submucosae ani*, *mucosal suspensory ligament*, and *musculus canalis ani* [14]. It has been hypothesized by Thomson that disruption of Treitz's muscles results in anal cushion prolapse, vascular outflow obstruction, and hemorrhoidal bleeding and thrombosis [15]. Haas and Fox have hypothesized that the conjoined longitudinal muscle, and the network of connective tissue that it supports, plays a role in minimizing anal incontinence after sphincterotomy [12].

External Anal Sphincter

The external anal sphincter (EAS) is composed of striated muscle that forms an elliptical tube around the internal anal sphincter and conjoined longitudinal muscle. As it extends beyond the distal most aspect of the internal anal sphincter, the intersphincteric groove is formed. At its distal most aspect, *corrugator cutis ani muscle* fibers from the conjoined longitudinal muscle traverse the external anal sphincter and insert into the perianal skin. Milligan and Morgan described the external anal sphincter as having three distinct divisions from proximal to distal that were termed sphincter ani externus profundus, superficialis, and subcutaneous [1]. With time, this theory of three distinct divisions was proven invalid by Goligher who demonstrated that the external anal sphincter was truly a continuous sheet of skeletal muscle extending up to the puborectalis and levator ani muscles [16]. While the external anal sphincter does not have three distinct anatomic layers, it is common to see the proximal portion of the EAS referred to as deep EAS, the midportion as the superficial EAS, and the most distal aspect as the subcutaneous EAS. The mid EAS has posterior attachment to the coccyx via the anococcygeal ligament, and the proximal EAS becomes continuous with the puborectalis muscle. Anteriorly, the proximal EAS forms a portion of the perineal body with the transverse perineal muscle. There are clear differences in the morphology of the anterior external anal sphincter that have been demonstrated on both MRI and three-dimensional endoanal ultrasound studies in normal male and female volunteers [17, 18]. The normal female external anal sphincter has a variable natural defect occurring along its proximal anterior length below the level of the puborectalis sling that was demonstrated in 75 percent of nulliparous volunteers. This defect correlated with findings on anal manometry, and the authors noted that it can make interpretation of an isolated endoanal ultrasound difficult resulting in overreporting of obstetric sphincter defects [17]. This natural defect of the anterior anal sphincter provides some justification as to why anterior anal sphincterotomy is not routinely recommended in women.

The external anal sphincter is innervated on each side by the inferior rectal branch of the pudendal nerve (S2 and S3) and by the perineal branch of S4. There is substantial overlap in the pudendal innervation of the external anal sphincter muscle on the two sides which enables reinnervation to be partially accomplished from the contralateral side following nerve injury [19].

Hemorrhoids

Hemorrhoids are a normal feature of human anatomy and have been identified as present in the embryonic stage of development [20]. While many perceive hemorrhoids as a pathologic phenomenon, they are present in all humans and function to improve anal continence. The pathogenesis and treatment of hemorrhoids will be discussed elsewhere in this book, but here we will review the features of non-pathologic hemorrhoids.

Hemorrhoids are blood-filled cushions that line the anal canal. Hemorrhoids are located above and below the dentate line and have three important components: (1) the lining (mucosa or anoderm), (2) the stroma (blood vessels surrounded by connective tissue), and (3) anchoring connective tissue that secures the hemorrhoid to the internal sphincter and conjoined longitudinal muscle [20]. Hemorrhoids receive their blood supply from terminal branches of the superior hemorrhoidal artery [21]. While it has been previously stated that the terminal branches of the superior hemorrhoidal artery end in the right anterior, right posterior, and left lateral positions of the anal canal [20], this has been disputed [21]. At the level of the hemorrhoidal cushion, arteriovenous anastomosis (A-V shunts) exists in a complex vascular network termed the "corpus cavernosum recti" by Steltzner [22]. This vascular network with an arterial blood

supply is why pulsatile bleeding can be seen at the time of hemorrhoidectomy.

Perineal Body

The perineal body represents the intersection of the external anal sphincter, superficial transverse perinei, deep transverse perinei, and bulbospongiosus (also referred to as bulbocavernosus) muscles (Fig. 1.2). Recent research, based on advanced magnetic resonance imaging and ultrasound, has suggested that the transverse perinei (TP) and bulbospongiosus (BS) muscles contribute significantly to anal incontinence [23]. It has been proposed that the EAS, TP, and BS muscles be collectively referred to as the "EAS complex muscles." In this theory, the EAS complex morphology is "purse string" shaped rather than the typical "donut" shape previously considered. When these muscles are considered as a functional unit, it lends further support to the idea that it is critical to attempt to repair the perineal body during overlapping sphincter reconstructions.

Pelvic Floor Muscles

In addition to the anal sphincter and perineal body, the levator ani (LA) muscles contribute to pelvic organ support. For example, injury to the LA is seen in 55% of women with pelvic organ prolapse but in only 16% without prolapse [24]. The LA has three subdivisions including the pubococcygeus (aka pubovisceral), puborectalis, and iliococcygeus. Some authors had previously suggested that the puborectalis was part of the deep portion of the EAS [25] or that the LA did not actually have three definable divisions [26]; however, a significant amount of evidence has been presented to the contrary. In vivo MRI measurements in women have shown distinct, visible muscle fascicle directions for each of the three LA component muscles [27]. Embryology studies have also demonstrated that the puborectalis muscle is a portion of the LA muscle and shares a common primordium with the iliococcygeus and pubococcygeus muscles [28].

Innervation of the levator ani muscles has been described in detailed cadaveric studies [29]. The contemporary cadaveric studies suggest that the LA muscles are innervated by the pudendal nerve branches: perineal nerve and inferior rectal nerve as well as direct sacral nerves S3 and/or S4 (aka levator ani nerve) [30]. The pubococcygeus muscle and puborectalis muscle are primarily innervated by the pudendal nerve branches, while the iliococcygeus muscle is primarily innervated by the direct sacral nerves S3 and/or S4 (Fig. 1.3).

Puborectalis Muscle

The puborectalis muscle (PRM) fibers arise from the lower part of the symphysis pubis and from the superior fascia of the urogenital diaphragm and run alongside the anorectal junction. Posterior to the rectum, the fibers join forming a sling. The "anorectal ring" is composed of the upper borders of the internal anal sphincter and puborectalis muscle [1]. Contraction of the PRM sling causes a horizontal force [27] that closes the pelvic diaphragm and decreases the anorectal angle during squeeze. This is widely considered the most important contributing factor to gross fecal continence.

Iliococcygeus Muscle

Iliococcygeus muscle (ICM) fibers arise from the ischial spines and posterior obturator fascia, pass inferior/posterior and medially, and insert into the distal sacrum, coccyx, and anococcygeal raphe. The ICM, along with the pubococcygeus muscle, contributes to "lifting" of the pelvic floor [27].

Pubococcygeus Muscle

The pubococcygeus (PCM) muscle lies medial to the PRM. PCM fibers arise from the anterior half of the obturator fascia and the high posterior pubis. The PCM fibers are directed posterior/inferior and medially, where they intersect with fibers from the opposite side and form the anococcygeal raphe (or anococcygeal ligament). PCM muscle fibers insert in the distal sacrum and tip of the coccyx. Portions of the PCM contribute to the conjoined longitudinal muscle. The PCM forms the "levator hiatus" as it ellipses the lower rectum, urethra, and either the vagina in women or the dorsal vein of the penis in men. The levator hiatus is connected to the intrahiatal organs by a fascial condensation called the "hiatal ligament" (Fig. 1.4). The hiatal ligament arises circumferentially around the hiatal margin as a continuation of the fascia on the pelvic surface of the levator muscle [31]. Enlargement of the levator hiatus has been implicated as a cause of female pelvic organ prolapse [32]. The PCM is the portion of the levator ani that is typically injured during traumatic vaginal delivery [33].

Anatomy of the Rectum

The rectum is arbitrarily considered to have three distinct parts: the upper, middle, and lower rectum. Although not anatomically distinct, the upper, mid, and lower rectal divisions are important when considering surgical treatment of rectal cancer. From the anal verge, the lower rectum is 0–7 cm; middle rectum, 7–12 cm; and upper rectum, 12–15 cm [34]. However, the rectum is actually variable in length and may

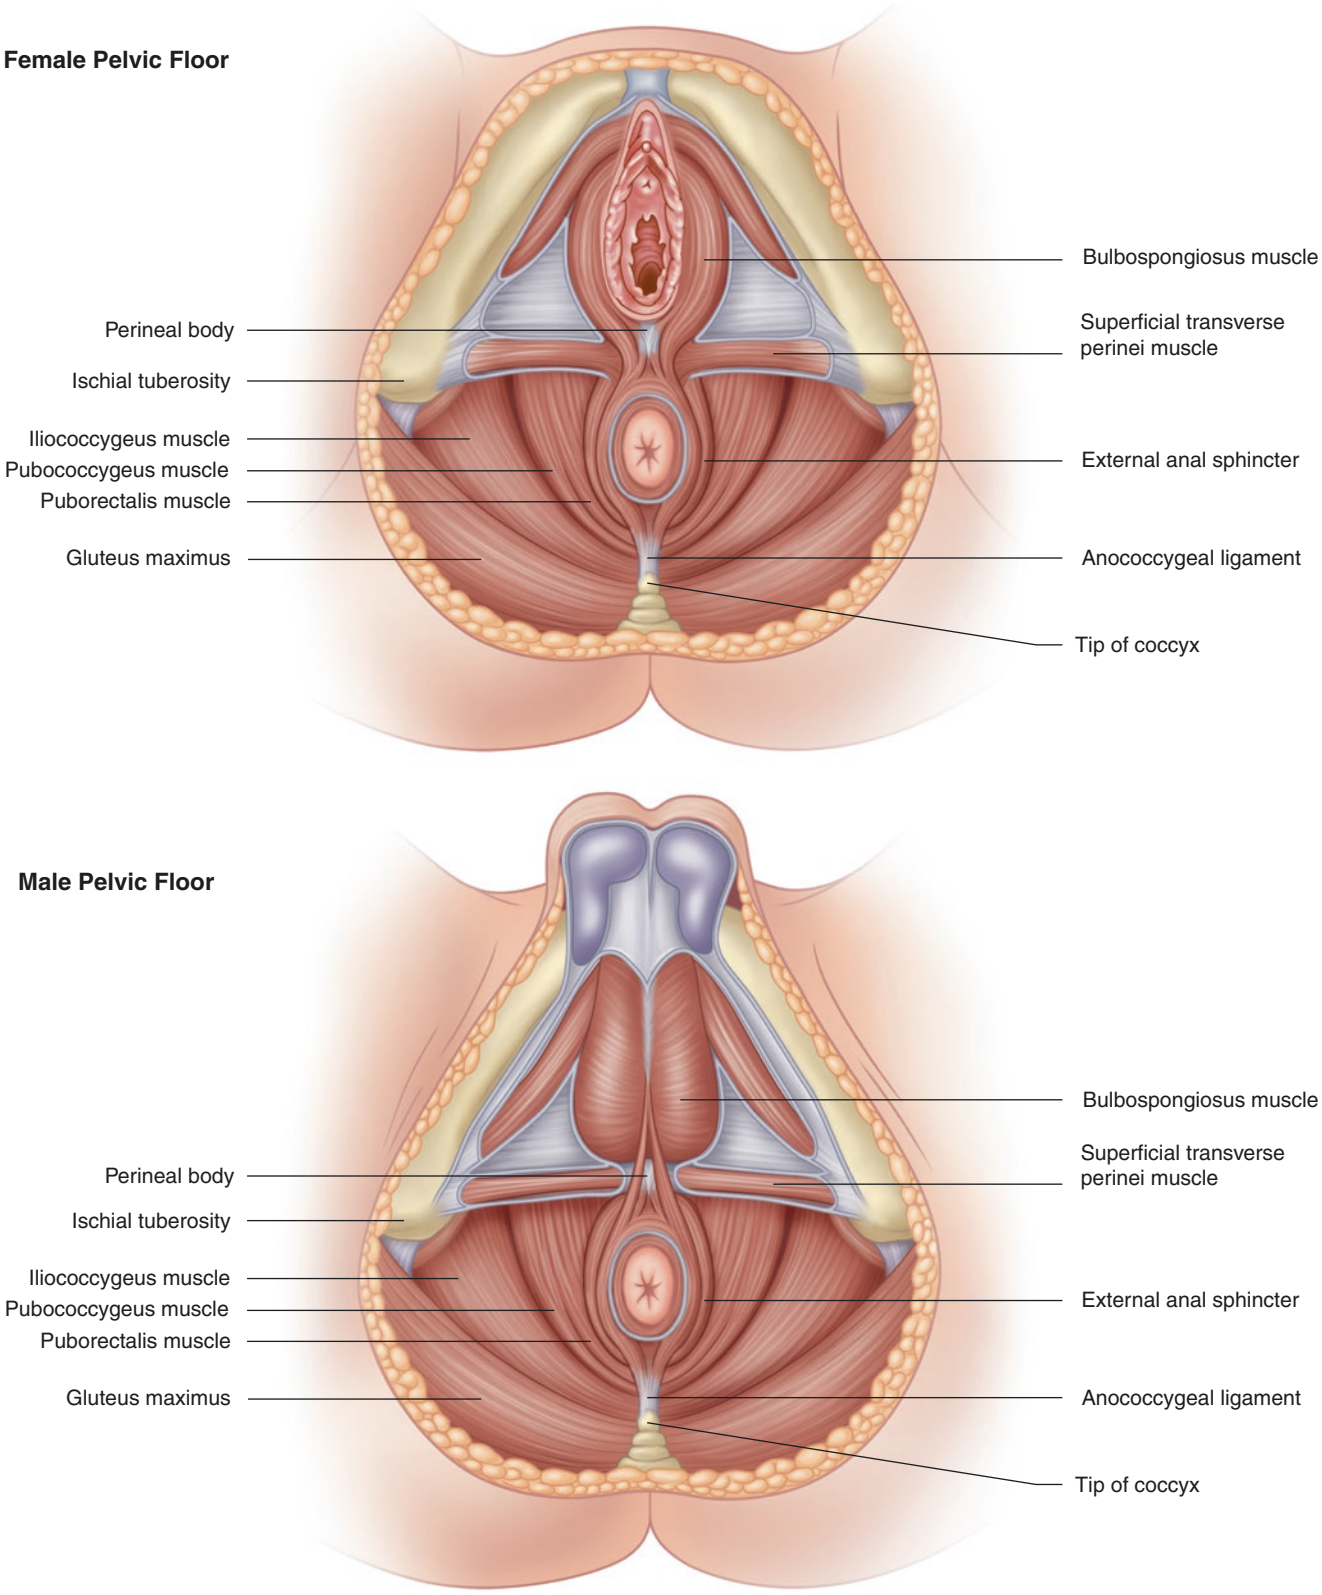

Fig. 1.2 Pelvic floor muscles

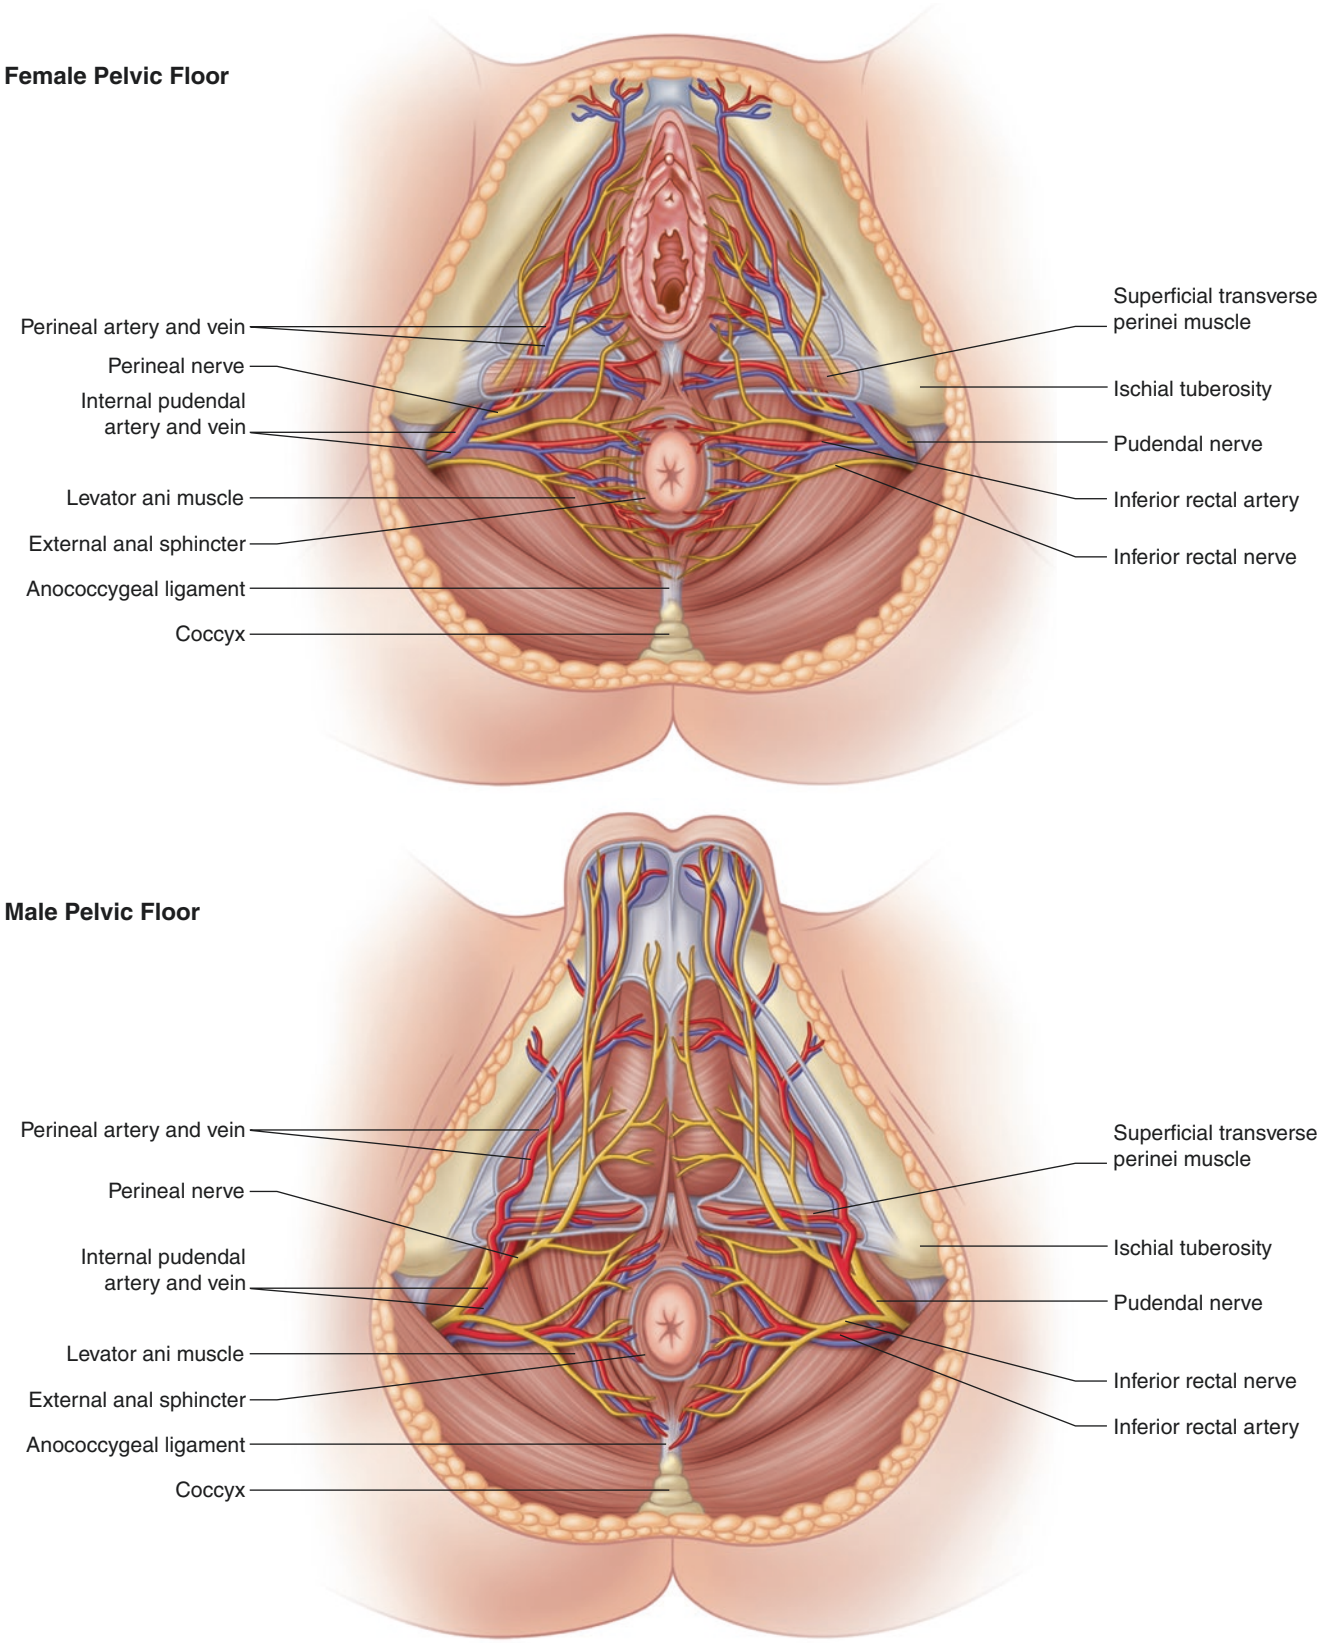

Fig. 1.3 Pelvic floor nerves and blood supply

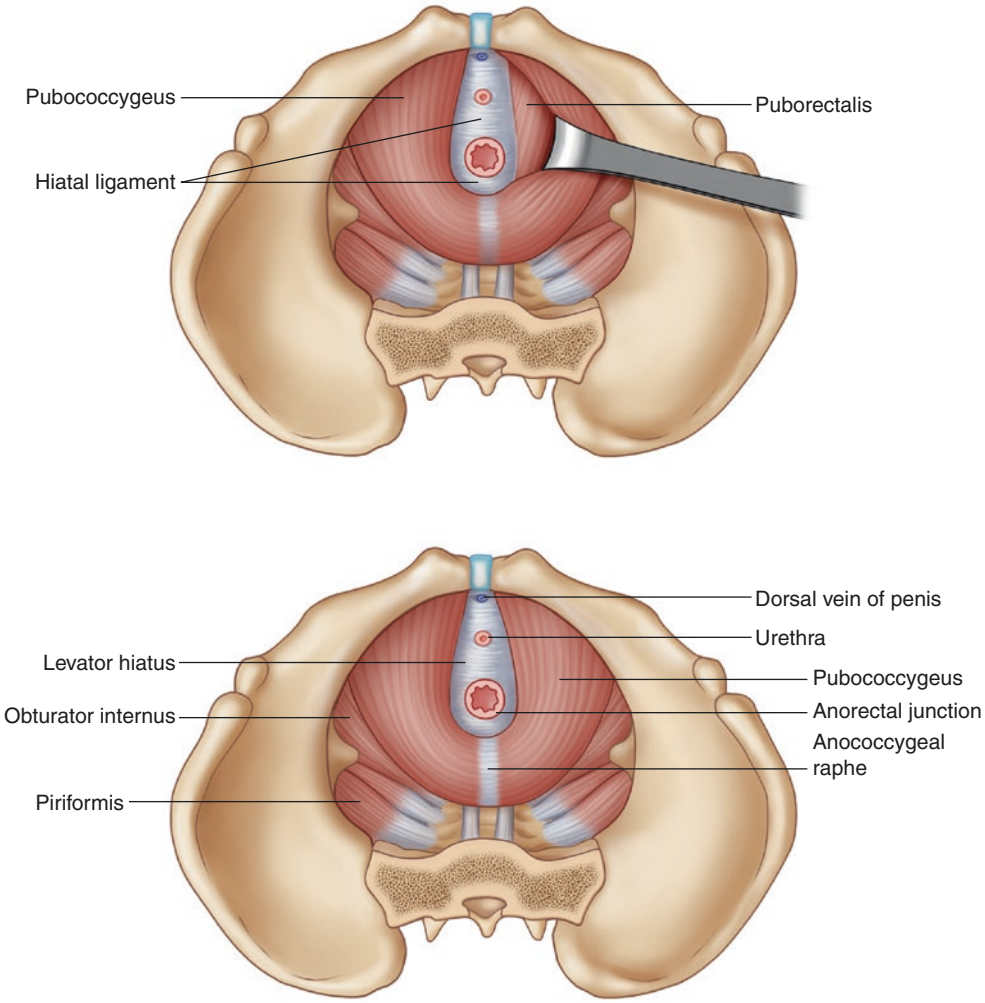

Fig. 1.4 Pelvic floor anatomy, abdominal view

extend beyond 15 cm from the anal verge. The upper rectum can be distinguished from the sigmoid colon by the absence of taenia coli and epiploic appendages.

The majority of the rectum lies outside of the peritoneal cavity, although anteriorly and laterally the upper rectum is covered by a layer of visceral peritoneum down to the peritoneal reflection. The location of the anterior peritoneal reflection is highly variable and can be significantly altered by disease such as rectal prolapse. Given the importance of the location of the peritoneal reflection with respect to transanal excision of rectal tumors, one study sought to identify the location of the anterior peritoneal reflection in 50 patients who were undergoing laparotomy [35]. It was found that the anterior peritoneal reflection was located on average 9 cm from the anal verge in females and 9.7 cm from the anal verge in males – there was no statistically significant difference based on gender.

Mesorectum

The origin of the word "mesorectum" is difficult to identify and may be attributed to Maunsell in 1892 [36] but was certainly later popularized by Heald [37]. Unfortunately, the term mesorectum is a misnomer that is not generally acknowledged in classic texts of anatomy such as the *Nomina Anatomica* [38]. In anatomic terms, the prefix "meso" refers to two layers of peritoneum that suspend an organ, and the suffix applied indicates the target organ (e.g., mesocolon). The term "meso" cannot be assigned to the rectum, as it implies a mobile, suspended rectum, which may only be the case in patients with rectal prolapse.

The mesorectum is a term employed by surgeons to describe the fascial envelope of the rectum that is excised during surgical treatment of rectal cancer. Indeed, failure to completely excise this envelope intact has been associated with an increased

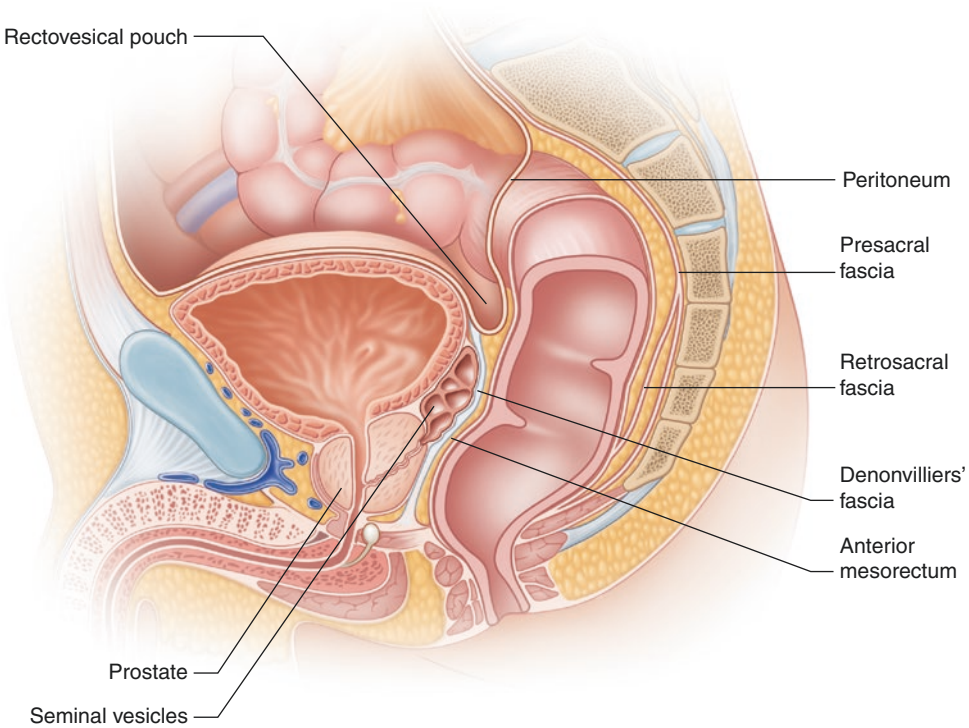

Fig. 1.5 Fascial relationships of the rectum

incidence of local recurrence of rectal cancer [39]. The mesorectum is contained within the fascia propria. The fascia propria is an upward projection of the parietal endopelvic fascia that lines the walls and floor of the pelvis. The fascia propria encloses the perirectal fat, lymphatics, blood vessels, and nerves and is not considered a barrier strong enough to prevent the spread of infection or malignancy [40].

Presacral Fascia

The presacral fascia is a thickened portion of the parietal endopelvic fascia overlying the sacrum that covers the presacral veins and hypogastric nerves (Fig. 1.5). It extends laterally to cover the piriformis and upper coccyx. As the presacral fascia extends laterally, it becomes continuous with the fascia propria and contributes to the lateral ligaments of the rectum. Caudally, this fascia extends to the anorectal junction covering the anococcygeal ligament. During total mesorectal excision, the fascia propria is elevated sharply off the presacral fascia. Leaving the presacral fascia intact eliminates the possibility of causing presacral bleeding.

Retrosacral Fascia

The retrosacral fascia originates at the third and fourth portion [41] of the sacrum and extends anteriorly to the posterior layer of the fascia propria 3–5 cm proximal to the anorectal junction [42]. This tough fascia layer is surgically relevant as it must be sharply incised during total mesorectal excision [40]. The space posterior to the retrosacral fascia is referred to as the supralevator or retrorectal space.

Waldeyer's Fascia

There is significant confusion about what Waldeyer's fascia represents as the eponym has been used to describe the presacral fascia, the retrosacral fascia, or all fascia posterior to the rectum. In Waldeyer's original description of pelvic fascia, there was no particular emphasis on the presacral component [40, 42]. While the debate continues regarding "Waldeyer's fascia," it is important to simply understand that the phrase can have the potential to mean presacral fascia, retrorectal fascia, or both [43].

Denonvilliers' Fascia

Denonvilliers' fascia arises from the fusion of the two walls of the embryological peritoneal cul-de-sac and extends from the deepest point of the rectovesical pouch to the pelvic floor [44]. Originally described by Denonvilliers in 1836 as a "prostatoperitoneal" membranous layer between the rectum and seminal vesicles, Denonvilliers fascia is also pres-

ent in females as part of the rectovaginal septum and is sometimes referred to as rectovaginal fascia. It is found immediately beneath the vaginal mucosa and is clearly what most would consider as part of the vaginal wall. It merges superiorly with the cardinal/uterosacral complex in females or the rectovesical pouch in males. It merges laterally with the endopelvic fascia overlying the levator muscle and distally with the perineal body. It contains collagen, some strands of smooth muscle, and heavy elastin fibers. Rectoceles represent a defect in this layer that allows the rectum to bulge anteriorly [45].

Microscopically, the Denonvilliers' fascia has two layers; however, it is not possible to discern two layers during pelvic dissection [44]. In the anterior rectal plane, the mesorectum is contained by the fascia propria which lies dorsal to Denonvilliers' fascia. The cavernous nerves run in neurovascular bundles at the anterolateral border of Denonvilliers' fascia.

Lateral Ligaments

While frequently referred to by surgeons, there are two controversial points regarding the lateral ligaments of the rectum. First, do the lateral ligaments exist? Second, what do they contain? Miles refers to division of the lateral ligaments of the rectum in his seminal description of abdominoperineal resection in 1908. Specifically, he notes "In these structures the middle haemorrhoidal arteries are found but seldom require a ligature" [46]. It is interesting to note that at least one modern cadaveric dissection study identified the presence of a middle rectal artery in only 22% of specimens [41] which could be a contributing factor as to why Miles saw no significant bleeding in this area.

Total mesorectal excision, as popularized and described by Heald, involves sharp dissection along the fascia propria circumferentially to the pelvic floor. While acknowledging that the middle rectal vessels are "divided as far from the carcinoma as possible," Heald does not mention "lateral ligaments" of the rectum at all [47].

In an extensive review of the anatomy of the lateral ligament, Church notes that it is a common misconception that the lateral ligaments contain the middle rectal artery at all. It appears that the lateral ligaments comprise "primarily nerves and connective tissue" and their division without bleeding attests to the absence of a "significant accessory rectal artery in this location in the majority of patients" [40].

In a separate cadaveric study, the lateral ligaments of the rectum were identified as trapezoid structures originating from mesorectum and anchored to the endopelvic fascia at the level of the midrectum. It was recommended that, as lateral extensions of the mesorectum, the ligaments must be cut and included in the total mesorectal excision (TME) specimen. It was further noted that the lateral ligaments did not contain middle rectal arteries or nerve structures of importance. The urogenital bundle runs just above the lateral ligament at its point of insertion on the endopelvic fascia, the middle rectal artery (if present) runs posterior to the lateral ligament, and the nervi recti fibers (which originate from the inferior hypogastric plexus) course transversely under the lateral ligament to the rectal wall [48]. Other modern cadaveric investigations note the rarity of middle rectal arteries and the absence of clinically relevant neurovascular structures in the lateral ligaments [49].

Rectal Valves: The Spiral Valves of Houston and Kohlrausch's Valve

The first anatomic description of rectal valves is credited to Giovanni Morgagni [50]; however, it was John Houston, an Irish anatomist and surgeon, who presented the first seminal work on the structures [51, 52]. Houston described an average of three oblique valves with an upward orientation and concave surface that were located successively on opposite sides of the rectum that formed "a sort of spiral tract down its cavity." Houston theorized that these valves might aid in continence by supporting "the weight of fecal matter"; however, this has not been substantiated elsewhere.

Modern anatomy texts usually also describe three rectal valves (Fig. 1.1) with the superior and inferior valves located on the left side of the rectum and the more prominent middle rectal valve on the right; however, this is not uniformly the case [53]. Only 45.5% of patients will have the classic three valve rectal anatomy; 32.5% will have only two valves; and 10.25% may have four valves.

After Houston's definitive description of rectal valves in 1830, Otto Kohlrausch, a physician and scientist in Germany, described a single mid-rectal valve in 1854 [54]. When there are three valves, current anatomists identify Kohlrausch's valve as the middle one [51]. This valve is usually the largest, located on the right and approximately 9–11 cm from the anal verge, and some authors have suggested this valve could serve as an intraluminal marker for the area of the anterior peritoneal reflection [55].

Anorectal Spaces

It is important to acknowledge and understand the anorectal spaces created by the various myofascial relationships in the pelvis as these spaces help us understand how anorectal sepsis can spread throughout the pelvis.

Perianal Space

The perianal space contains external hemorrhoid cushions, the subcutaneous external anal sphincter and the distal internal anal sphincter. The perianal space is in communication

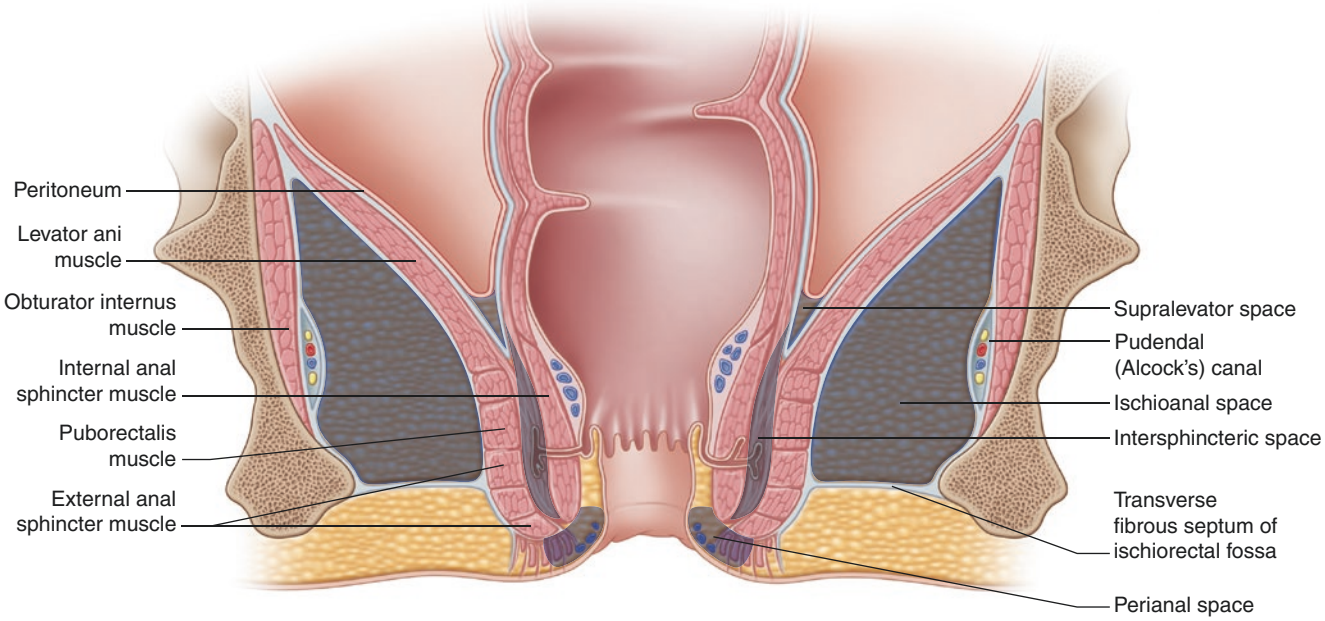

Fig. 1.6 Perianal and perirectal spaces, coronal view

with the intersphincteric space (Fig. 1.6). The perianal space has its cephalad boundary at the dentate line and laterally to the subcutaneous fat of the buttocks or is contained by fibers extending from the conjoined longitudinal muscle often referred to as *corrugator cutis ani* muscle fibers. Otherwise, the perianal space is contained by anoderm.

Intersphincteric Space

The intersphincteric space is the potential space that lies between the internal and external anal sphincter and is continuous with the perianal space. It is of clinical importance as cryptoglandular infections tend to begin in this area and expand elsewhere to create anal fistula [6].

Submucous Space

This space lies between the medial boarder of the internal anal sphincter and the anal mucosa proximal to the dentate line. It is continuous with the submucosa of the rectum. This area contains internal hemorrhoid vascular cushions.

Ischioanal/Ischiorectal Space

The ischioanal (also referred to as ischiorectal) space is the largest anorectal space. It has been described as a pyramid shape with its apex at the levator muscle insertion into the obturator fascia. The medial boarder is thus the levator ani muscle and external anal sphincter. The obturator internus muscle and obturator fascia make up the lateral boarder of the ischioanal space. The posterior boundary is formed by the lower border of the gluteus maximus muscle and the sacrotuberous ligament. The space has an anterior boundary formed by the superficial and deep transverse perineal muscles. The caudal boundary is skin of the perineum. The ischioanal fossa contains adipose tissue, pudendal nerve branches, and superficial branches of the internal pudendal vessels. The right and left ischioanal space communicate posteriorly through the deep postanal space between the levator ani muscle and anococcygeal ligament (Fig. 1.7) [56]. When the ischioanal and perianal spaces are regarded as a single space, it is referred to as the ischioanal fossa [43].

Supralevator Space

The upper boundary of the supralevator space is the peritoneum, the lateral boundary is the pelvic wall, the medial boundary is the rectum, and the inferior boarder is the levator ani muscle (Fig. 1.8).

Superficial and Deep Postanal Spaces

These spaces are located posterior to the anus and inferior to the levator muscle. The superficial postanal space is more caudal and is located between the anococcygeal ligament and the skin. The superficial postanal space allows communication of perianal space sepsis.

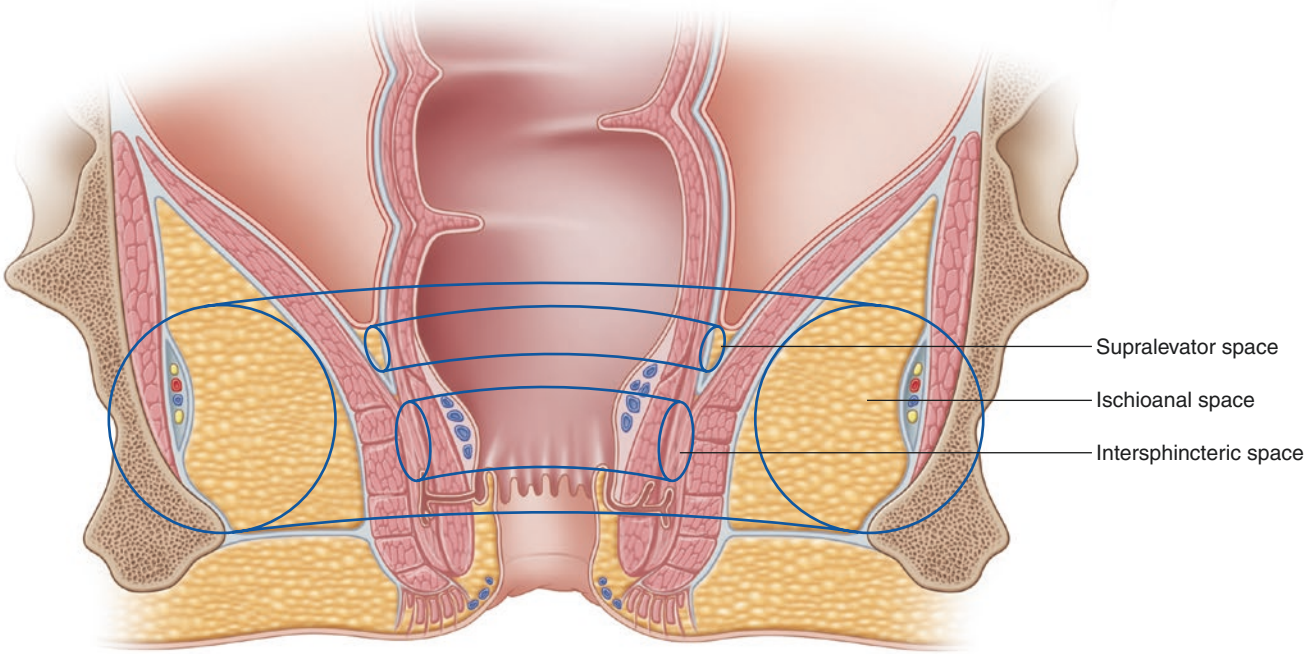

Fig. 1.7 Communication of the anorectal spaces

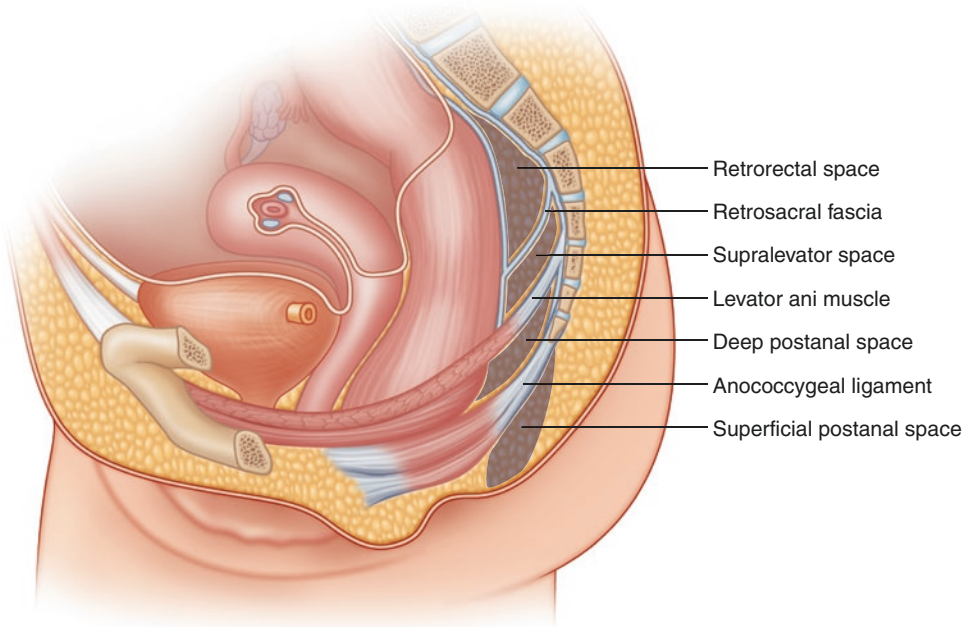
Fig. 1.8 Perianal and perirectal spaces, lateral view



The deep postanal space (retrosphincteric space of Courtney) [57] is located between the levator ani muscle and the anococcygeal raphe. This space allows ischioanal sepsis to track from one side to the other resulting in the so-called "horseshoe" abscess.

Retrorectal Space

The retrorectal space is found between the presacral fascia and fascia propria. It contains no major blood vessels or nerves. It is limited laterally by the lateral ligaments of the

piriformis fascia and inferiorly by the retrosacral fascia. The fascia propria and presacral fascia come together at the apex of this space [40].

Rectal Blood Supply

The rectum is supplied by the superior, middle, and inferior rectal (hemorrhoidal) arteries (Fig. 1.9). Both the middle and inferior hemorrhoidal vessels are paired arteries, and the superior rectal artery is not.

Superior Rectal Artery

The superior rectal artery (SRA) is the continuation of the inferior mesenteric artery and is so named after the inferior mesenteric artery crosses the left iliac vessels. The SRA gives off a rectosigmoid branch, an upper rectal branch, and then bifurcates into right and left terminal branches in 80% [58] of cases as it descends caudally in the mesorectum. On average, eight terminal branches of the SRA have been identified in the distal rectal wall [21].

Middle Rectal Artery

The middle rectal artery (MRA) has been variably noted in many studies. It may be found on one or both sides of the rectum and has been noted to be present 12–28% of the time [49, 59]. At least one study reported the presence of the middle rectal artery in at least 91% of cadaveric specimens [48]. The MRA originates from the anterior division of the internal iliac or pudendal arteries. Please see the "Lateral Ligament" discussion above for more review on the anatomic course of the middle rectal artery.

Inferior Rectal Artery

The inferior rectal arteries (IRA) are paired vessels that originate as branches of the internal pudendal artery which receives its blood supply from the internal iliac artery. The artery originates in the pudendal canal and is entirely extrapelvic (caudal to the levator ani) in its distribution. The IRA traverses the obturator fascia and the ischiorectal fossa and pierces the wall of the anal canal in the region of the external anal sphincter [40].

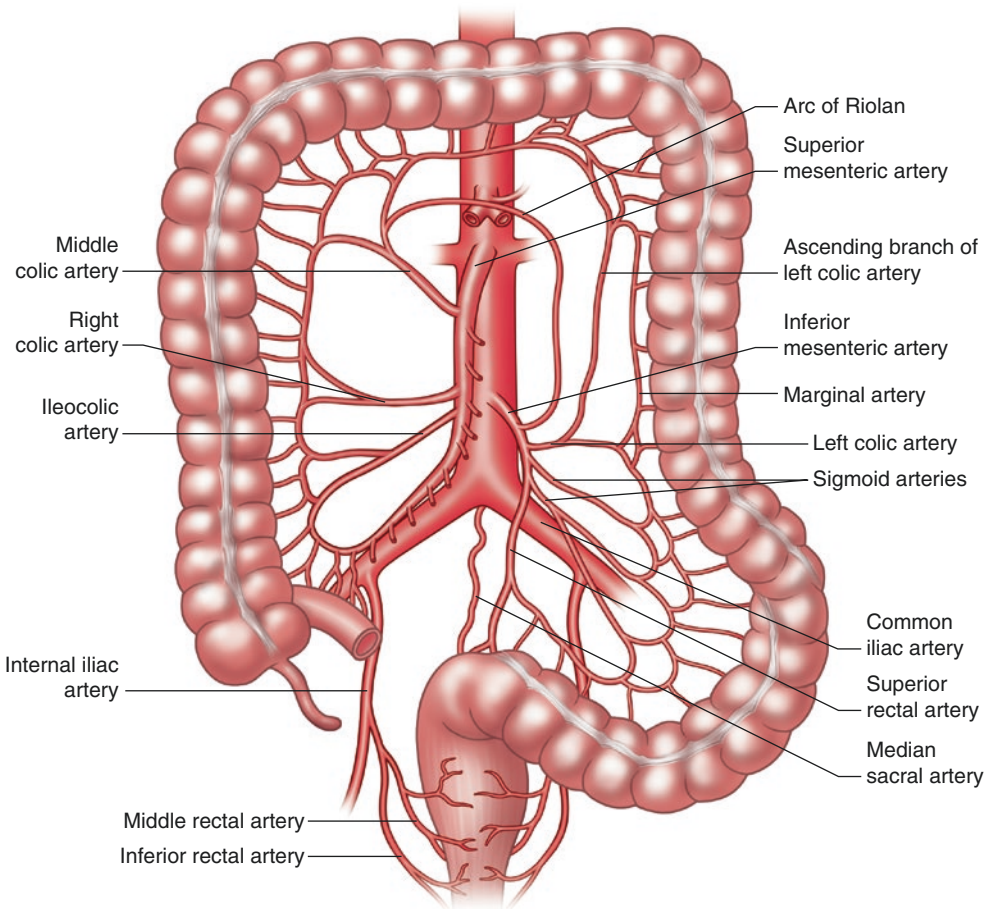


Fig. 1.9 Arterial anatomy of the colon and rectum

Venous and Lymphatic Drainage of the Rectum and Anus

Venous drainage from the rectum and anus occurs via both the portal and systemic systems. Middle and inferior rectal veins drain to the systemic systems via the internal iliac vein, while the superior rectal vein drains the rectum and upper anal canal into the portal system via the inferior mesenteric vein (Fig. 1.10). The two systems of drainage in the rectum, thus, explain the potential development of rectal varices in patients with portal hypertension.

Lymphatics from the upper two-thirds of the rectum drain to the inferior mesenteric lymph nodes and then to the para-aortic lymph nodes. Lymphatic drainage from the lower third of the rectum occurs along the superior rectal artery and laterally along the middle rectal artery to the internal iliac lymph nodes. In the anal canal, lymphatics above the dentate drain to the inferior mesenteric and internal iliac lymph nodes. Below the dentate line, lymphatics drain along the inferior rectal lymphatics to the superficial inguinal nodes.

Innervation of the Rectum and Anus

Sympathetic fibers arise from L1, L2, and L3 and pass through the sympathetic chains and join the preaortic plexus (Fig. 1.11). From there, they run adjacent and dorsal to the inferior mesenteric artery as the mesenteric plexus and innervate the upper rectum. The lower rectum is innervated by the presacral nerves from the hypogastric plexus. Two main hypogastric nerves, on either side of the rectum, carry sympathetic information from the hypogastric plexus to the pelvic plexus. The pelvic plexus lies on the lateral side of the pelvis at the level of the lower third of the rectum adjacent to the lateral stalks (please see discussion of lateral stalks above).

Parasympathetic fibers to the rectum and anal canal originate from S2, S3, and S4 to penetrate through the sacral fora-

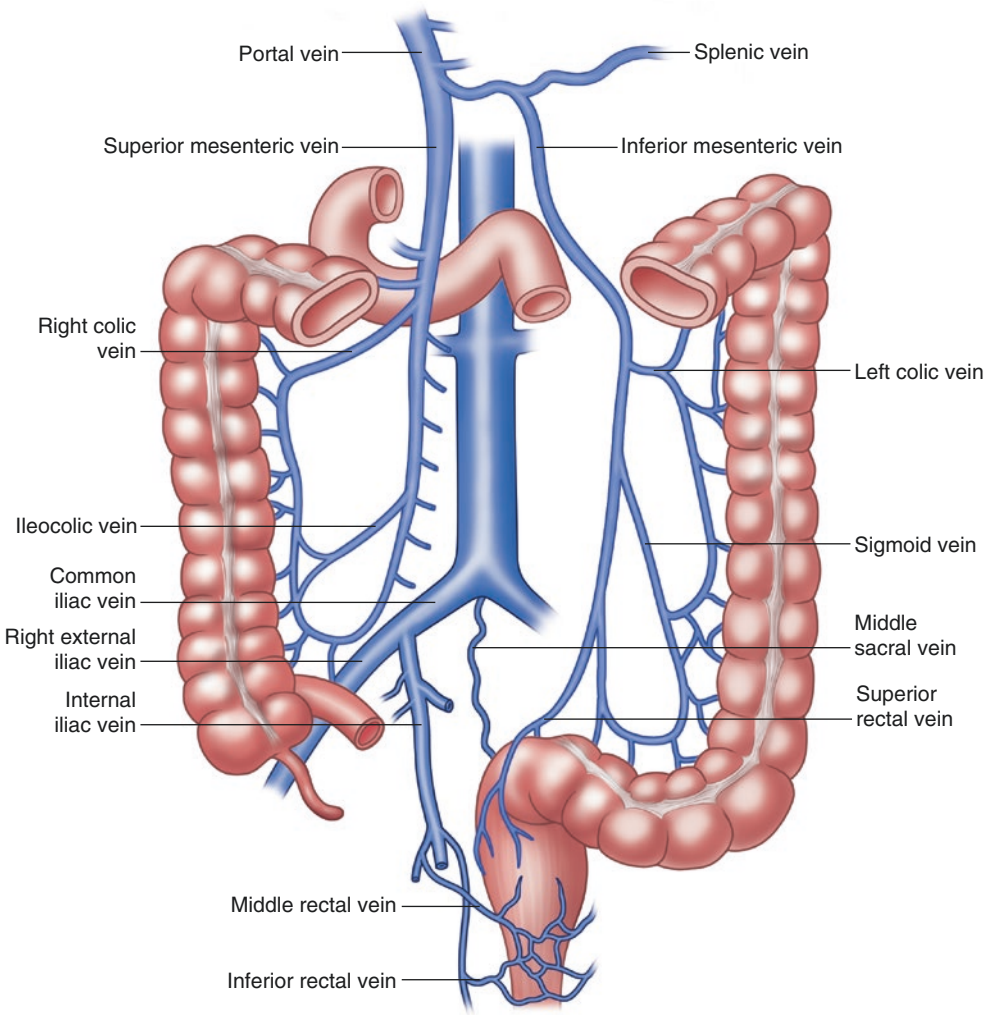

Fig. 1.10 Venous anatomy of the colon and rectum

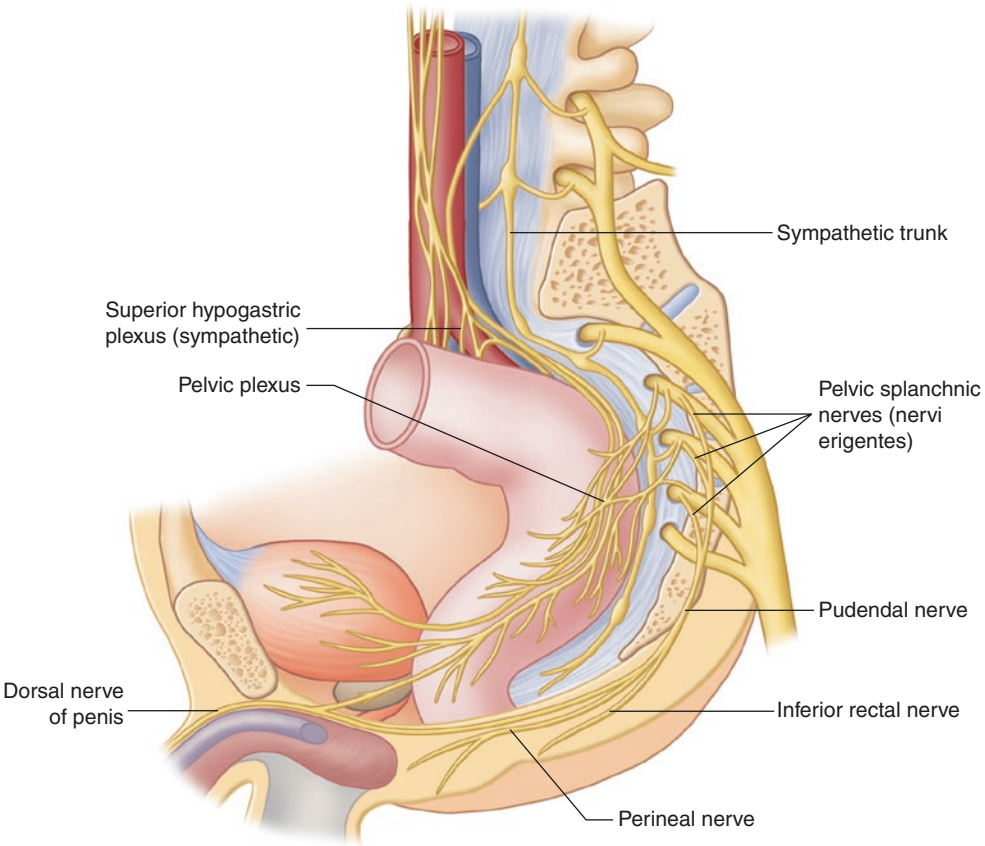

Fig. 1.11 Nerves of the rectum

men and are called the nervi erigentes. These nerves course laterally and anteriorly to join the sympathetic hypogastric nerves and form the pelvic plexus on the pelvic sidewall. From here, postganglionic mixed parasympathetic and sympathetic nerve fibers supply the rectum, genital organs, and anal canal. The periprostatic plexus is considered a subdivision of the pelvic plexus and supplies the prostate, seminal vesicles, corpora cavernosa, vas deferens, urethra, ejaculatory ducts, and bulbourethral glands.

The internal anal sphincter is innervated by sympathetic (L5) and parasympathetic (S2, S3, and S4) nerves following the same route as the nerves to the rectum as noted above. The external anal sphincter is innervated on each side by the inferior rectal branch of the internal pudendal nerve (S2 and S3) and by the perineal branch of S4. Anal sensation is mediated by the inferior rectal branch of the pudendal nerve.

Anatomy of the Colon

The colon is a long tubular organ consisting of muscle and connective tissue with an inner mucosal layer. The diameter of the colon differs depending upon which segment is evaluated and generally decreases from proximal to distal (cecum about 7 cm and sigmoid colon about 2.5 cm in diameter). The overall length is variable with an average length approximating 150 cm. The right and left sides of the colon are fused to the posterior retroperitoneum (secondarily retroperitonealized), while the transverse colon and sigmoid colon are relatively free within the peritoneum. The transverse colon is held in position via its attachments to the right/left colon at the flexures (hepatic and splenic, respectively) and is further fused to the omentum. Generally, the colon is located peripherally within the abdomen with the small bowel located centrally.

There are three classic anatomic points of differentiation between the colon and the small intestine: the appendices epiploicae, the taeniae coli, and the haustra. The appendices epiploicae are non-mesenteric fat protruding from the serosal surface of the colon. They are likely residual from the antimesenteric fat of the embryologic intestine which dissipates (unlike the omentum on the stomach). The taenia coli are three thickened bands of outer, longitudinal muscle of the colon. This outer layer of muscle is indeed circumferentially complete [60] but is considerably thicker in three areas represented by the taenia. The three taeniae have been given separate names by some: *taenia libera* to represent the anterior band, *taenia mesocolica* for the posteromedial band, and *taenia omentalis* for posterolateral band. The bands are continuous from their origin at the base of the appendix until the

rectosigmoid junction where they converge (marking an anatomically identifiable differentiation between the sigmoid colon and rectum). Though they run along the full length of the colon, they are not as long as the bowel wall. This difference in length results in outpouchings of the bowel wall between the taenia referred to as haustra. The haustra are further septated by the plicae semilunares.

Cecum

The proximal most portion of the colon is termed the cecum, a saclike segment of the colon below (proximal to) the ileocecal valve. The cecum is variable in size but generally is about 8 cm in length and 7 cm in diameter. At its base is the appendix. Terminating in the posteromedial area of the cecum is the terminal ileum (ileocecal valve). The cecum is generally covered by visceral peritoneum, with more variability near the transition to the ascending colon (upper or distal cecum). The ileocecal valve is a circular muscular sphincter which appears as a slit-like ("fish-mouth") opening noted on an endoscopic evaluation of the cecum. The valve is not competent in all patients, but when present, its competence leads to the urgency of a colon obstruction as it develops into a closed-loop obstruction. Regulation of ileal emptying into the colon appears to be the prime task in ileocecal valve function [61].

The Appendix

The appendix is an elongated, true diverticulum arising from the base of the cecum. The appendiceal orifice is generally about 3–4 cm from the ileocecal valve. The appendix itself is of variable length (2–20 cm) and is about 5 mm in diameter in the non-inflamed state. Blood is supplied to the appendix via the appendiceal vessels contained within the mesoappendix. This results in the most common location of the appendix being medially on the cecum toward the ileum, but the appendix does have great variability in its location including pelvic, retrocecal, preileal, retroileal, and subcecal. Though traditionally thought to be an unnecessary vestige, modern research points to the appendix which is rarely absent and rarely altered actually playing an important role in immune function and/or the colonic microbiome [62].

Ascending Colon

From its beginning at the ileocecal valve to its terminus at the hepatic flexure where it turns sharply medially to become the transverse colon, the ascending colon measures on average, about 15–18 cm. Its anterior surface is covered in visceral peritoneum, while its posterior surface is fused with the retroperitoneum. The lateral peritoneal reflection can be seen as a thickened line termed the white line of Toldt, which can serve as a surgeon's guide for mobilization of the ascending colon off of its attachments to the retroperitoneum, most notably the right kidney (Gerota's fascia) and the loop of the duodenum located posterior and superior to the ileocolic vessels. The right ureter and the right gonadal vessels pass posteriorly to the ascending mesocolon within the retroperitoneum.

Transverse Colon

The transverse colon traverses the upper abdomen from the hepatic flexure on the right to the splenic flexure on the left. It is generally the longest section of colon (averaging 45–50 cm) and swoops inferiorly as it crosses the abdomen. The entire transverse colon is covered by visceral peritoneum, but the greater omentum is fused to the anterosuperior surface of the transverse colon. Superior to the transverse mesocolon, inferior to the stomach, and posterior to the omentum is the pocket of the peritoneal cavity termed the lesser sac, with the pancreas forming the posterior most aspect. The splenic flexure is the sharp turn from the transversely oriented transverse colon to the longitudinally oriented descending colon. It can be adherent to the spleen and to the diaphragm via the phrenicocolic ligament.

Descending Colon

The descending colon travels inferiorly from the splenic flexure for the course of about 25 cm. It is fused to the retroperitoneum (similarly to the ascending colon) and overlies the left kidney as well as the back/retroperitoneal musculature. Its anterior and lateral surfaces are covered with visceral peritoneum, and the lateral peritoneal reflection (white line of Toldt) is again present.

Sigmoid Colon

The sigmoid colon is the most variable of the colon segments. It is generally 35–45 cm in length. It is covered by visceral peritoneum, thereby making it mobile. Its shape is considered "omega-shaped," but its configuration and attachments are variable. Its mesentery is of variable length but is fused to the pelvic walls in an inverted-V shape creating a recess termed the intersigmoid fossa. Through this recess travel the left ureter, gonadal vessels, and often the left colic vessels.

Rectosigmoid Junction

The end of the sigmoid colon and the beginning of the rectum is termed the rectosigmoid junction. It is noted by the

confluence of the taeniae coli and the end of epiploicae appendices. While some surgeons have historically considered the rectosigmoid junction to be a general area (comprising about 5 cm of distal sigmoid and about 5 cm of proximal rectum), others have described a distinct and clearly defined segment. It is the narrowest portion of the large intestine, measuring 2–2.5 cm in diameter. Endoscopically, it is noted as a narrow and often sharply angulated area above the relatively capacious rectum and above the three rectal valves.

In the early nineteenth century, it was proposed that the sigmoid acts as a reservoir for stool, thus aiding in continence [63]. Subsequently, an area of thickened circular muscle within the wall of the rectosigmoid was described and felt to function as a sphincter of sorts. Historically, it has been variably named the *sphincter ani tertius*, *rectosigmoid sphincter*, and *pylorus sigmoidorectalis* [64–68]. A more recent evaluation of the rectosigmoid junction utilizing anatomic and histologic studies as well as radiographic evaluation concluded that there was an anatomic sphincter at the rectosigmoid junction [69]. Microscopic evaluation of the area does reveal thickening of the circular muscle layer as it progresses toward the rectum. Though not identifiable externally, radiologic evaluation can identify the area as a narrow, contractile segment [69].

Blood Supply

The colon receives blood supply from two main sources, branches of the superior mesenteric artery (SMA) (cecum, ascending, and transverse colon) and branches of the inferior mesenteric artery (IMA) (descending and sigmoid colon) (Fig. 1.9). There is a watershed area between these two main sources located just proximal to the splenic flexure where branches of the left branch of the middle colic artery anastomose with those of the left colic artery. This area represents the border of the embryologic midgut and hindgut. Though the blood supply to the colon is somewhat variable, there are some general common arteries. The cecum and right colon are supplied by the terminus of the SMA, the ileocolic artery. The right colic artery is less consistent and, when present, can arise directly from the SMA, from the ileocolic, or from other sources. The transverse colon is supplied via the middle colic artery, which branches early to form right and left branches. The middle colic artery originates directly from the SMA. The left colon and sigmoid colon are supplied by branches of the IMA, namely, the left colic and a variable number of sigmoid branches. After the final branches to the sigmoid colon, the IMA continues inferiorly as the superior hemorrhoidal (rectal) artery.

Superior Mesenteric Artery

The superior mesenteric artery (SMA) is the second, unpaired anterior branch off of the aorta (the first being the celiac trunk). It arises posterior to the upper edge of the pancreas (near the L1 vertebrae), courses posterior to the pancreas, and then crosses over the third portion of the duodenum to continue within the base of the mesentery. From its left side, the SMA gives rise to up to 20 small intestinal branches, while the colic branches originate from its right side. The most constant of the colic branches is the ileocolic vessel which courses through the ascending mesocolon where it divides into a superior (ascending) branch and an inferior (descending) branch [70]. A true right colic artery is absent up to 20% of the time and, when present, typically arises from the SMA. Alternatively, the right colic artery can arise from the ileocolic vessels or from the middle colic vessels [58, 70, 71]. The middle colic artery arises from the SMA near the inferior border of the pancreas. It branches early to give off right and left branches. The right branch supplies the hepatic flexure and right half of the transverse colon. The left branch supplies the left half of the transverse colon to the splenic flexure. In up to 33% of patients, the left branch of the middle colic artery can be the sole supplier of the splenic flexure [70, 72]. Recent reports describe an accessory middle colic artery (AMCA). One single-center study demonstrates that more than one-third of patients had an AMCA (36.4%) supplying the splenic flexure with about 85% originating off of the SMA and coursing along the inferior border of the pancreas toward the splenic flexure [73].

Inferior Mesenteric Artery

The inferior mesenteric artery (IMA) is the third unpaired, anterior branch off of the aorta, originating 3–4 cm above the aortic bifurcation at the level of the L2 to L3 vertebrae. As the IMA travels inferiorly and to the left, it gives off the left colic artery and several sigmoidal branches. After these branches, the IMA becomes the superior hemorrhoidal (rectal) artery as it crosses over the left common iliac artery. The left colic artery divides into an ascending branch (splenic flexure) and a descending branch (the descending colon). The sigmoidal branches form a fairly rich arcade within the sigmoid mesocolon (similar to that seen within the small bowel mesentery). The superior hemorrhoidal artery carries into the mesorectum and into the rectum. The superior hemorrhoidal artery bifurcates in about 80% of patients.

The Marginal Artery and Other Mesenteric Collaterals

The major arteries noted above account for the main source of blood within the mesentery. However, the anatomy of the mesenteric circulation and the collaterals within the mesentery remain less clear. Haller first described a central artery anastomosing all mesenteric branches in 1786 [74]. When Drummond demonstrated its surgical significance in the early twentieth century, it became known as the marginal artery of Drummond [75, 76]. The marginal artery has been

shown to be discontinuous or even absent in some patients, most notably at the splenic flexure (Griffiths' critical point), where it may be absent in up to 50% of patients [77]. This area of potential ischemia is the embryologic connection between the midgut and hindgut. Inadequacy of the marginal artery likely accounts for this area being most severely affected in cases of colonic ischemia. Another potential (though controversial) site of ischemia is at a discontinuous area of marginal artery located at the rectosigmoid junction termed Sudeck's critical point. Surgical experience would question whether this potential area of ischemia exists; a recent fluorescence study indicates that it does [78], though its clinical importance remains in doubt.

Venous Drainage

Venous drainage of the colon largely follows the arterial supply with superior and inferior mesenteric veins draining both the right and left halves of the colon (Fig. 1.10). They ultimately meet at the portal vein to reach the intrahepatic system. The superior mesenteric vein (SMV) travels parallel and to the right of the artery. The inferior mesenteric vein (IMV) does not travel with the artery but rather takes a longer path superiorly to join the splenic vein. It separates from the artery within the left colon mesentery and runs along the base of the mesentery where it can be found just lateral to the ligament of Treitz and the duodenum before joining the splenic vein on the opposite (superior) side of the transverse mesocolon. Dissecting posterior to the IMV can allow for separation of the mesenteric structures from the retroperitoneal structures during a medial-to-lateral dissection.

Lymphatic Drainage

The colon wall has a dense network of lymphatic plexuses. These lymphatics drain into extramural lymphatic channels which follow the vascular supply of the colon. Lymph nodes are plentiful and are typically divided into four main groups. The *epiploic* group lies adjacent to the bowel wall just below the peritoneum and in the epiploicae. The *paracolic* nodes are along the marginal artery and the vascular arcades. They are most filtering of the nodes. The *intermediate* nodes are situated on the primary colic vessels. The *main* or *principal* nodes are on the superior and inferior mesenteric vessels. Once the lymph leaves the main nodes, it drains into the cisterna chili via the para-aortic chain.

Nervous Innervation

The colon is innervated by the sympathetic and parasympathetic nervous systems and closely follows the arterial blood supply. The sympathetic innervation of the right half of the colon originates from the lower six thoracic splanchnic nerves which synapse within the celiac, preaortic, and superior mesenteric ganglia. The postganglionic fibers then follow the SMA to the right colon. The sympathetic innervation for the left half originates from L1, L2, and L3. Parasympathetic fibers to the right colon come from the posterior (right) branch of the vagus nerve and celiac plexus. They travel along the SMA to synapse with the nerves within the intrinsic autonomic plexuses of the bowel wall. On the left side, the parasympathetic innervation comes from S2, S3, and S4 via splanchnic nerves.

Embryology

Though the embryologic development of the GI system is complex, a working knowledge of the development of the small bowel, colon, and anorectum is critical for a colorectal surgeon as it can aid in understanding pathophysiology and is essential for recognizing surgical planes.

Anus and Rectum

The colon distal to the splenic flexure, including the rectum and the anal canal (proximal to the dentate line), is derived from the hindgut and therefore has vascular supply from the inferior mesenteric vessels (Fig. 1.9). The dentate line (Fig. 1.1) is the fusion plane between the endodermal and ectodermal tubes. The cloacal portion of the anal canal has both endodermal and ectodermal components which develop into the anal transitional zone [79]. The terminal portion of the hindgut or cloaca fuses with the proctodeum (an ingrowth from the anal pit).

The cloaca originates at the portion of the rectum below the pubococcygeal line, while the hindgut originates above it. Before the fifth week of development, the intestinal and urogenital tracts are joined at the level of the cloaca. By the eighth week, the urorectal septum migrates caudally to divide the cloacal closing plate into an anterior urogenital plate and a posterior anal plate. Anorectal rings result from a posterior displacement in the septum and the resultant smaller anal opening. By the tenth week, the anal tubercles fuse into a horseshoe-shaped structure dorsally and into the perineal body anteriorly. The external anal sphincter forms from the posterior aspects of the cloacal sphincter earlier than the development of the internal sphincter. The internal sphincter develops from enlarging fibers of the circular muscle layer of the rectum [80]. The sphincters migrate during their development with the internal sphincter moving caudally, while the external sphincter enlarges cephalad. Meanwhile, the longitudinal muscle descends into the intersphincteric plane [9]. In females, the female genital organs form from the Müllerian ducts and join the urogenital sinus by the 16th week of development. In contrast, in males, the urogenital membrane obliterates with fusion of the genital folds, while the sinus develops into the urethra.

Colon and Small Intestine

The endodermal roof of the yolk sac develops into the primitive gut tube. This initially straight tube is suspended upon a common mesentery. By week 3 of development, it has three discernible segments: namely, the foregut, midgut, and hindgut. The midgut starts below the pancreatic papilla to form the small intestine and the first half of the colon (all supplied by the superior mesenteric artery). The distal colon and rectum, as well as the anal canal, develop from the hindgut and are therefore supplied by the inferior mesenteric artery.

Midgut Rotation

There is a normal process by which the intestinal tract rotates (Fig. 1.12) [81]. The first stage is the physiologic herniation of the midgut, the second stage is its return to the abdomen, and the third stage is the fixation of the midgut. Abnormalities in this

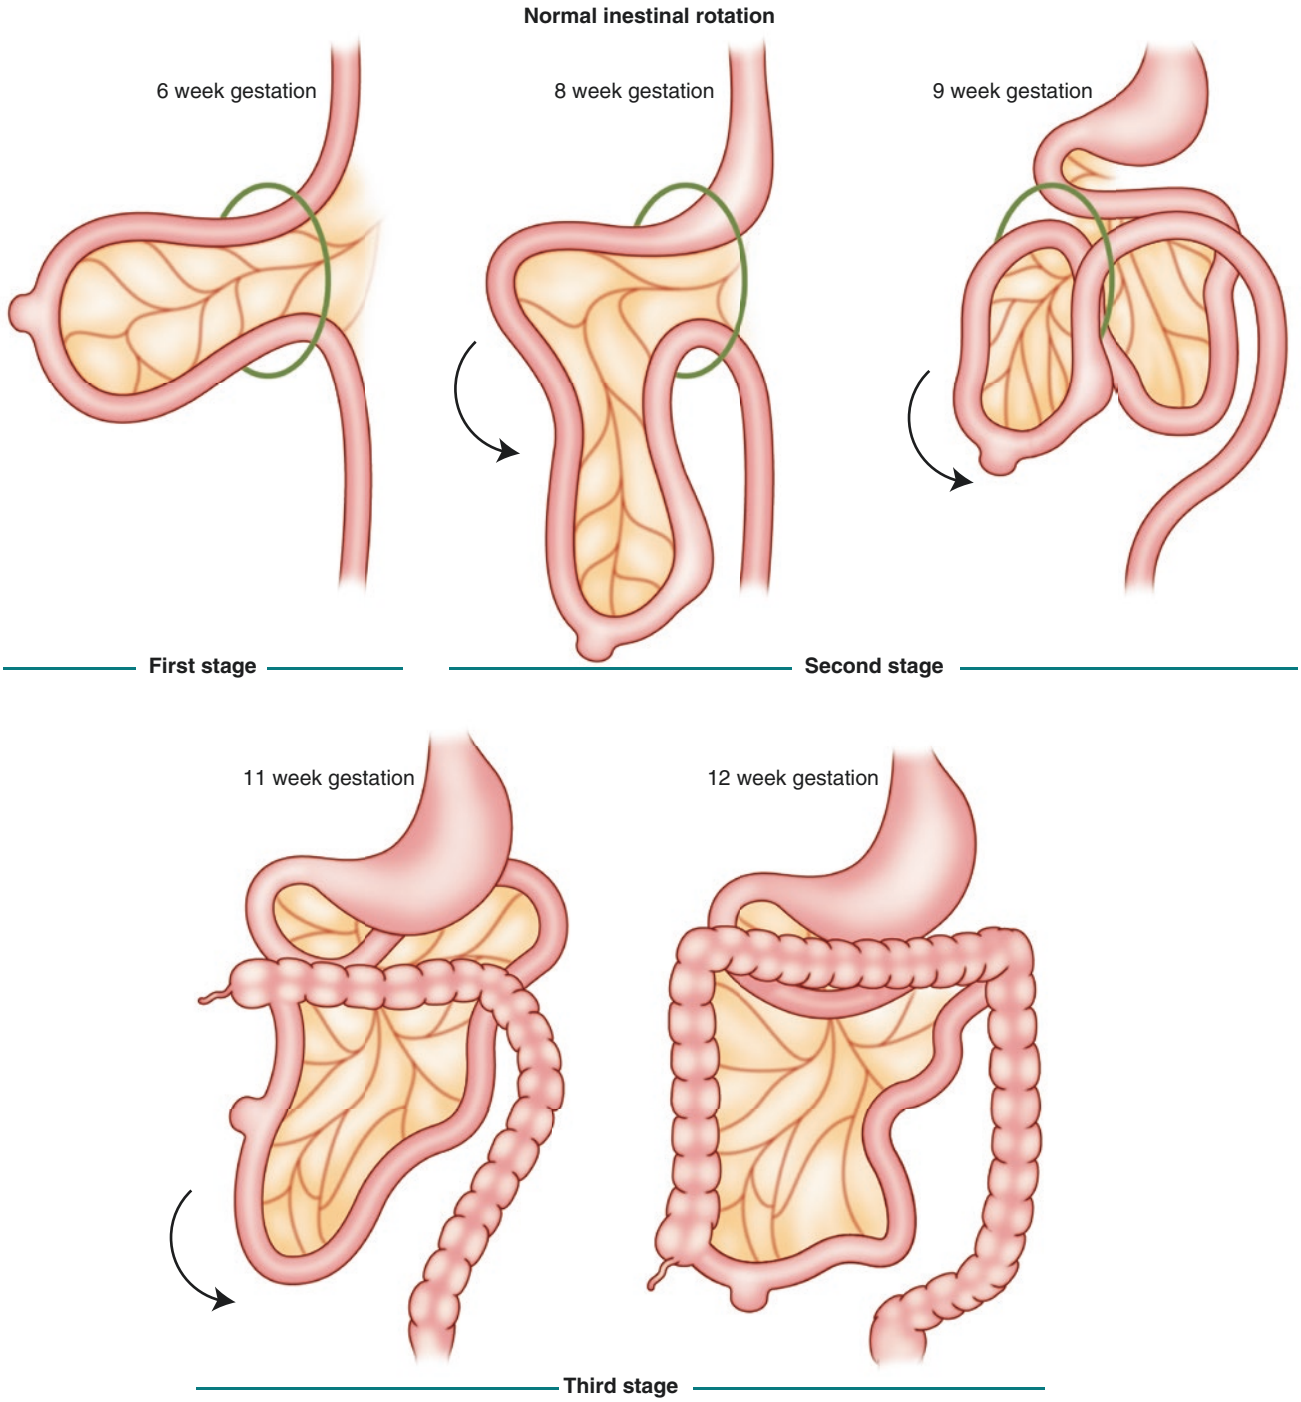

Fig. 1.12 Summary of normal intestinal rotation during development

normal process lead to various malformations (see below). The physiologic herniation (first stage) occurs between weeks 6 and 8 of development. The primitive gut tube elongates over the superior mesenteric artery and bulges out through the umbilical cord (Fig. 1.13). During the eighth week, these contents move in a counterclockwise fashion, turning 90° from the sagittal to the horizontal plane (Fig. 1.14). Anomalies at this stage are rare but include situs inversus, duodenal inversion, and extroversion of the cloaca. During the second stage (tenth week of gestation), the midgut loops return to the peritoneal cavity and simultaneously rotate an additional 180° in the counterclockwise direction (Fig. 1.15). The pre-arterial portion of the duodenum returns to the abdomen first, followed by the counterclockwise rotation around the superior mesenteric vessels, resulting in the duodenum lying behind them. The colon returns after the rotation, resulting in their anterior location. Anomalies in this stage are more common and result in non-rotation, malrotation, reversed rotation, internal hernia, and omphalocele. The third stage (fixation of the midgut) begins once the intestines have returned to the peritoneal cavity and ends at birth. The cecum migrates to the right lower quadrant from its initial position in the upper abdomen (Fig. 1.16). After the completion of this 270° counterclockwise rotation, fusion begins, typically at weeks 12–13. This results in fusion of the duodenum as well as the ascending and descending colons (Fig. 1.17).

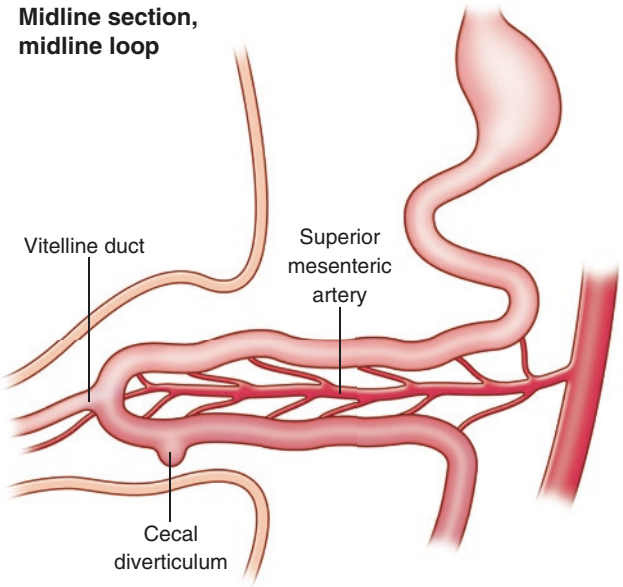

Fig. 1.13 Elongation of the midgut loop

Major Anomalies of Rotation

Non-rotation

The midgut returns to the peritoneum without any of the normal rotation. This results in the small intestine being on the right side of the abdomen and the colon on the left side (Fig. 1.18). This condition can remain asymptomatic (a finding noted at laparoscopy or laparotomy) or result in volvulus affecting the entirety of the small intestine. The twist generally occurs at the duodenojejunal junction as well as the midtransverse colon.

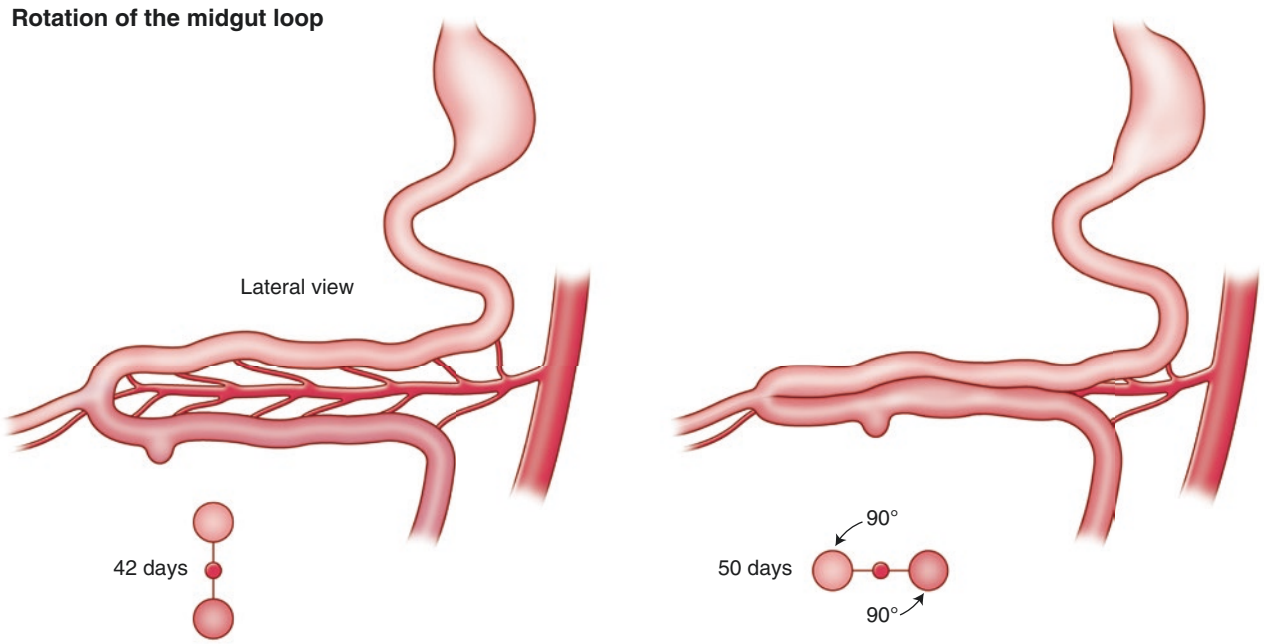

Fig. 1.14 Rotation of the midgut loop

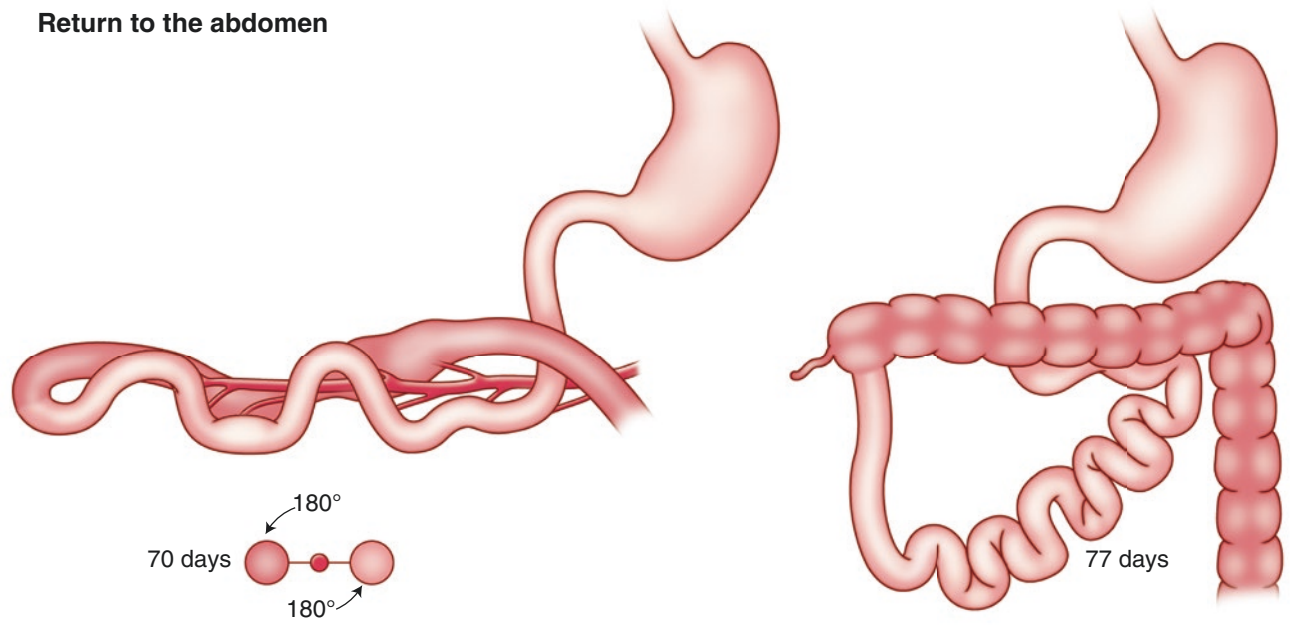

Fig. 1.15 Return of the intestinal loop to the abdomen

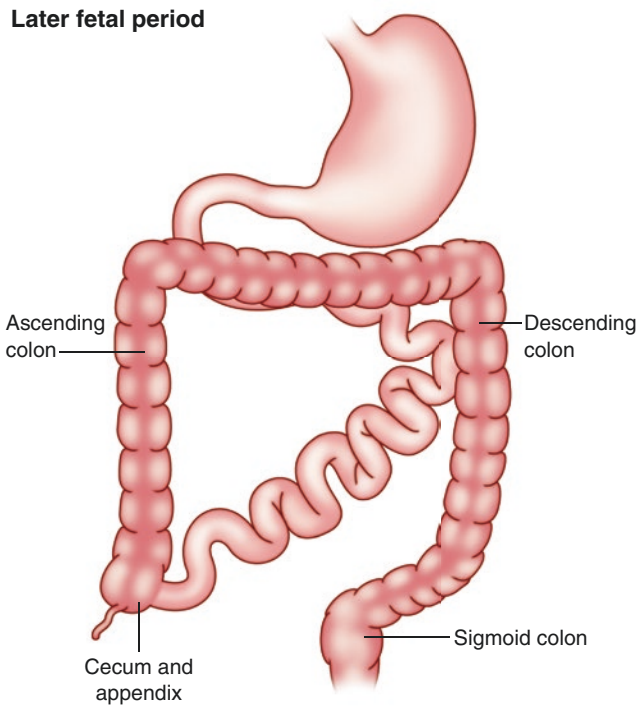

Fig. 1.16 Later fetal development

Malrotation

There is normal initial rotation, but the cecum fails to complete the normal 270° rotation around the mesentery. This results in the cecum being located in the mid-upper abdomen with lateral bands (Ladd's bands) fixating it to the right abdominal wall (Fig. 1.19). These bands can result in extrinsic compression of the duodenum.

Reversed Rotation

Clockwise (rather than counterclockwise) rotation of the midgut results in the transverse colon being posterior to the superior mesenteric artery while the duodenum lies anterior to it.

Omphalocele

An omphalocele is, basically, the retention of the midgut within the umbilical sac and its failure to return to the peritoneal cavity. The bowel remains enclosed in a membrane as it herniates through a defect larger than 4 cm [82].

Internal Hernias

Internal hernias, as well as congenital obstructive bands, can cause congenital bowel obstructions. These are considered failures of the process of fixation (the third stage

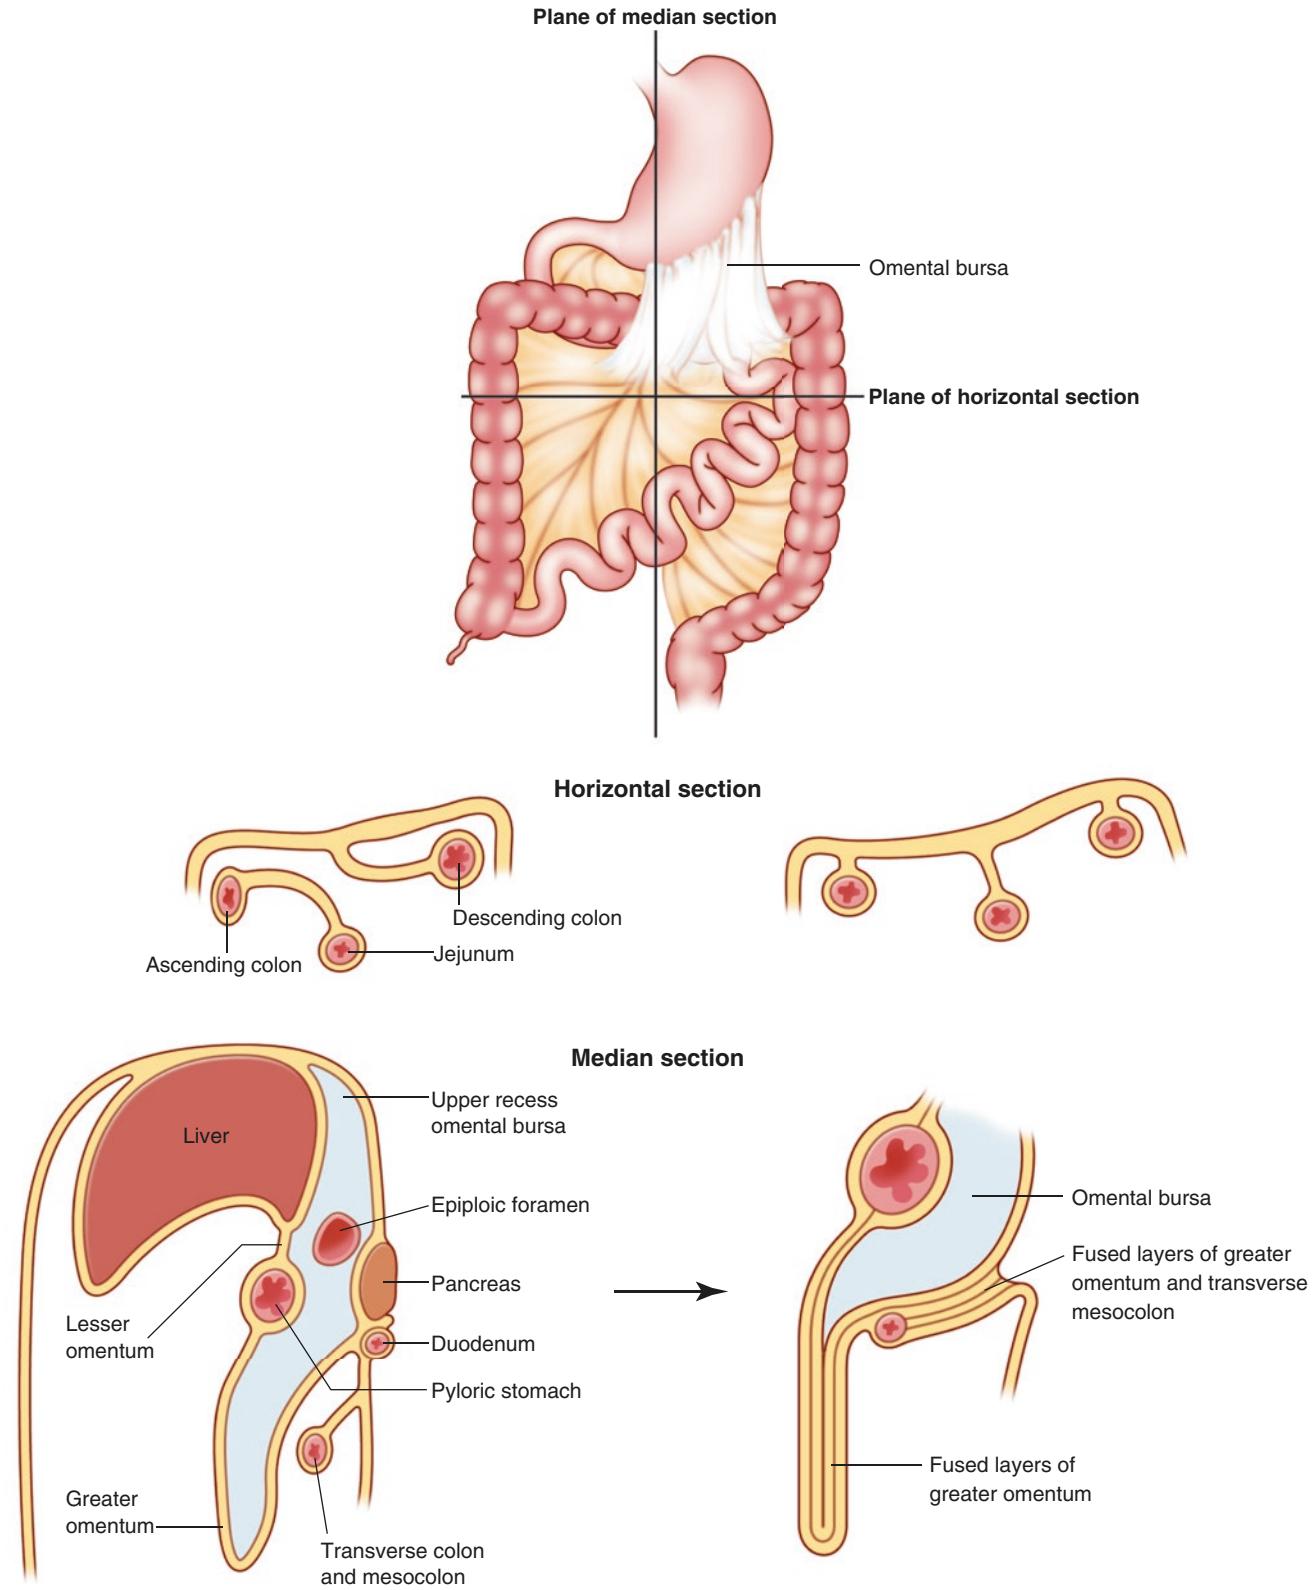

Fig. 1.17 Development of the mesentery and omental fusion

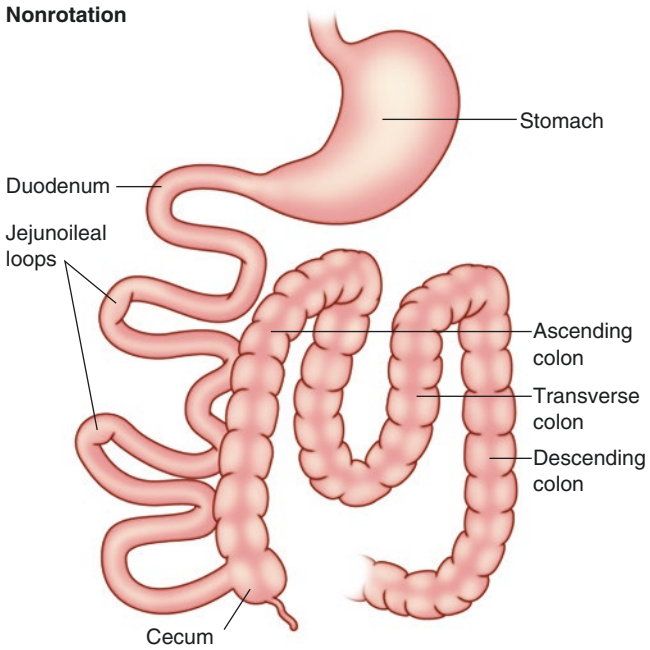

Fig. 1.18 Intestinal non-rotation

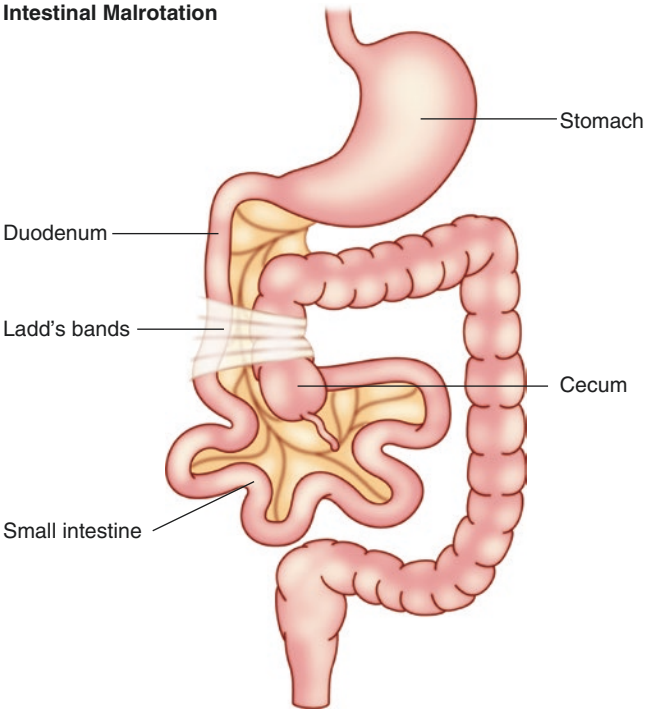

Fig. 1.19 Intestinal malrotation

of rotation). This can be the result of an incomplete fusion of the mesothelium or when structures are abnormally rotated. Retroperitoneal hernias can occur in various positions, most notably paraduodenal, paracecal, and intersigmoid.

Other Congenital Malformations of the Colon and Small Intestine

Proximal Colon Duplication

There are three general types of colonic duplication: mesenteric cysts, diverticula, and long colon duplication [83]. Mesenteric cysts are lined with intestinal epithelium and variable amounts of smooth muscle. They are found within the colonic mesentery or posterior to the rectum (within the mesorectum). They may be closely adherent to the bowel wall or separate from it. They generally present as a mass or with intestinal obstruction as they enlarge. Diverticula can be found on the mesenteric or antimesenteric sides of the colon and are outpouchings of the bowel wall. They often contain heterotopic gastric or pancreatic tissue. Long colonic duplications of the colon are the rarest form of duplication. They parallel the functional colon and often share a common wall throughout most of their length. They usually run the entire length of the colon and rectum, and there is an association with other genitourinary abnormalities.

Meckel's Diverticulum

A Meckel's diverticulum is the remnant of the vitelline or omphalomesenteric duct (Fig. 1.13). It arises from the antimesenteric aspect of the terminal ileum, most commonly within 50 cm of the ileocecal valve. They can be associated with a fibrous band connecting the diverticulum to the umbilicus (leading to obstruction), or it may contain ectopic gastric mucosa or pancreatic tissue (leading to bleeding or perforation) (Fig. 1.20). An indirect hernia containing a Meckel's diverticulum is termed a Littre's hernia. Meckel's diverticulum is generally asymptomatic and, per autopsy series, is found in up to 3% of the population [84]. Surgical complications, which are more common in children than adults, include hemorrhage, obstruction, diverticulitis, perforation, and umbilical discharge. Generally, there is no hard indication for excision of an incidentally discovered Meckel's diverticulum, though its removal is generally safe [85, 86].

Atresia of the Colon

Colonic atresia, representing only 5% of all gastrointestinal atresias, is a rare cause of congenital obstruction. They are likely the result of vascular compromise during development [87]. They vary in severity from a membranous diaphragm blocking the lumen to a fibrous cord-like remnant, on to a complete absence of a segment [88].

Hirschsprung's Disease

This nonlethal anomaly, which is more common in males, results from the absence of ganglion cells within the myenteric plexus of the colon. It is caused by interruption of the normal migration of the neuroenteric cells from the neural

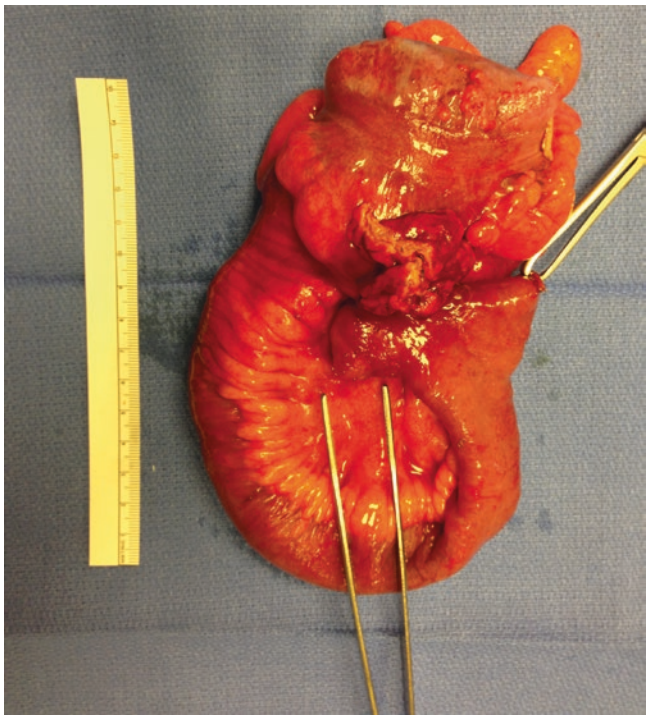

Fig. 1.20 Perforated Meckel's diverticulum with fistula to the ileum

crest before they reach the rectum. This results in dilation and hypertonicity of the proximal colon. The extent of the aganglionosis is variable, though the internal sphincter is always involved. Its severity is dependent upon the length of the involved segment. It will be discussed fully in a subsequent chapter.

Anorectal Malformations

Abnormalities in the normal development of the anorectum can be attributed to "developmental arrest" at various stages of normal development. These abnormalities are often noted in concert with spinal, sacral, and lower limb defects, as noted by Duhamel, and theorized to be related to a "syndrome of caudal regression" [89]. Indeed, skeletal and urinary anomalies are associated in up to 70% [90], while digestive tract anomalies (e.g., tracheoesophageal fistula or esophageal stenosis) and cardiac and abdominal wall abnormalities are also noted in patients with anorectal anomalies.

Anal Stenosis

While anal stenosis in a newborn is relatively common, noted in 25–39% of infants, symptomatic stenosis is only noted in 25% of these children [91]. The majority of these children undergo spontaneous dilation in the first 3–6 months of life.

Membranous Atresia

This very rare condition is characterized by the presence of a thin membrane of skin between the blind end of the anal canal and the surface. It is also termed the covered anus. It is more common in males.

Anal Agenesis

The rectum develops to below the puborectalis where either it ends in an ectopic opening (fistula) in the perineum, vulva, or urethra or it ends blindly (less commonly). The sphincter is present at its normal site.

Anorectal Agenesis

Anorectal agenesis is the most common type of "imperforate anus." More common in males, the rectum ends well caudal to the surface, and the anus is represented by a dimple with the anal sphincter usually being normal in location. In most cases, there is a fistula to the urethra or vagina. High fistulae (to the vagina or urethra) with anorectal agenesis develop as early as the sixth or seventh week of gestation, while the low fistulae (perineal) or anal ectopia develop later, in the eighth or ninth week of development.

Rectal Atresia or "High Atresia"

In rectal atresia, the rectum and the anal canal are separated from one another by an atretic portion. It is embryologically the distal most type of colon atresia but is still considered an anorectal disorder clinically.

Persistent Cloaca

This rare condition, which only occurs in female infants, is the result of total failure of descent of the urorectal septum. It occurs at a very early stage of development.

Acknowledgments This chapter builds on previous chapters written by José Marcio Neves Jorge and Angelita Habr-Gama in the first and second editions of this textbook and by Steven Mills and Joseph Carmichael in the third edition of this textbook.

Colonic Physiology

2

Glenn T. Ault and Jennifer S. Beaty

Key Concepts

- Colonic innervation is supplied by both extrinsic and intrinsic pathways. The extrinsic pathways are derived from the autonomic nervous system. The parasympathetic input is excitatory, while the sympathetic input is inhibitory to colonic motor function. The intrinsic consists of the myenteric plexus.
- The interstitial cells of Cajal (ICC) are the primary pacemaker cells of the enteric nervous system.
- The short-chain fatty acid (SCFA) butyrate is the primary energy source of the colon. It is produced by the colon as a result of fermentation of complex carbohydrates by colonic flora.
- The colon absorbs sodium and water and secretes bicarbonate and potassium. Aldosterone mediates the process of active sodium absorption in the colon.
- Colonic contractile events are divided into (1) segmental contractions and (2) propagated contractions, including low-amplitude propagating contractions (LAPC) and high-amplitude propagating contractions (HAPC). The main function of HAPC is to propagate colonic contents toward the anus.

> No organ in the body is so misunderstood, so slandered and so maltreated as the colon. Its sorrows are numerous and real. (Sir Arthur F. Hurst. 1921 [1])

Embryology

Familiarity with the complex embryologic process of colon and rectal development is important to understanding its function and pathologic processes. During the third and fourth weeks of gestation, the primitive gut arises from the cranio-caudal and lateral folding of the dorsal endoderm-lined yolk sac. The mucosa arises from the endodermal layer, while the muscular wall, connective tissue, and outer serosal surface arise from the mesodermal layer. By the fourth week of gestation, three distinct regions (foregut, midgut, and hindgut) have differentiated based on their blood supply. The foregut, supplied primarily by the celiac artery, consists of the distal end of the esophagus, stomach, and initial portion of the duodenum. The midgut, supplied by the superior mesenteric artery, begins distal to the confluence of the common bile duct in the third portion of the duodenum and includes the proximal two-thirds of the transverse colon. This portion of the intestine maintains a connection to the yolk sac via the vitelline duct. Absence of its obliteration results in a Meckel's diverticulum. The hindgut, which comprises the rest of the distal GI tract, includes the distal transverse colon, descending colon, sigmoid colon, and rectum. This is supplied by the inferior mesenteric artery [2].

During the fifth week of gestation, the midgut undergoes a rapid elongation which exceeds the capacity of the abdominal cavity. This results in a physiologic herniation through the abdominal wall at the umbilicus. Through the sixth week of gestation, continued elongation results in a 90° counterclockwise rotation around the superior mesenteric artery. The small intestine continues its significant growth, forming loops, while the caudal end enlarges into the cecal bud. During the tenth week of gestation, herniated bowel returns to the abdominal cavity, completing an additional 180° counterclockwise loop. Anomalies of this stage of development may include nonrotation, malrotation, reversed rotation, internal hernia, and omphalocele. After the bowel is returned to the abdominal cavity, the disposition of the embryonic proximal jejunum is on the left and the primitive colon is on the right. The cecum is the last component to reenter the abdomen. It is initially located in the right upper quadrant but then migrates inferiorly to the right iliac fossa, as the dorsal mesentery suspending the ascending colon shortens and then recedes [3] (Fig. 2.1). As the cecal bud descends,

the appendix appears as a narrow diverticulum. The loss of the dorsal mesentery of the ascending and descending colon produces their retroperitoneal fixation, absent in the cecum, transverse colon, and sigmoid colon [2].

The embryology of the distal rectum is more complex. It initially begins as the cloaca which is a specialized area comprising endodermal and ectodermal tissue. The cloaca exists as a continuation between the urogenital and GI tracts; however, during the sixth week of gestation, it begins to divide and differentiate into the anterior urogenital, posterior anorectal, and sphincter components. At the same time, the urogenital and GI tracts become separated by caudal migration of the urogenital septum. During the tenth week of gestation, while the majority of the midgut is returning to the abdomen, the external anal sphincter is formed in the posterior cloaca as the descent of the urogenital septum becomes complete. The internal anal sphincter is formed during the 12th week of gestation by enlargement and specialization of the circular muscle layer of the rectum [2].

Colonic Anatomy

Introduction

Human fecal production is approximately 128 g/day, increased by high dietary fiber intake. The chemical composition and pH of the fecal output are influenced by diet, with the major organic component (25–54% of dry solid) of feces derived from bacterial biomass [4]. The colonic epithelium is highly efficient at absorbing sodium, chloride, water, and short-chain fatty acids. In addition, the colonic epithelium secretes bicarbonate, potassium chloride, and mucus. Under normal conditions, the colon receives approximately 1500 to 2000 mL of fluid material from the ileum over a 24-hour period, absorbing all but 100 mL of fluid and 1 mEq of sodium and chloride, resulting in excretion of feces with a sodium concentration of approximately 30 mmol/l and potassium concentration of 75 mmol/l [5]. Colonic absorptive capacity can increase up to 5 or 6 liters and 800–1000 mEq of sodium and chloride daily when challenged by larger fluid loads entering the cecum, a feature that allows the large bowel to compensate for impaired absorption in the small intestine. Several factors determine colonic absorption ability, including volume of fluid, composition of fluid, and rate of flow of luminal fluid. Since the work of Cannon in 1902, the proximal colon has been recognized to be the primary site responsible for storage, mixing, and absorption of water and electrolytes [6]. While the rectosigmoid colon functions primarily as a conduit, it can also participate in this compensatory absorptive response.

Colonic Wall Anatomy

There are four layers to the colonic wall: mucosa, submucosa, muscularis propria, and serosa. The mucosa consists of epithelium, lamina propria, and muscularis mucosae (Fig. 2.2). The epithelium lines the luminal surface of the colon. The submucosal layer is just deep to the epithelium and contains vasculature, lymphatics, and Meissner's

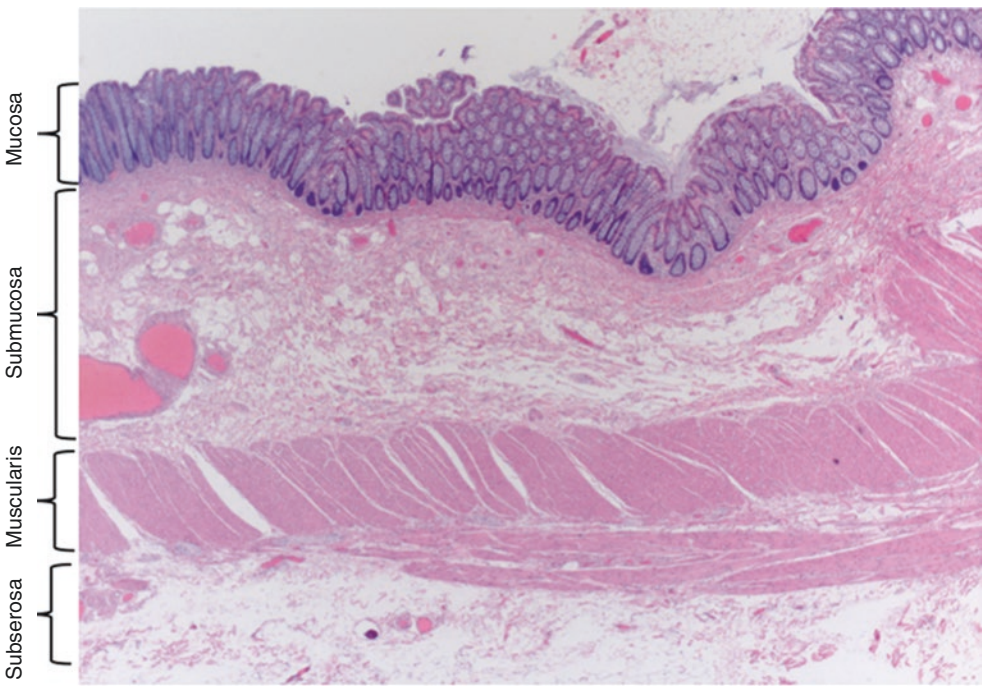

Fig. 2.2 Normal colonic mucosa. H&E, 250×. The layers of the normal colonic wall are indicated by the brackets. (*Courtesy of Julieta E. Barroeta, MD*)

nerve plexus. The submucosa consists largely of loose connective tissue with collagen and elastin fibrils. The muscular layers of the large intestine are composed of both longitudinally and circularly arranged fibers. Longitudinal muscle fibers are concentrated into three flat bands called the taenia coli. These run from the cecum to the rectum, where the fibers fan out to form a more continuous longitudinal coat. The circular layer of muscle fibers is continuous from the cecum to the anal canal, where it increases in thickness to form the internal anal sphincter. Auerbach's myenteric plexus is found between the circular and longitudinal smooth muscle layers. The interstitial cells of Cajal (ICC) are specialized mesenchymal, c-kit-positive cells. The ICC are thought to primarily serve as the pacemaker cell of the enteric nervous system, linking the colonic submucosa electrochemically with the myenteric plexus. There are multiple subtypes of ICC dispersed throughout the musculature of the colon, and controversy exists surrounding their distribution [7]. The ICC are the cells of origin of GI stromal tumors (GISTs) which arise from the colonic wall rather than the mucosa. The serosa is the outermost layer of the colon and is surrounded by visceral peritoneum [8]. The colonic epithelium is highly specialized with multiple ion channels, carrier proteins, and pumps. An in-depth review of these mechanisms is well beyond the scope of this chapter.

Epithelial Types

There are three main types of colonic epithelial cells: enterocytes, goblet cells, and neuroendocrine cells. Enterocytes are simple columnar epithelial cells. They are the major cell type in colonic epithelium, and they play important roles in nutrient absorption and in secretion. Goblet cells secrete mucus to lubricate the passage of food through the intestines. Enterocytes and goblet cells comprise nearly 95% of the epithelial cells in the colon. Neuroendocrine cells are known to act as chemoreceptors, initiating digestive actions, detecting harmful substances, and initiating protective responses [9].

All types of epithelial cells differentiate from common stem cells, which are located at the bottom of the crypts, and most differentiated cells migrate to the surface epithelium (Fig. 2.3). The epithelium lining is continuously renewed by dividing cells every 4–5 days. Crypt epithelium is highly proliferative and relatively undifferentiated and secretes chloride. The surface epithelium, in contrast, has low proliferative activity, is well-differentiated, and is highly absorptive. Ion absorption and secretion occurs at both the surface and crypt levels [10].

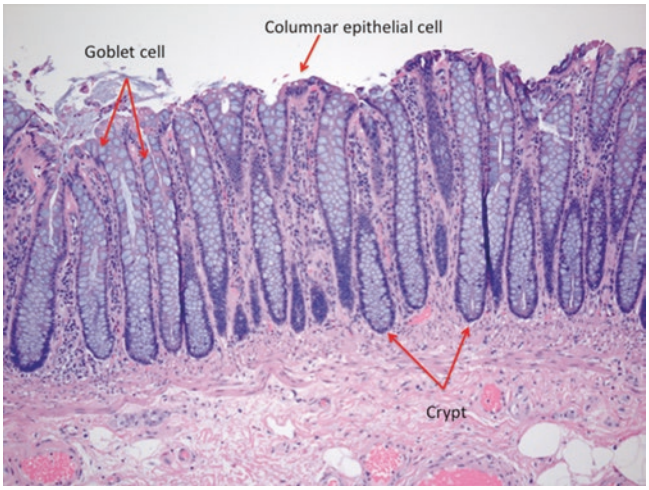

Fig. 2.3 Normal colonic mucosa. H&E, 1000×. Epithelial cell types are clearly visible including goblet cells and columnar epithelial cells. The crypts are the source of the continually regenerating mucosal cells. (*Courtesy of Julieta E. Barroeta, MD*, used with permission)

Secretory Role of Colonic Epithelium

Sodium

Absorption of sodium and secretion of bicarbonate in the colon are active processes, occurring against an electrochemical gradient. This process resides primarily in the crypt cells and is responsible for maintaining a liquid chyme. Ninety percent of sodium is actively absorbed in exchange for secretion of potassium. The transcellular secretion of chloride accounts for most of the secretory activity. Chloride enters the cell through a sodium carrier located in the basolateral membrane. The majority of sodium chloride absorption occurs in the proximal colon and is driven primarily through the electroneutral absorption by tightly coupled luminal Na^+/H^+ and Cl^-/HCO_3^- exchange. The sodium gradient is established by Na $^+$-K $^+$-ATPase, and each pump cycle results in the extrusion of three sodium ions in exchange for the basolateral uptake of two potassium ions, resulting in the net transfer of one positively charged sodium ion across the basolateral membrane (Fig. 2.4). The resulting secretion of sodium and potassium establishes an osmotic gradient drawing water into the lumen [10]. The epithelial Na^+/H^+ exchange is a pleiotropic membrane transport mechanism that participates in intestinal NaCl transport. It also helps to regulate basic cellular functions and the extracellular milieu to facilitate other nutrient absorption and to regulate the gut microbial microenvironment [11].

In the distal colon, the epithelial sodium channel (ENAC) mediates sodium absorption. Sodium is taken up by the ENAC on the luminal side and is excreted on the basolateral

surface by the Na $^{+}$-K $^{+}$-ATPase. Chloride is absorbed through the luminal cystic fibrosis conductance regulator (CFTR) and is then excreted on the basolateral side via multiple mechanisms, including KCl cotransporter (KCCl), Cl^{-} channels, and Cl^{-}/HCO_3^{-} anion exchangers. The net result is tight regulation of electrolyte secretion in excreted stool (Fig. 2.4) [2].

Clinical applications of abnormalities associated with sodium continue to emerge. For example, *Clostridium difficile*, the leading cause of nosocomial diarrhea and pseudomembranous colitis, also exerts inhibitory effects on epithelial Na^{+}/H^{+} exchange mechanism. However, in inflammatory bowel disease (IBD), both electrogenic sodium transport mediated by sodium channels and electroneutral Na^{+}/H^{+}

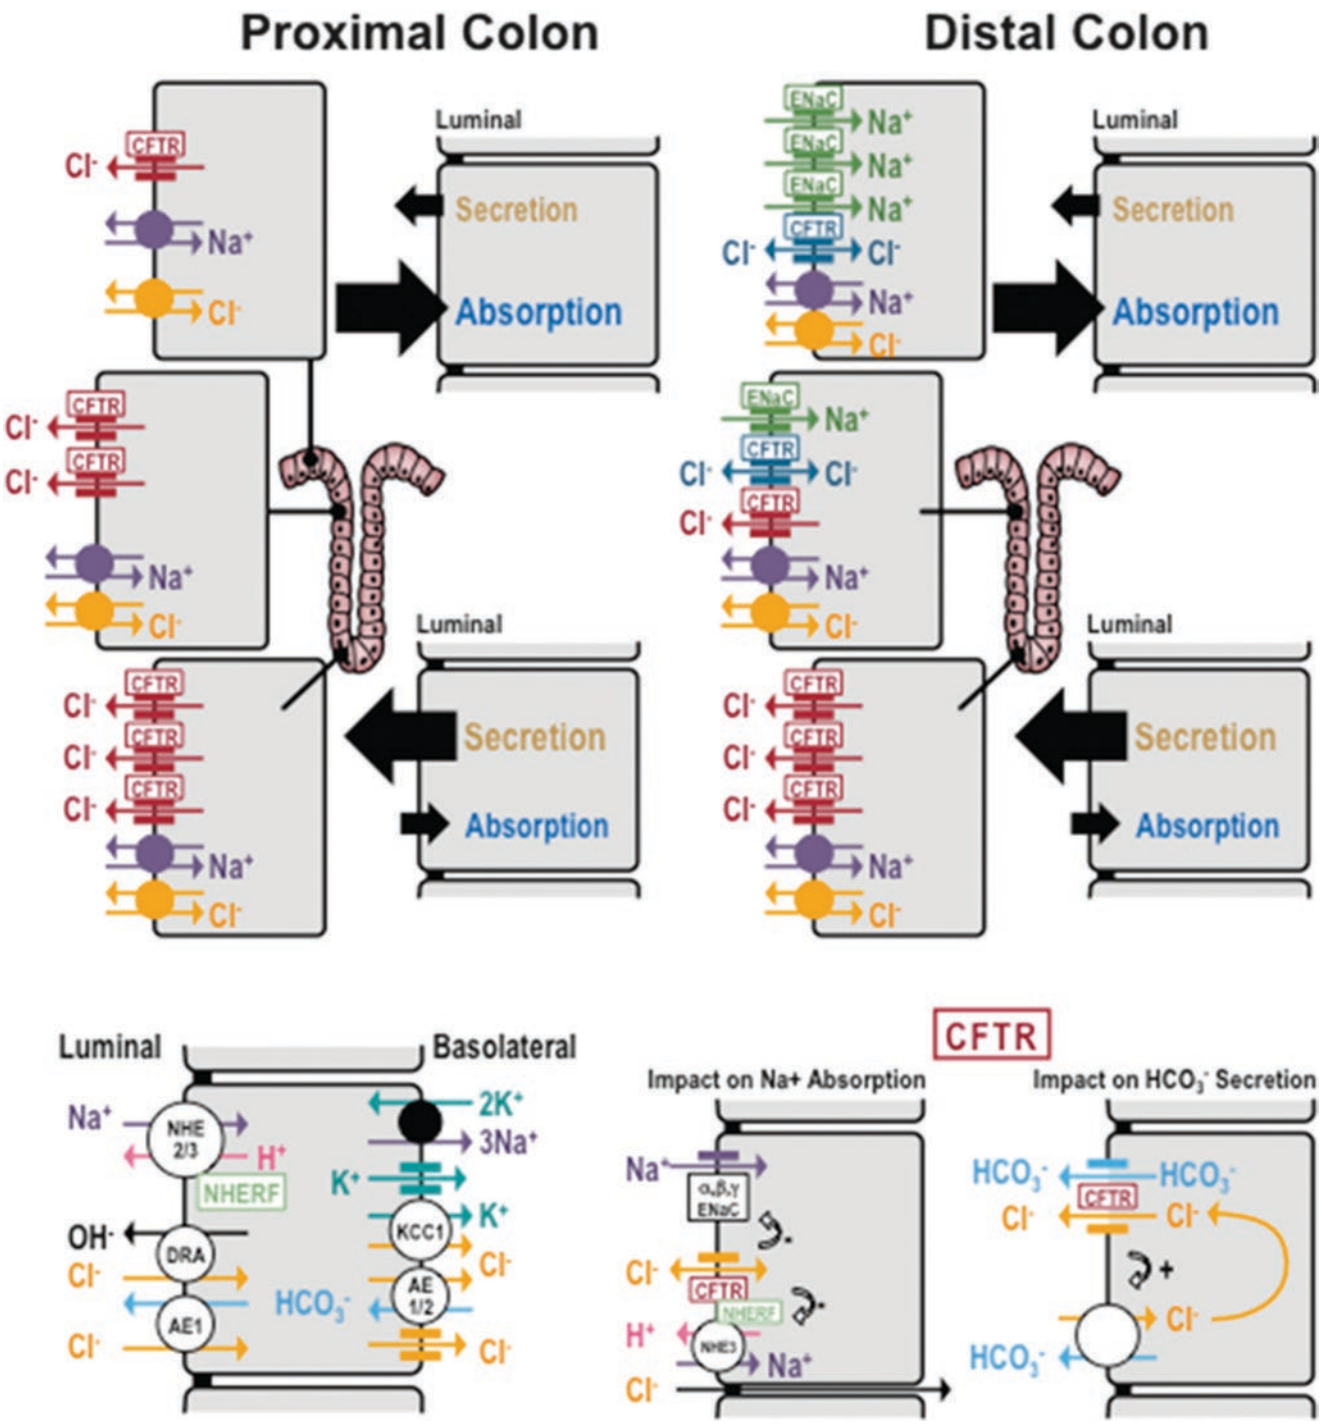

Fig. 2.4 Schematic of ion-transport channels in proximal and distal colonocytes. (*Courtesy of Robin Noel*, used with permission)

exchange-coupled NaCl absorption are reduced [12]. The Na^+/H^+ exchangers are frequent targets of inhibition in gastrointestinal pathologies, by either intrinsic factors (e.g., bile acids, inflammatory mediators) or infectious agents and associated microbial toxins [11]. A separate Cl^-/OH^- exchange is represented by a protein called DRA (downregulated in colonic adenomas). Human DRA mutations are responsible for congenital chloride diarrhea [13].

In infectious diarrhea, active and excessive chloride secretion is predominant. Cholera is a classic example leading to significant watery diarrhea. If uncontrolled, it can lead to the loss of large quantities of fluid and electrolytes, which can result in dehydration and electrolyte imbalances, and ultimately death. In this instance, cholera toxin binds to the brush border of crypt cells and increases intracellular adenylyl cyclase activity. Adenylyl cyclase synthesizes cAMP from ATP. The result is a dramatic increase in intracellular cAMP that stimulates active Cl^- and $HCO3^-$ secretion into the lumen. Water follows the osmotic gradient and enters the lumen leading to a secretory diarrhea.

Potassium

The colonic epithelial apical and basolateral membranes are permeable to potassium. There is a high concentration of intracellular potassium maintained by the Na^+-K^+ pump; therefore, some potassium will leak passively across the apical membrane of epithelial cells. The concentration of potassium in the colonic lumen remains roughly equal to the serum potassium (4 or 5 mEq/L). In the colon, net potassium secretion occurs. Because of potassium secretion and the exchange of chloride for bicarbonate in the colon, prolonged diarrhea results in hypokalemic metabolic acidosis. This also contributes to the alkaline pH of stool water.

Aldosterone

Mineralocorticoids can decrease the sodium concentration in fecal water from 30 to 2 mEq/L and increase the potassium concentration from 75 to 150 mEq/L. There is an increase in sodium permeability of the brush border membrane caused by the activation of new sodium channels. In addition, aldosterone increases the number of sodium pump molecules in the basolateral membrane. The influence of aldosterone on sodium transport is exerted at two points. In the distal colon, epithelial Na^+-K^+-ATPase is activated by aldosterone. In the proximal colon, the Na^+-H^+ exchange is activated by aldosterone. Therefore, aldosterone works by two different mechanisms, in different portions of the colon, to conserve sodium at the expense of potassium.

Mechanism for Water Absorption

The human colon has a nominal mucosal surface area of about 2000 cm^2 [14]; however, the total absorptive area is even greater because colonic crypt cells are capable of absorption as well as secretion [15]. The continued production of solutes by colonic bacteria, together with the relative impermeability of the colonic membrane to water, usually causes stool water to be hypertonic, 350–400 milliosmoles (mOsm)/L, to plasma. The volume of fluid moving from blood to lumen (secretion) is less than that moving from the lumen to the blood (absorption), thus resulting in net absorption. Absorption generally results from the passive movement of water across the epithelial membrane in response to osmotic and hydrostatic pressures. The autonomic nervous system has effects on NaCl transport affecting absorption. Adrenergic (α-receptor) or anticholinergic stimuli tend to increase absorption [10].

Short-Chain Fatty Acid Absorption

In the proximal colon, bacteria ferment organic carbohydrates to short-chain fatty acids (SCFA), predominantly acetate, propionate, and butyrate. Butyrate is the main energy substrate for the colonic epithelium. SCFA provides approximately 10% of the daily caloric requirements [16]. SCFA are among the most important microbial metabolites that interact with host cells, with up to 100 mMols of SCFA produced in the colonic lumen by bacteria. Since luminal SCFA are absorbed by colonic epithelial cells into the submucosa and the systemic circulation, a variety of SCFA signaling pathways are likely involved in acute and long-term physiological responses to luminal bacterial activity [17].

SCFA are potent stimuli of sodium and water absorption in the colon, with butyrate being the most effective. SCFA are rapidly absorbed from the colon which augments sodium, chloride, and water absorption. SCFA have several potentially therapeutic effects in vitro. They regulate proliferation, differentiation, gene expression, immune function, and colonic wound healing. In acute diarrhea, fecal SCFA concentrations are reduced, and this may contribute to impaired sodium absorption. SCFA potentially reduce inflammation in ulcerative colitis and diversion colitis. Butyrate has also been hypothesized to reduce the risk of colon cancer [18].

Vitamin K Absorption

The lipid-soluble vitamin K plays an essential role in facilitating blood coagulation by activating clotting factors; it also plays a role in signal transduction, cell proliferation, and bone and cartilage metabolism. Vitamin K is widely distributed in our diets and is also produced by the normal colon microbiota. Humans cannot synthesize vitamin K endogenously and, thus, must obtain it from exogenous sources via intestinal absorption. Absorption of dietary vitamin K in the small intestine is carrier-mediated and is an energy-dependent process, while absorption in the microbiota-generated vitamin K in the colon is via passive diffusion [19].

Colonic Innervation

The gastrointestinal tract is densely innervated to provide information on its luminal contents, processes regulating digestion and absorption, and potential threats [20].

The enteric nervous system is the largest single division of the autonomic nervous system (ANS), containing between 200 and 600 million enteric neurons throughout the GI tract [21]. The colon and rectum are innervated by nerves of both extrinsic and intrinsic origin. The extrinsic pathways originate from the central and autonomic (sympathetic and parasympathetic) nervous systems. Autonomic pathways run along parasympathetic and sympathetic chains. Each of these pathways include afferent (sensory) and efferent (motor) innervation. The intrinsic innervation consists of the enteric nervous system. Two major sets of ganglia are found in the colon. The myenteric or Auerbach's plexus is located between the longitudinal and circular smooth muscle layers and plays a crucial role in colonic smooth muscle function. The submucosal or Meissner's plexus regulates ion transport. The extreme importance of these two plexuses is clear in children with Hirschsprung's disease in which the ganglia of the myenteric and submucosal plexuses are congenitally absent. The aganglionic segments do not relax and peristalsis is disturbed resulting in severe constipation [22].

Extrinsic innervation to the large intestine comes from both parasympathetic and sympathetic branches of the ANS. Colonic motility is modulated by sympathetic neurons in prevertebral ganglia, which has potent effects on colonic function (Fig. 2.5). The proximal regions of the large intestine are sympathetically innervated by fibers that originate from the superior mesenteric ganglion. More distal regions receive input from the inferior mesenteric ganglion. There is evidence for ongoing tonic inhibition of colonic secretion, since disrupting the pathway causes a substantial increase in secretion. This is largely mediated by a strong inhibitory drive to secretomotor neurons in submucosal ganglia, via α-2-adrenergic receptors [23]. Sympathetic activation also directly contracts sphincters via indirect effects (i.e., by reducing acetylcholine release from cholinergic neurons) and inhibits activation of enteric neurons. Both actions delay GI and colonic transit. The distal rectum and anal canal are innervated by sympathetic fibers from the hypogastric plexus.

There are two pathways of parasympathetic innervation. The cecum and the ascending and transverse portions of the colon are innervated by the vagus nerve, whereas the descending and sigmoid areas of the colon and the rectum are innervated by pelvic nerves from the sacral region of the spinal cord. The pelvic nerves enter the colon near the rectosigmoid junction and project orally and aborally within the plane of the myenteric plexus. The vagus and pelvic nerves consist primarily of preganglionic efferent fibers and many afferent fibers. The efferent fibers synapse with the nerve cell bodies of the myenteric and other intrinsic plexuses. The external anal sphincter, a striated muscle, is innervated by the somatic pudendal nerves. Sacral parasympathetic pathways to the colon primarily synapse onto myenteric neurons.

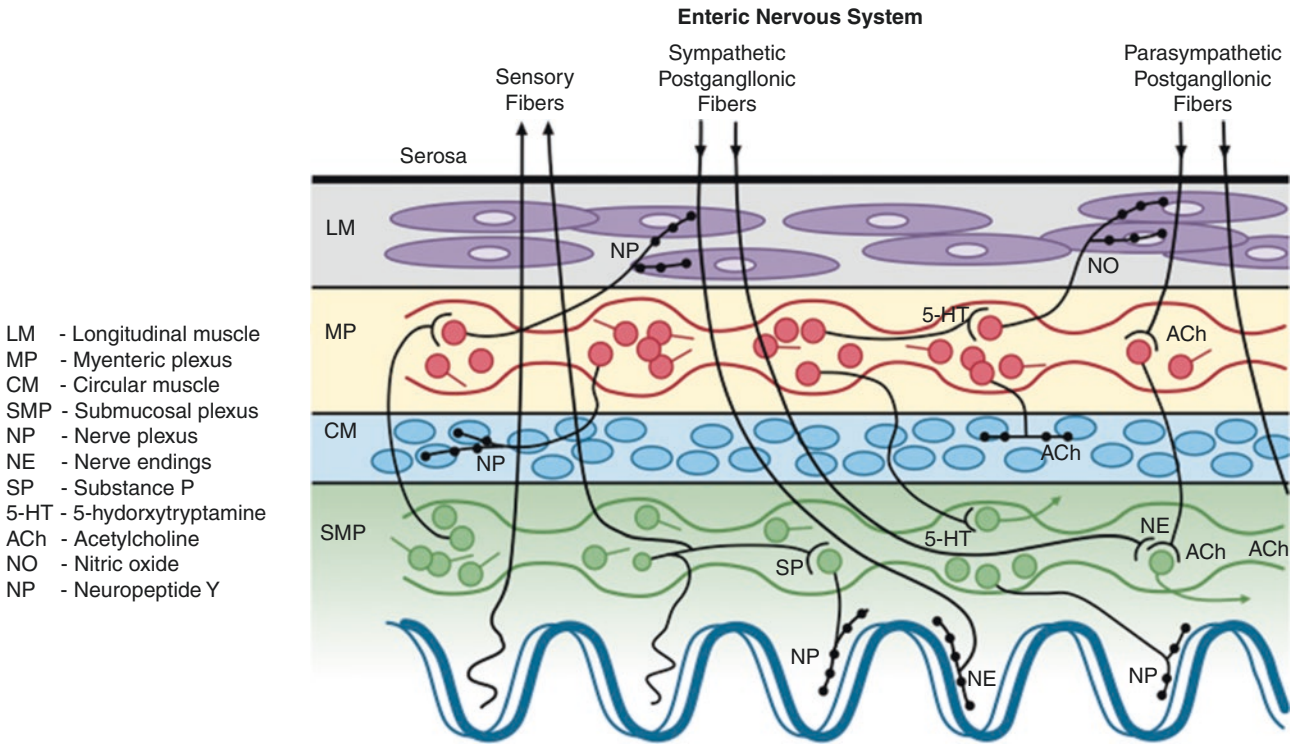

Fig. 2.5 Schematic representation of the components of the enteric nervous system. (*Courtesy of Robin Noel*, used with permission)

Excitatory pathways are important for colonic propulsive activity, especially during defecation; damage to these pathways can cause severe constipation [24].

As in other regions of the gut, several diverse chemicals serve as mediators at presynaptic and postsynaptic junctions within the autonomic innervation to the large intestine. Acetylcholine (ACh) and tachykinins such as substance P serve as major excitatory mediators, and nitric oxide (NO), vasoactive intestinal peptide (VIP), and possibly adenosine triphosphate (ATP) serve as major inhibitory mediators. Transmission between the pudendal nerves and the external anal sphincter is mediated by ACh [10].

Pain

The sensation of pain appears to be mediated by different afferents depending on the location of the GI tract undergoing the noxious stimulus. Pain from the rectum primarily involves pelvic pathways. Inflammation (or inflammatory mediators) can change both the response properties of specific classes of sensory neurons and the involvement of specific ascending pathways, which is relevant in post-inflammatory hypersensitivity and postinfectious irritable bowel syndrome (IBS) [25].

Visceral sensory neurons activate reflex pathways that control gut function and give rise to important sensation, such as fullness, bloating, nausea, discomfort, urgency, and pain. Sensory neurons are organized into three central nervous system pathways: vagal, thoracolumbar, and lumbosacral [22]. Experimental distension of the descending or sigmoid colon is perceived as a sensation of cramping, gas, or pressure in the lower abdomen, lower back, or perineum [26].

Both central and peripheral mechanisms have been suggested to be involved in the development of pain symptoms. Several studies have provided evidence that IBS is associated with a dysregulation of the brain-gut axis, with peripheral sensory alterations dominating in some patients and disturbed central processing dominating in others [27]. It is now widely accepted that an altered visceral sensitivity through abnormal endogenous pain processing plays an important role in the pathogenesis of IBS [28]. IBS is associated with decreased epithelial expression of the serotonin-selective reuptake transporter (SERT) in many studies; however, it is unknown if the disturbance is responsible for the symptoms of IBS [29].

Colonic Motility

The motor function of the colon includes propulsion, accommodation, and rapid emptying of a variable portion of the colon during defecation. In addition, the colon must be able to store fecal material until socially acceptable to eliminate. Colonic motility is mediated by the enteric nervous system in association with autonomic parasympathetic and sympathetic input and with input from the extrinsic nervous system. Colonic motility is characterized by patterns of contraction of longitudinal and circular muscle layers with elimination of feces. Motility is integrated with colonic secretion and absorption. Propulsion is achieved by numerous motor events including individual contractions, contractile bursts, high-amplitude propagated contractions (HAPCs), and possibly changes in tone [22]. Accommodation, storage, and distribution of material within the colon are mediated by colonic tone. Tone and phasic activity in the colon show considerable diurnal variation, increasing slowly after a meal, reducing during sleep, and increasing dramatically upon waking [30]. HAPCs occur more frequently during the morning, during the postprandial period, and preceding defecation [30–32]. The colonic motor response to eating consists of an increase in phasic and tonic contractile activity that begins within several minutes of ingestion of a meal and continues for a period of up to 3 hours. This response is influenced by both the caloric content and composition of the meal with fat and carbohydrate stimulating colonic motor activity, while amino acids and protein inhibit motor activity [30].

A more prolonged state of contraction, referred to as tone, is not regulated by slow waves and may be recognized clearly in the colon (response to feeding), as well as in some sphincteric regions. Tone is regulated by actin-myosin interaction mediated by cellular mechanisms that are modulated by neurogenic and mechanical stimuli. Phasic contractions, such as those regulating lumen occlusion, may be superimposed on tonic activity. Thus, tone can increase the efficiency of phasic contractions by diminishing the diameter of the lumen. Tone also modifies wall tension in response to gut filling and is therefore one determinant of perception of distension.

This motor input interacts with myogenic mechanisms to create regional patterns of contraction and relaxation which mix and propel content. It is likely that regular contractile bursts – colonic motor complexes – do occur, each burst occurring once or twice per hour and lasting approximately 6 minutes [22]. Periodic or cyclic motor activity is evident more clearly in the rectum, the so-called rectal motor complexes. They do not appear to be synchronized with the small intestinal motor migrating complexes, and their precise function and regulation remain unclear [22].

The anorectum functions in defecation and continence. Defecation is achieved through the integration of a series of motor events and involves both striated and smooth muscle. A sensation of rectal fullness is generated by rectal afferents when colonic contents reach the rectum. Rectal filling also induces the rectoanal inhibitory or rectosphincteric reflex

that leads to internal anal sphincter relaxation and external sphincter contractions. At this stage, the individual can decide to postpone or proceed with defecation. To facilitate defecation, the puborectalis muscle and external anal sphincter relax, thereby straightening the rectoanal angle and opening the anal canal. The propulsive force enabling defecation is generated by contractions of the rectosigmoid, diaphragm, and the muscles of the abdominal wall to propel the rectal contents through the open sphincter. The internal anal sphincter is a continuation of the smooth muscle of the rectum, is under sympathetic control, and provides approximately 80% of normal resting anal tone. The external anal sphincter and pelvic floor muscles are striated muscles innervated by sacral roots and the pudendal nerve.

Modulators of Colonic Motility

Muscarinic agonists (i.e., hyoscamine) and cholinesterase inhibitors (i.e., neostigmine) increase colonic motility. The α-2 adrenergic antagonist yohimbine also increases colonic motility and promotes fluid and electrolyte absorption, while the α-2 agonist clonidine reduces motility. Clonidine reduces colonic tone and phasic pressure activity, as well as the colonic perception of distention which can increase colonic compliance. Clonidine can be used to treat diarrhea predominant IBS.

Serotonin 5-HT receptors (5-HT_3) antagonists such as alosetron increase colonic compliance, reduce postprandial rectal motor activity, improve stool consistency, delay colon transit, and reduce rectal sensitivity in IBS. Alosetron was approved for IBS-diarrhea predominant in women [33]. A systematic review of published clinical trials through the Food and Drug Administration (FDA) Adverse Events Reporting System documented the risk of ischemic colitis was higher with alosetron than placebo (0.15% vs. 0.0%) [34], and it was subsequently withdrawn from the market.

A newer high selectivity affinity 5-HT_4 receptor agonist, prucalopride, has been approved by the FDA. Extensive cardiovascular assessment suggests it does not affect the Q-T interval. For chronic constipation patients, prucalopride can be used to accelerate intestinal and colonic transit [35, 36].

The GI tract contains three opioid receptors (δ, μ, κ), with the gastrointestinal effects mediated primarily by μ receptors. Opioids reduce neuronal excitability and release of neurotransmitters. Morphine increases colonic phasic segmental activity, reduces fasting colonic tone, and attenuates the gastrocolonic response. Opioids also increase fluid absorption partly by delaying transit and increasing mucosal contact time. Opioid-induced constipation or opioid bowel dysfunction is common, affecting 41–81% of patients treated with opioids [18].

Lubiprostone is a synthetic bicyclic fatty acid derived from prostaglandin E1 that activates apical CIC-2 chloride channels. Lubiprostone also activates prostaglandin EP receptors and the apical cystic fibrosis transmembrane regulator (CFTR), causing intestinal fluid secretion [37]. These secretory effects likely explain why lubiprostone accelerates small intestinal and colonic transit in healthy subjects. Lubiprostone does not affect colonic motor activity in healthy individuals [38] but is approved by the FDA for treating chronic constipation and female constipation predominant IBS [18, 39].

Bile acids infused directly into the human sigmoid and rectum at concentrations of 5 mmol/L stimulated colonic phasic contractions; however, such concentrations are seldom achieved in the colon unless there has been an ileal resection. Rectal infusion of chenodeoxycholic acid at physiological concentrations stimulates proximal colonic propagated contractions and increases rectal sensitivity. Hence, chenodeoxycholic acid accelerates colonic transit in healthy subjects. These effects have pathophysiological and therapeutic consequences. When enterohepatic circulation of bile acids is disrupted by ileal disease (e.g., Crohn's disease, surgical resection, or radiation ileitis) or idiopathic mechanisms (idiopathic bile-acid malabsorption), bile acids spill into the colon, causing diarrhea. Idiopathic bile-acid malabsorption may explain diarrhea in some patients with IBS. From a therapeutic perspective, delayed-release chenodeoxycholic acid, results in accelerated colonic transit and improved bowel function in females with constipation-predominant IBS [18].

Laxatives work either via osmotic effects (e.g., polyethylene glycol-based solutions, magnesium citrate-based products, sodium phosphate-based products, and nonabsorbable carbohydrates [lactulose, sorbitol]) or by stimulating colonic propulsive activity [18]. Osmotic agents, which are hypertonic, pull fluid into the intestinal lumen, causing diarrhea.

Stimulant laxatives (e.g., bisacodyl, sodium picosulfate, and glycerol) stimulate HAPC wave sequences, thereby leading to mass movements; bisacodyl and sodium picosulfate also have anti-absorptive plus secretory effects [18, 40, 41]. Bisacodyl exerts its motor effect through mucosal afferent nerve fibers, because the response can be blocked by topical mucosal application of lidocaine [18].

While sacral nerve stimulation is approved by the FDA to treat fecal incontinence, its role for treating constipation is unclear [42]. Sacral nerve stimulation modulates the extrinsic nerves innervating the pelvic floor and colon. In addition, stimulation of the S3 root also induces propulsive activity throughout the entire colon and has been shown to increase stool frequency in patients with slow transit constipation [43]. In Kamm's study, colonic transit was assessed in 27 of 45 patients with medically refractory chronic constipation who proceeded to permanent sacral nerve stimula-

tion [42]. Of these 27 patients, 20 had delayed colonic transit before but only 9 had delayed transit after sacral nerve stimulation.

Microbiome

A normally functioning GI tract has healthy, well-established colonizing microbiota in its mucosa and lumen, which are major contributors to the maintenance of whole-body homeostasis. It is well established that the species composition and relative abundance of the gut microbiota are impacted by the diet, lifestyle, and overall health of an individual. Humans have developed a commensalistic relationship with the gut microbiome. Over time, this relationship has evolved to become a mutual and interdependent one, in which the physiologic activity of the microbiota has a significant impact on the host and the activity of the host impacts the genera comprising the microbiota. In support of life, gut microbial metabolism supplies the host with short-chain fatty acids and essential vitamins (vitamins B and K) and contributes to the synthesis and absorption of essential amino acids.

The adult human intestine contains approximately 110 trillion bacteria. Gas chromatography-mass spectrometry analysis detected more than 700 volatile organic compounds from human feces [44]. Our microbiota is established in the period after birth and although it can be modulated by factors, such as diet, illness, and antibiotic treatment, is relatively resistant to change in later life. The microbial composition changes along the length of the gut, in response to changes in the luminal environment including presence of nutrients, acidity, and oxygen content. Microbial diversity has been used as an index of a "healthy" microbiota, but this is probably a simplistic notion as some beneficial plant foods will decrease diversity yet produce a beneficial host response. There is considerable variability that likely depends predominantly on diet and lifestyle [45].

The role the human microbiome plays in health and disease is actively under investigation. The composition of feces is altered in diseases such as IBS [46], IBD, colorectal cancer [47], and autism [48], implicating that the pathogenesis of these diseases is associated with dysbiosis. Several studies demonstrate alterations in the fecal and colonic mucosal microbiome in constipation and diarrhea. Absent interventional trials, it is unclear whether these associations reflect cause and effect. However, even after adjusting for demographic features, diet, and colonic transit, the microbiome discriminated between health and constipation with an accuracy of 92% [18].

Patients with IBD have altered microbiota, and they may have changes in their gut microbiota that precede a diagnosis. IBD is thought to be an aberrant immune response to luminal content including the microbiota. A shift in the delicate balance (dysbiosis) of "good" bacteria and "bad" pro-inflammatory bacteria may be important for the development and maintenance of IBD. For example, *Roseburia* spp. are decreased in those already diagnosed with IBD, and as such, the manipulation of the microbiota using antibiotics, probiotics, and prebiotics might be useful in treating IBD [49, 50]. Crohn's disease (CD) is associated with lower overall microbial diversity when compared to healthy controls. The abundance of both the *Proteobacteria* and *Bacteroidetes* was significantly higher in CD when compared to healthy controls and those with ulcerative colitis (UC). Low numbers and the absence of *Faecalibacterium prausnitzii*, a common member of the healthy gut microbial community, have been associated with UC. Antibiotics have been used to treat IBD with the goal of decreasing concentrations of bacteria in the lumen and altering the community composition.

These observations and many others have been the motivating force for the National Institutes of Health (NIH) Human Microbiome Project (NIH HMP) [51]. The NIH HMP is a roadmap for biomedical research and has three main goals: (1) utilize new high-throughput screening technology to characterize the microbiome more completely by studying multiple body sites from 250 "normal" individuals; (2) determine if there are associations between changes in the microbiome and health and disease; and (3) standardize data resources and new technologies for the wider scientific community [52, 53]. Phase II of this project has begun, and it aims to examine changes in three microbiome-associated conditions: (1) preterm birth, (2) IBD, and (3) type 2 diabetes [54–57].

The indigenous human microbiome is dominated by two bacterial phyla: *Firmicutes* and *Bacteroidetes*. In many studies, the *Firmicutes* and *Bacteroidetes* account for greater than 98% of the bacteria present in the human gut. It has long been appreciated that different classes of antibiotics affect the human gut microbial community, both targeted and off-target [58, 59]. The use of antibiotics can open niches that were otherwise occupied and allow for new species (good or bad) to take up residency [60].

For example, changes in human gut microbiome community structure after exposure to the fluoroquinolone antibiotic, ciprofloxacin, have shown that much of the community is altered [61]. Dethlefsen et al. reported that all aspects of the gut microbiome community, that is, diversity, richness, and evenness, were decreased and the abundance of approximately one-third of the species present was changed [61]. The loss of diversity may cause acute human disease by impacting the role of the microbiome on nutrition, metabolism, and pathogen resistance. After antibiotic treatment was stopped, many of the communities rebounded and closely resembled the original community. In some cases, it took nearly 6 months for the microbiome to rebound. It has been

suggested that broad-spectrum antibiotics, especially those with activity against anaerobes, might cause longer-lasting changes in the gut microbial community [62].

Conclusion

The colorectum is a complex organ with multiple roles in homeostasis. By increasing understanding of its anatomy and complex physiology, the colorectal surgeon can gain a better understanding of the etiology of derangements in pathophysiologic conditions. In addition, a thorough understanding of colorectal physiology allows an opportunity to develop new therapies based on its known functions. These examples are demonstrated with much greater detail throughout other chapters of the text.

Anorectal Physiology

3

Pasithorn A. Suwanabol and Scott E. Regenbogen

Key Concepts

- Maintenance of fecal continence and defecation are complex processes requiring both voluntary and involuntary reflexes that have yet to be fully characterized.
- Normal continence is dependent on coordination between neuronal reflexes, sensory and motor pathways, the rectum, anal sphincters, and pelvic floor and requires adequate rectal compliance and competence of the anal sphincter.
- During defecation, sensory mechanisms allow the rectum to stretch to accommodate feces, the pelvic floor muscles relax, and intraabdominal pressure increases. Simultaneously, the puborectalis relaxes and straightens the anorectal angle, the anal canal shortens, and the pelvic floor descends. Finally, the anal sphincters relax and evacuation is initiated.
- Anatomy and physiology of the rectum and anus are intrinsically related, allowing physiologic testing to be exceedingly useful for diagnosis and management of anorectal pathologies.
- Disorders of continence can derive from deficits of mental, anatomic, and physiologic functions, including reflexes, sensory and motor nerves, and the muscles of the rectum, sphincters, and pelvic floor.
- Functional defecatory disorders frequently coexist with urogynecologic conditions likely due to the shared musculature of the pelvic floor and urogenital diaphragm, as well as from the overlap in peripheral innervation and spinal nerve roots.

Introduction

Recognition and appropriate management of anorectal pathology require an understanding of both anatomy and physiology of the rectum, anus, and pelvic floor. The purpose of this chapter is to review the anatomy and innervation of the rectum and anus, characterize normal continence and defecation, and provide an overview of physiologic testing relevant to anorectal physiology and pathophysiology. In addition, we will briefly review the pathophysiology of functional disorders of the anus and rectum.

In general, defecation and maintenance of fecal continence are complex processes requiring both voluntary and involuntary reflexes that have yet to be fully characterized. Much of what is known is based on an understanding of pathologic disorders and functional studies among healthy subjects or animals. Despite our incomplete understanding of anorectal physiology, it is critical to gain as much knowledge of normal and abnormal physiology as possible as it will enable the surgeon to advise and intervene when needed.

Anatomy

For detailed discussion of the anatomy and physiology of the rectum and anus, please refer to Chap. 1.

The rectum serves as a reservoir for feces, measuring approximately 12–15 cm in length, yet its proximal and distal margins continue to be debated – particularly in light of differences in treatment approaches for lower gastrointestinal cancers [1]. The rectum, which is identified in the abdomen by the lack of haustra, taeniae, or epiploica, is located along the curve of the sacrum and coccyx and becomes the anal canal as it passes through the levators [2]. The rectal wall contains a layer of longitudinal smooth muscle and a layer of circular smooth muscle that are in continuity with the gastrointestinal tract [3]. The rectum encompasses three folds, known as the valves of Houston, which do not contain all the muscle wall layers and are not believed to serve any

S. R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, https://doi.org/10.1007/978-3-030-66049-9_3

specific function. The middle valve corresponds to the anterior peritoneal reflection and is the most consistent with regard to location and its presence [2].

Like the rectum, the definition of the anus or anal canal is controversial and is distinguished by embryologic origin and mucosal histology or by its function. The embryologic anal canal, which does not incorporate anal function, is defined as the area from the anal verge to the dentate line [2]. First described by Milligan and Morgan in 1934 in order to guide anorectal surgery, the functional or surgical anal canal begins where the rectum enters the pelvic hiatus and passes through the puborectalis. It encompasses the area from the anal verge to the anorectal ring and is surrounded by the anal sphincters and the puborectalis [4]. On average, the functional or surgical anal canal measures approximately 2.5–5 cm in length and is shorter in females [5]. The anal canal is characterized by columnar mucosa above the dentate line and squamous epithelia below, which are important as they represent two separate inputs, supplied by different aspects of the arterial-venous, lymphatic, and nervous systems [6]. Above the dentate line, the anal canal is supplied and drained by the hypogastric vessels and innervated by the sympathetic and parasympathetic nervous systems. Below the dentate line, the anal canal is supplied by the inferior hemorrhoidal vessels and innervated by the somatic nervous system [2] The 1–2 cm area between these two regions is known as the transition or cloacogenic zone, which is composed of columnar, transitional, and stratified squamous epithelium [6].

The anal sphincter complex consists of the internal anal sphincter (IAS), the conjoined longitudinal muscle (CLM), and the external anal sphincter (EAS). The IAS is a 2–3 mm thick circular band composed of the distal inner circular smooth muscle layer of the rectum, which is always maximally contracted to prevent involuntary loss of stool and flatus [3]. The IAS is encompassed proximally by the levator ani and distally by the superficial external sphincter muscle and subcutaneous external straited anal sphincter muscle [7, 8]. The CLM, located between the IAS and the EAS, is composed of the fibers of the outer layer of the rectum at the level of the anorectal ring and runs distally to the puborectalis muscle [9]. The CLM's functions are unclear, but it may contribute minimally to maintaining continence and defecation [10, 11]. More importantly, the CLM may act as a scaffolding for the entire anal sphincter complex [12]. The EAS comprises striated muscle as a continuation of the puborectalis muscle and is attached anteriorly to the perineal body and posteriorly to the anococcygeal ligament. The EAS is in constant state of tonic contractile activity, even at rest, and voluntarily contracts during any threat of incontinence [13].

The pelvic floor muscles include the levator ani, which consists of the pubococcygeus, puborectalis, and iliococcygeus (Fig. 3.1). These muscles function to support the viscera of the pelvic cavity and play a key role in defecation [7]. The pubococcygeus arises from the posterior pubis, travels alongside the anorectal junction, and inserts into the anococcygeus ligament and the coccyx. The puborectalis is a U-shaped

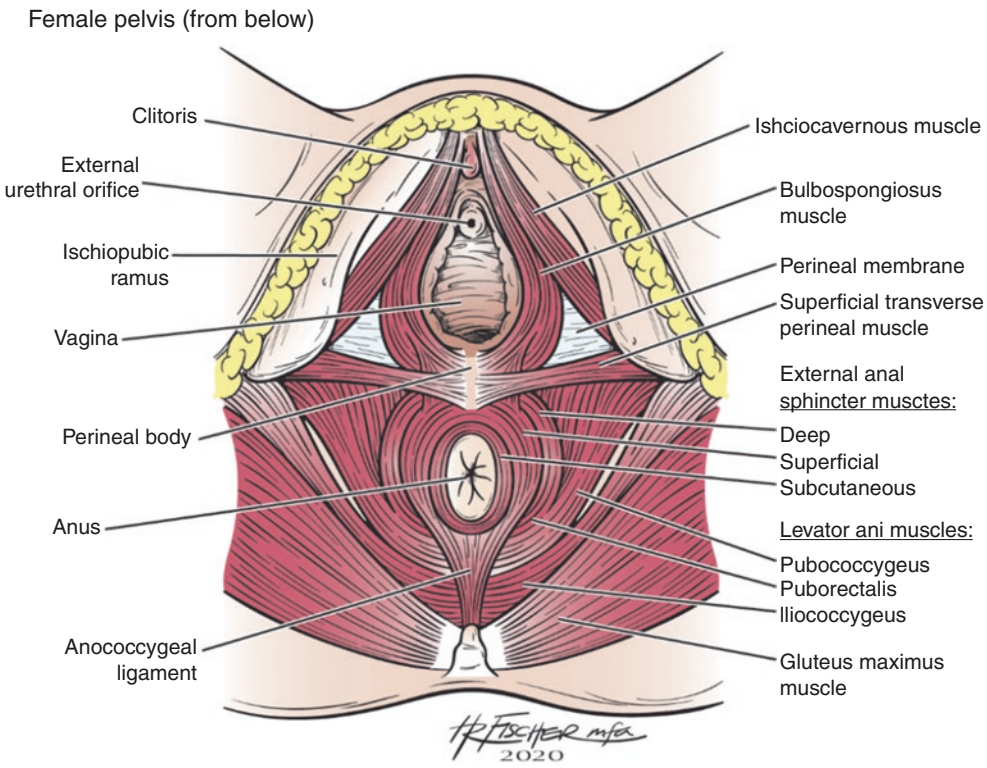

Fig. 3.1 Muscles of the pelvic floor. (Illustration created by H.R. Fischer, MFA)

muscle that slings the anorectal junction to the posterior pubis to pull the rectum anteriorly and forms the anorectal angle. It is palpable on digital rectal exam as the top of the anorectal ring [3]. The iliococcygeus arises from the ischial spine and obturator fascia, travels inferiorly and medially, and inserts into the anococcygeal raphe and coccyx [2].

Physiology

Innervation of the Anus and Pelvic Floor

Sympathetic nerves derived from L1, L2, and L3 join the preaortic plexus, which then extend to form the hypogastric plexus below the aorta. These then join parasympathetic fibers called nervi erigentes (S2, S3, and S4) to form the pelvic plexus (Fig. 3.2) [14]. Motor innervation of the IAS is supplied by the sympathetic (L5) and parasympathetic nerves (S2, S3, and S4) from the autonomic nervous system. In contrast, the EAS is supplied by the inferior rectal branch of the pudendal nerve (S2 and S3) and by the perineal branch of S4 from the somatic nervous system. Unilateral transection of the pudendal nerve does not impact EAS function due to fiber crossover at the spinal cord level [15]. The sacral roots of S3 and S4, the perineal branch, and the inferior rectal nerve of the pudendal nerve innervate the levator ani [16]. The pudendal nerve branches supply the pubococcygeus and puborectalis, whereas direct sacral nerves S3 and S4 innervate the iliococcygeus [17].

Upper anal canal sensory innervation is supplied by both free and organized sensory nerve endings, including Meissner's corpuscles (touch), Krause's bulbs (temperature), Golgi-Mazzoni bodies (pressure), and genital corpuscles (friction) [18, 19]. Within the transition zone of the anal canal, these organized nerve endings may play a role in sampling [20]. The inferior rectal branch of the pudendal nerve provides anal sensation and may provide some maintenance of fecal continence [2, 21, 22]. In addition, it may play a smaller role in discriminating between solid and gas [23].

Normal Continence

Normal continence requires adequate rectal compliance to accommodate fecal contents and competence of the anal sphincter to resist propulsive forces of the distal gastrointestinal tract, assess its contents, and release them under voluntary control [7, 24]. Although normal continence is incompletely understood, it is known to be dependent on complex coordination between neuronal reflexes, sensory and motor pathways, the rectum, anal sphincters, and pelvic floor [25, 26].

Rectal Sensation and Compliance

Rectal sensation encompasses the feeling of both rectal filling and anal reflexes, which is distinct from the rest of the lower gastrointestinal tract where distension evokes pain [27, 28]. The rectum's function is to store feces, which requires the ability to accommodate volumes of feces without substantially altering rectal pressures. Accommodation is reliant on both the content and the contractile state of the rectum [3, 29]. Baseline rectal pressure is low (approximately 5 mmHg) compared to anal canal pressures, which measure approximately 10–14 times that of the rectum. This pressure differential may allow for stool deferment, forcing stool back into the sigmoid and rectum, until defecation is initiated [19]. Although the rectum does not have proprioceptive receptors, rectal compliance may be due to unique, slowly adapting mechanoreceptors that respond to tension and rapid distension, termed rectal intra-ganglionic laminar endings (rIGLEs) [30]. This idea is consistent with the observation that rectal filling sensations coincide with increased rectal pressure during rectal distension [27]. Instead, defecation is sensed at the level of the levators and the anal canal, which may underlie the preserved sense of defecation among patients after proctectomy with ileoanal or coloanal anastomoses [31, 32].

Anorectal Reflexes

The rectoanal inhibitory reflex (RAIR) is an intrinsic intramural reflex critical to normal continence. It occurs in response to distension of the rectum, relaxing the upper IAS to allow fecal material or flatus to interact with specialized receptors in the upper anal canal. This sampling enables flatus to pass without fecal incontinence as the lower IAS resting pressure, the contraction of the EAS, and puborectalis push feces to the upper rectum and delays defecation [3, 33, 34]. The RAIR occurs every 8–10 minutes and lasts less than 10 seconds [35, 36]. The RAIR is absent in those with Hirschsprung's disease due to the absence of myenteric ganglia in the rectum [37]. Furthermore, injury or alteration to the RAIR may play a role in patients with poor functional outcome or incontinence after rectal resection [38–41].

Less studied anorectal reflexes include the cutaneous anal sphincter reflex, the bulbocavernosus reflex, and the cough-anal reflex. The cutaneous anal sphincter reflex is defined as contractions of the EAS with touch or pain of the anal skin, while the bulbocavernosus reflex is characterized by contractions of the EAS when squeezing the glans penis or clitoris. The bulbocavernosus reflex can also occur when a urethral catheter is removed. Finally, the cough-anal reflex is described as contractions of the EAS when coughing or sniffing. The cough-anal reflex is important in maintaining continence during sudden increases of intraabdominal pressures, such as coughing, sneezing, or laughing [42].

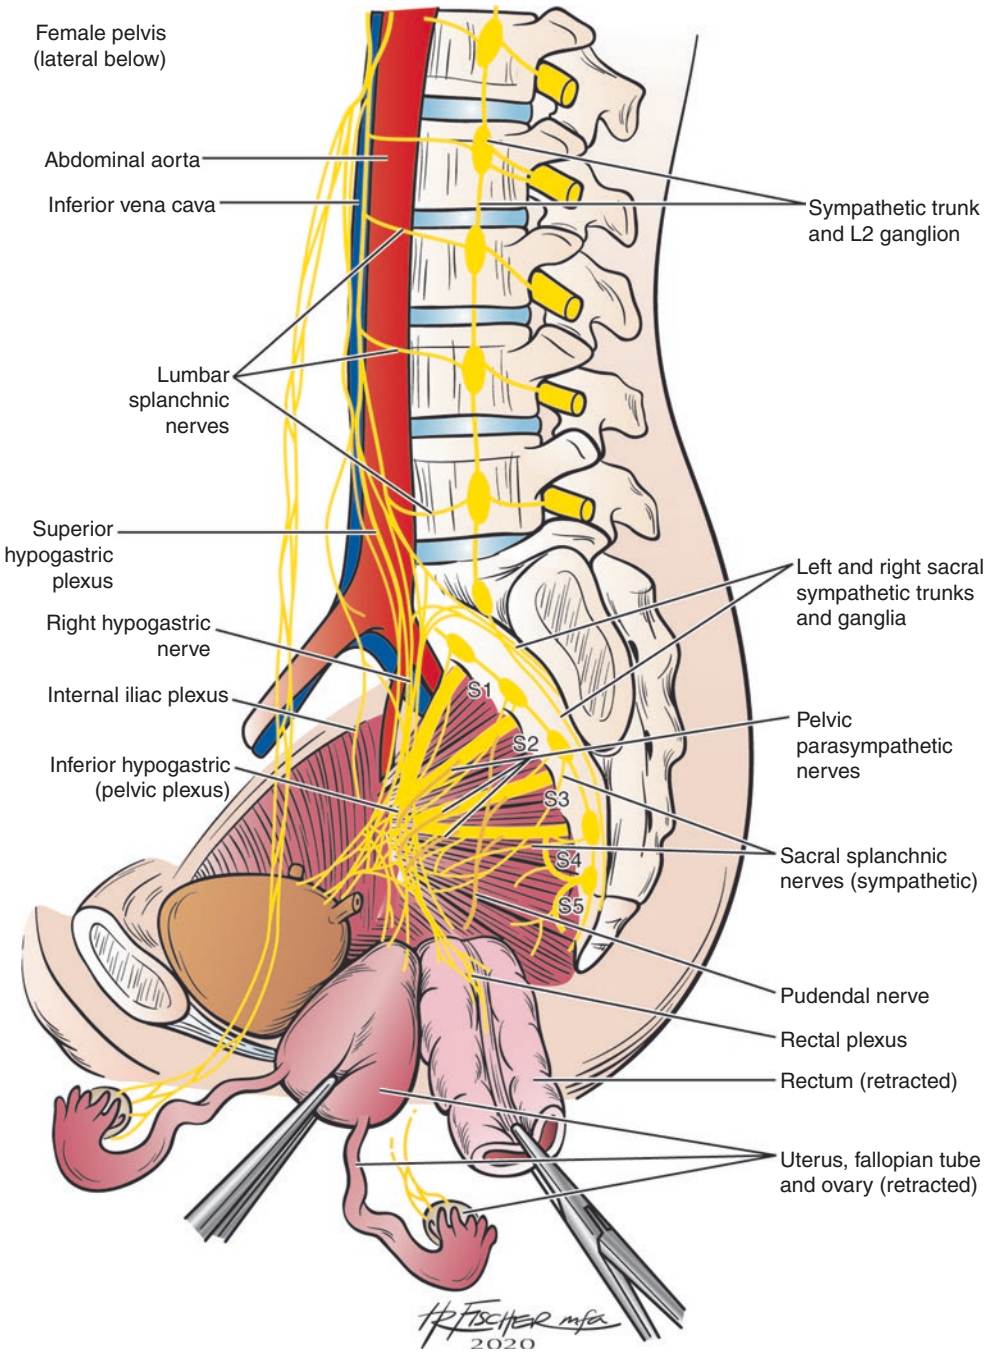

Fig. 3.2 Innervation of the anus and pelvic floor. (Illustration created by H.R. Fischer, MFA)

Internal and External Anal Sphincters

The IAS constitutes approximately 50–70% of resting tone or pressure and is maximally contracted at rest, with the hemorrhoid complexes accounting for an additional 15% of resting tone or pressure [2, 43–46]. Hemorrhoid complexes contribute to continence by expanding to create a seal proximal to the anal opening [46]. Due to the intrinsic function of smooth muscle, most of the resting tone is due to myogenic tone, which is characterized by slow, constant waves of contraction [42, 47]. The IAS receives additional excitatory sympathetic input and inhibitory parasympathetic input, which are mediated by nitric oxide [3, 48–50]. Injury to the IAS leads to passive fecal incontinence or leakage, whereas injury to the EAS is associated with urge fecal incontinence [3, 51]. Whereas the EAS plays a smaller role in resting tone, its primary contribution to continence involves voluntary or reflexive contraction in response to rectal distention and threat of incontinence, for example, during increases in intraabdominal pressure [3, 52]. Similarly, defecation may be deferred by contraction of the EAS to oppose increased rectal pressure. After EAS contraction, the sensation of urgency and tenesmus will diminish over a period of time

that allows rectal adaptation to occur [53–55]. The EAS differs from the IAS, however, in its fatigability, demonstrated by the deferment of large volumes of stool for mere seconds or minutes, despite normal rectal compliance [27, 56].

Puborectalis and the Pelvic Floor

As briefly described above, the puborectalis is a striated muscle that acts as a sling located at the anorectal junction, from which a 90- to 100-degree angle is formed at rest. Its critical role in continence is believed to be due to this anorectal angle. Theories for its underlying mechanism include that the puborectalis pushes the anterior rectal wall against the upper anal canal, preventing feces from passing distally, particularly during times of increased intraabdominal pressure (known as the flap-valve theory), or that the puborectalis acts as a deeper sphincter mechanism that works in coordination with the EAS [27, 31].

Normal Defecation

Defecation requires coordination between the colon and movement of its contents, increases in intraabdominal and rectal pressures, and finally, pelvic floor relaxation. First, sensory mechanisms allow the rectum to stretch to accommodate feces once fecal material or flatus is sensed. In response to distension of the rectum, the IAS reflexively relaxes. The RAIR response requires an intact subcutaneous nervous plexus in order to function and is under autonomic control. The RAIR allows distinction between feces and flatus as well as solid and liquid waste, and the initiation of defecation [2, 24, 57]. If defecation is not desired, the anal sphincters will contract and the rectum will continue to distend until the individual becomes aware [27]. However, the urge to defecate lasts only a few seconds and is controlled by continued EAS contraction (conscious suppression) [27, 56]. Sampling may continue throughout this process even with a full rectum [27, 56].

During defecation, the pelvic floor muscles relax and the intraabdominal pressure increases (Valsalva). Several actions occur simultaneously: (1) the puborectalis relaxes and lengthens, which straightens of the anorectal angle; (2) the CLM contracts, which leads to shortening of the anal canal; and (3) the pelvic floor descends. Finally, the anal sphincters relax and evacuation is initiated by the rectosigmoid contractions, which propel feces through the anal canal [3, 11, 26, 27, 58]. A squatting or hip flexion position facilitates this process by optimally straightening the anorectal angle and increasing intraabdominal pressure [59]. Sensory input from the anus ensures that the contractions continue until the rectum is completely emptied [27, 60]. Anal closure at the end of defecation is termed the "closing reflex" and is described as an exaggerated contraction of the EAS and restoration of IAS resting tone [27].

Physiologic Testing

Please refer to Chap. 55 for an in-depth discussion of pelvic floor testing. In general, the surgeon is uniquely equipped to understand the rectum and anus through a combination of dissection in the operating room, endoscopic evaluation, and physiologic investigation. It should be stressed that the anatomy of the rectum and anus is intrinsically related to its physiology, which is why physiologic testing can prove to be highly beneficial in the diagnosis and appropriate management of anorectal pathologies [2, 61, 62].

Anal Manometry

Using a pressure-sensitive catheter in the rectum and anal canal, manometry is a test that measures sphincter function including resting tone and maximum squeeze pressure, presence of RAIR, response to cough or Valsalva reflex, and anal canal length [26, 63, 64]. Resting tone (normal 40–80 mmHg) is due to the resting pressure of the IAS and the length of the anal canal, which is known as the high-pressure zone (normal 2.0–4.0 cm). Maximum squeeze pressure reflects EAS function (normal 40–80 mmHg) [2, 43]. Presence of the RAIR is determined by inflating a balloon in the distal rectum. The absence of RAIR is found in impaired myenteric nerve plexus such as Hirschsprung's disease or following proctectomy as described above [65–68]. Due to limited knowledge of normal defecation and lack of standardization of the technique and normal values even between healthy patient populations (e.g., younger vs. older, males vs. females), interpretation of anal manometry results may be challenging [2, 69, 70].

Pudendal Nerve Terminal Motor Latency

Neurophysiological testing of the pudendal nerve, which again innervates the EAS, is performed by stimulation at the site where the nerve enters the ischiorectal fossa at the level of the coccyx [3]. Pudendal nerve terminal motor latency (PNTML) measures the time between the stimulation of the pudendal nerve and contraction of the EAS. Normal values are approximately 2 ± 0.2 milliseconds [42, 69, 71]. Prolonged or abnormal values demonstrating neuropathy can be seen in those with idiopathic fecal incontinence, rectal prolapse, or sphincter injuries [3, 72]. However, PNTML testing is operator dependent and limited by low sensitivity and specificity [42].

Balloon Insufflation

Rectal sensation and compliance are tested by balloon insufflation, which measures the first detectable sensation, the urge to defecate, and the maximum tolerable volume [28, 73]. Urge to defecate is characterized by an increase in compliance, as indicated by volume increasing with pressure changes. This represents "adaptive relaxation" of the rectum [7]. Delayed sensation or hyposensitivity manifests at higher volumes for these three parameters and may be detected in those with neuropathies or altered rectal reservoirs. Hypersensitivity is characterized by reduced sensory threshold to rectal distension, lower volumes for the three parameters, and complaints of urgency and frequency. Hypersensitivity is often demonstrated in those with inflammatory bowel disease, proctitis, and functional bowel disorders [3, 55, 74–76].

Defecography

Defecography is a dynamic study to assess the defecatory process, specifically, the function of the pelvic floor during defecation (Fig. 3.3) [77, 78]. The most common method to perform defecography involves the instillation of liquid barium and air into the rectum followed by barium paste into the rectum and/or vagina depending on clinical indication. With the patient sitting on a commode and attempting to recreate normal defecation, radiographs are obtained at rest, during squeeze, and during Valsalva [79]. The anorectal angle and perineal descent are commonly measured, as well as whether paradoxical contraction of the puborectalis occurs [77, 78, 80].

Functional Anorectal Disorders

In this chapter, we will discuss the physiologic features and considerations in the evaluation of functional disorders. The diagnostic workup algorithms and management strategies will be discussed in later chapters and are cross-referenced wherever relevant.

Fecal Incontinence

Anal continence requires integrated and coordinated mental, anatomic, and physiologic functions, including reflexes, sensory and motor nerves, and the muscles of the rectum, sphincters, and pelvic floor. Thus, disorders of continence can derive from deficits in any of these contributors, or as a result of high stool volume or liquid consistency, even in patients with normal anatomy and function [81]. Yet, the various mechanisms of continence are likely somewhat redundant, as single, isolated deficits in any one of these functions may often be tolerated without symptomatic incontinence. For example, the functional consequences of obstetric trauma suffered during childbearing years may not be experienced until decades later, as compensatory mechanisms are weakened or disrupted [82]. These observations suggest that the physiologic etiology of fecal incontinence is most often multifactorial [83].

Fecal incontinence due to sphincter muscle defects may result from iatrogenic injury associated with sphincterotomy, fistula surgery, and hemorrhoidectomy or from obstetric injury or other trauma (Fig. 3.4). Idiopathic fecal incontinence, in the absence of defined functional bowel disorder or anatomic deficit, is most commonly associated with denervation of the pelvic floor and/or sphincter muscles. This nerve dysfunction may itself be idiopathic, for example associated with advanced age, or may be secondary to trauma from obstetric injury, chronic prolonged straining, distention from constipation, or outlet dysfunction [84, 85]. There is evidence of decreased sphincter pressures in older adults, and in women especially after menopause [86–88]. Pudendal nerve terminal motor latencies are likewise observed to be prolonged in older women.

Compared to individuals with normal continence, patients with idiopathic fecal incontinence are more likely to have evidence of pelvic floor motor neuropathy, including lower anal canal resting and voluntary contraction pressures, longer pudendal nerve terminal motor latency, and higher thresholds to mucosal electrosensitivity in the anal canal [89]. On average, these patients have reduced anal resting pressures and reduced squeeze pressures, as well as lower volume and pressure thresholds for the urge to defecate [90]. In addition, compared to continent controls, patients with fecal incontinence tend to exhibit significant impairment of anal sensation [91]. This combination of motor and sensory

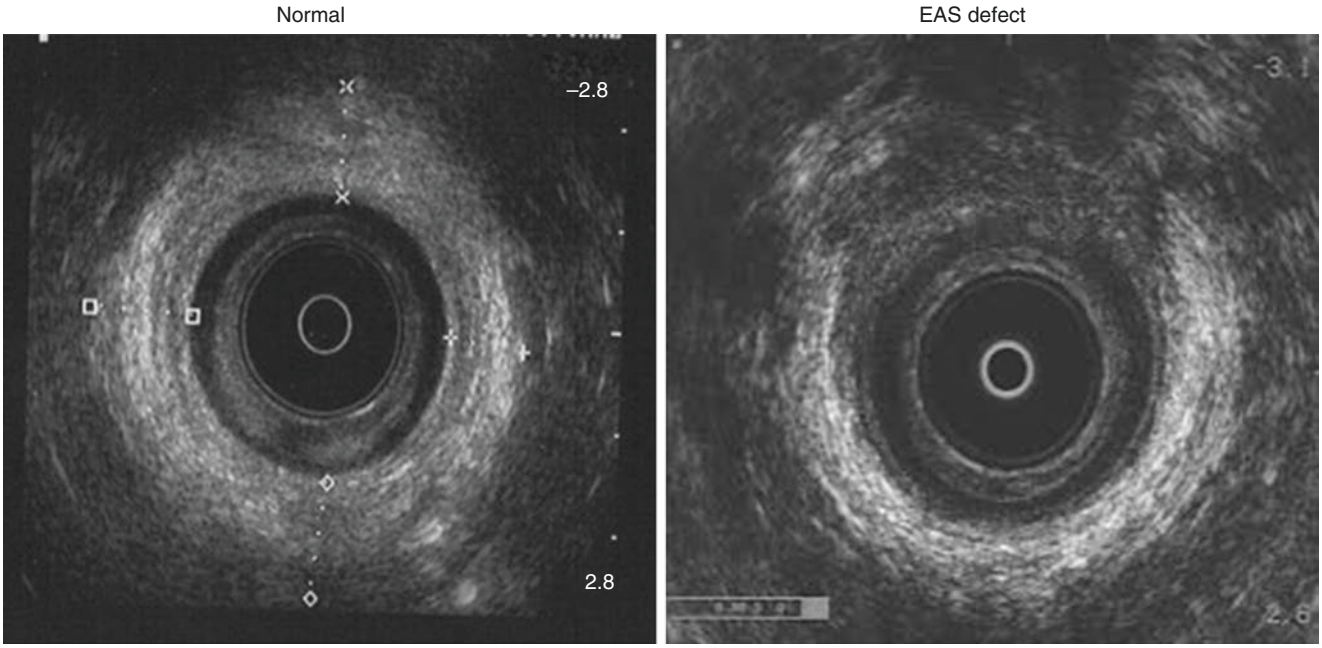

Fig. 3.4 Endorectal ultrasound. (Courtesy of S. Menees, MD, used with permission)

deficits may underlie the ameliorative effects of sacral nerve and posterior tibial nerve stimulation, which can influence neural innervation for both the sensory and motor functions of the anus and rectum. These findings also motivate the rationale for manometry and pudendal nerve terminal motor latency testing in the evaluation of incontinence, as discussed in Chap. 59. The etiology of this deficit has been proposed to be repeated traction on the pudendal nerve and consequent denervation of the external anal sphincter and fibrous replacement [92].

Additional insights into the pathophysiology of fecal incontinence come from the evaluation of patients with spinal cord injuries and other neurologic diseases. Loss of rectal sensation may contribute to deficits in RAIR, while exaggerated, unopposed stimulation during distention may induce involuntary sphincter relaxation, and impaired spinal reflex activity may reduce rectal compliance [82, 93, 94]. Incontinence in this setting may therefore derive from any combination of the following, depending on the level and completeness of injury: decreased anal sphincter resting tone, loss of voluntary control, or loss of anorectal reflexes.

Disorders of Defecation

In patients with constipation associated with anal outlet dysfunction, physiological abnormalities may include inadequate defecatory propulsion, dyssynergic defecation, or some combination thereof. Obstructed defecation can also be associated with pathologic anatomic conditions, including rectocele, intussusception, prolapse, or stricture. The diagnostic evaluation of defecatory disorders is discussed in detail in Chaps. 56 and 57.

Patients with idiopathic outlet dysfunction may exhibit a variety of manometric anomalies, including elevated anal resting pressures, but this finding varies widely and may be normal in many of these patients [95]. Some may have impaired rectal sensation, or decreased RAIR, which may reduce the autonomic emptying response, but these findings are also varied among numerous studies [96, 97]. The finding that women with new-onset constipation following a hysterectomy experienced decreased rectal sensory perception implies a role for the parasympathetic plexus of nerves, which reach the rectum via the lateral vaginal walls as they are susceptible to injury during lateral pelvic dissection [98]. Some have suggested that decreased rectal tone and intrarectal pressure with straining are consistent with findings in those with idiopathic constipation, implying that diminished propulsion contributes to the outlet dysfunction [99, 100].

In other patients, obstructed defecation may result from dyssynergic contraction of the external anal sphincter and/or puborectalis muscle during efforts to evacuate the rectum. Patients with obstructed defecation exhibit clinically significant limitation of emptying despite puborectalis activity, as demonstrated through electromyography (EMG), and adequate rectal pressure with straining [101]. These patients will exhibit paradoxical increase in puborectalis muscle contraction during EMG with straining and Valsalva maneuver, also known as anismus [100, 102]. Nevertheless,

the anatomic physiologic correlates of defecatory disorders may not reliably predict the clinical syndrome. In one study, there was no difference in the degree of perineal descent or the manometric assessment of the external anal sphincter between patients with incontinence and patients with obstructed defecation [103].

Anorectal Pain

In the absence of identifiable anatomic source of pain from trauma, fissure, thrombosed hemorrhoid, abscess, tumor, or other finding, idiopathic or functional anorectal pain disorders may be diagnosed. These pain syndromes have been subclassified as either chronic proctalgia (chronic or recurring pain lasting more than 20 minutes, without identifiable source) or proctalgia fugax (episodes lasting less than 20 minutes, with resolution between episodes). Patients with chronic proctalgia may be considered to have levator ani syndrome if digital rectal exam with posterior traction on the puborectalis muscle reproduces the pain [104]. On occasion, either of these conditions may arise following anorectal surgery, but they are more commonly associated with psychological disturbances, including anxiety and post-traumatic stress [105]. The physiologic findings from manometry or other testing are variable.

Urogynecological Considerations

Functional defecatory disorders, including fecal incontinence, obstructed defecation, rectal prolapse, rectocele, enterocele, sigmoidocele, and anorectal pain, frequently coexist with urogynecologic conditions such as urinary incontinence or retention, uterine prolapse or procidentia, and chronic pelvic pain. These relationships likely result from the shared musculature of the pelvic floor and urogenital diaphragm, as well as from the overlap in peripheral innervation and spinal nerve roots. The overlap between colorectal and gynecologic surgical considerations will be discussed in more detail in Chap. 65.

Endoscopy

4

Matthew D. Zelhart and Brian R. Kann

Key Concepts

- Endoscopic examination is essential in the evaluation of patients with colorectal complaints and is a key component of a complete colorectal examination.
- Physical examination, anoscopy, rigid proctoscopy, and flexible sigmoidoscopy are components of the exam that can easily be performed in the office setting to evaluate complaints arising from the anus, rectum, and rectosigmoid colon.
- Colonoscopy allows for complete evaluation of the entire colon and rectum, as well as the terminal ileum.
- Multiple regimens for bowel preparation prior to colonoscopy exist, and the endoscopist should be aware of the differences. A split-dose prep has been shown to be more effective than a single-dose prep.
- The endoscopist should be familiar with sedation regimens for endoscopy, including possible adverse effects.
- A number of adjunctive maneuvers for difficult exams and alternative techniques to improve the quality of endoscopy can be employed.
- The endoscopist should be able to recognize and manage complications of endoscopic procedures and employ appropriate measures to prevent their occurrence.
- Quality measures to ensure adequacy of colonoscopic examinations include adenoma detection rate and withdrawal time.

Introduction

The ability to safely and effectively visualize the lower gastrointestinal (GI) tract is a necessary skill for any physician caring for patients with colorectal disorders. Endoscopic evaluation of the lower gastrointestinal tract should be considered an essential extension of the physical exam. Colorectal surgeons should be both familiar and facile with all of the commonly utilized endoscopic diagnostic and therapeutic techniques.

Anorectal Examination

Prior to examining a patient with anorectal complaints, it is imperative to obtain a detailed history, as this will often lead to a presumptive diagnosis and help tailor the exam. Perhaps the most important part of the anorectal examination is to create an environment that preserves the patient's modesty and reduces anxiety. It is often preferable to speak with the new patient initially, obtain the history, establish rapport, and explain how the examination will proceed. The provider can then leave the room to have the patient disrobe and have a medical assistant/nurse position the patient appropriately before returning to the exam room.

It is essential that there be a chaperone in the room during the examination. The exam room should be well lit, ideally with a sink in the room, and have a toilet nearby (preferably in an adjoining room). A portable light source or head light should be available. Preparation and ensuring easy access to instrumentation is important, as searching or fumbling for equipment while the patient is already positioned for the exam can prove awkward.

Patient Positioning

The two most reliable positions in which to perform a thorough anorectal examination are prone jackknife and left lat-

S. R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, https://doi.org/10.1007/978-3-030-66049-9_4

eral (Sim's position). The choice of position depends on availability of equipment/exam tables, patient factors such as age and mobility, and individual physicians' preference.

The prone jackknife position provides the best exposure for examination of the anorectum, but this requires a specialized proctoscopic table. The patient kneels on a padded ledge and leans forward, resting their chest and abdomen on the table; the table is then raised to an appropriate height for the examiner and angled forward, raising the buttocks upward. While sometimes awkward for the patient, this position provides for excellent visualization of the anorectum and easily facilitates office procedures such as anoscopy, proctoscopy, and hemorrhoid banding. This position should be avoided in certain situations, such as decreased mobility, recent abdominal surgery, morbid obesity, late pregnancy, and arthritic conditions affecting the knees, hips, and lower back.

The left lateral decubitus (Sim's) position is more suitable when a proctoscopic table is not available or if the aforementioned factors make the prone jackknife position difficult. The patient lies on their left side with their back close to the edge of the exam table and their hips and knees both flexed at 90°. The buttocks should extend out over the edge of the table for a short distance to allow for rotation of an anoscope if needed. Visualization is often not as good in this position as compared with the prone jackknife position, particularly in obese patients. Often, an assistant is required to retract the right buttock to improve visualization, especially in the anterior perineum.

Inspection and Palpation

Careful stepwise inspection of the perineum, anal margin, anal verge, and sacrococcygeal region should be performed before any other part of the examination. Adequate lighting is essential, and retraction of the buttocks by an assistant should be performed if necessary. Specific conditions to visually inspect for include pilonidal disease, lesions of the anal margin skin or anal verge, hemorrhoidal disease, skin irritation, maceration or excoriation, perianal dermatoses, erythema, ulceration, drainage sites, condyloma, scarring or evidence of prior anorectal surgery, purulence, fecal soiling, anal discharge, and prolapsing tissue. The appearance of the anal sphincter at rest should be noted, and an assessment of perineal body bulk in females should be performed. The presence of a patulous anus may indicate underlying incontinence or prolapse. The patient should then be asked to perform a Valsalva maneuver and assessment should be made of the degree of perineal descent and the presence of genitourinary or rectal prolapse. Lightly touching the perianal skin should provoke the anocutaneous reflex, or "anal wink." Palpation can reveal tenderness, induration, or fluctuance, which may be indicative of a suppurative process. Gentle effacement of the anal verge may reveal a fissure-in-ano. When documenting physical findings, describe the location in relation to anatomic position (anterior, posterior, right, left), as opposed to using clockface descriptors, as these depend on the position that the patient is in when examined.

Digital Rectal Examination

A great deal of information can be obtained from a properly performed digital rectal examination (DRE). Communication with the patient in regard to what to expect is key to easing any anxiety they may have about the procedure. When the patient is anxious and tense, they are more likely to be less cooperative and the exam tends to yield less useful information. Patients who are needlessly made to feel uncomfortable may be less willing to undergo future examinations. There are certain conditions in which a DRE may be omitted. These include anal fissure, thrombosed external hemorrhoids, nonreducible internal hemorrhoids, tight anal stricture, and a large anorectal mass. Common teaching has been that DRE should be avoided in the setting of neutropenia due to the risk of causing translocation of gut flora through the rectal mucosa. However, there is little data to support this, and therefore neutropenia is considered a relative contraindication to DRE.

Once there has been proper communication with the patient, a well-lubricated index finger is gently inserted past the anal verge into the anal canal. Gentle pressure on the anus prior to insertion may initiate sphincter relaxation. If resistance is met, the patient should be asked to bear down as if attempting to pass a stool, which should cause relaxation of the external anal sphincter and more easily enable insertion [1]. Once the finger is fully inserted, stepwise organized assessment should ensue. If there is stool present in the rectal vault, one should note its consistency. Assessment of resting sphincter tone should be noted upon insertion of the examining finger, and a subjective assessment of squeeze tone can be made by asking the patient to squeeze. Patients with underlying sphincter dysfunction often rely on compensatory mechanisms to maintain continence, and, when asked to squeeze, they will instinctively squeeze their buttocks and not their sphincter. In this instance, the patient often needs "coaching" in order to have them focus on squeezing their anal sphincter instead of the buttocks to make an accurate assessment of their squeeze pressure. Gentle sweeping of the finger circumferentially allows for the assessment of any intraluminal mass lesion. If a mass is present, note its size, mobility, firmness, and relationship to the anal verge, anorectal ring, and other surrounding structures. A presacral/retrorectal lesion may be palpated posteriorly. Anteriorly, assessment of the prostate gland should be performed in males, and the cervix is also often palpable in females.

Assessment for rectocele should also be performed anteriorly, and bimanual exam may be needed to fully assess the rectovaginal septum. Induration or fluctuance may be appreciated when there is infectious pathology present, and a firm "cord" may be palpated in the presence of an anal fistula. The presence of stenosis or stricturing should be noted, especially in patients who have undergone prior anorectal surgery or pelvic radiation. The patient should be asked to perform a Valsalva maneuver to allow more proximal lesions to descend to the reach of the examining finger.

Assessment of the pelvic floor can also be accomplished during DRE. Gentle pressure on the posterior anorectal ring at the level of the puborectalis may elicit discomfort, possibly indicating a pelvic pain disorder. The strength and function of these muscles can be assessed during a Valsalva maneuver and with voluntary contraction. When good function is present, the examiner should feel these muscles tighten with a voluntary contraction. When posterior pressure is placed on the puborectalis, the anal opening should "gape" before returning to a normal configuration, indicating an intact reflex pathway to the thoracolumbar spinal cord.

Fig. 4.1 Examples of anoscopes

Fig. 4.2 Disposable anoscope with self-contained light source

Anoscopy

Anoscopy is a simple, inexpensive, and effective means of visualizing the anal canal and distal rectum and is an essential adjunct to the examination of the patient who presents with anorectal complaints. There may be certain clinical scenarios, such as in the presence of an anal fissure or thrombosed hemorrhoid, when anoscopy cannot be performed due to patient discomfort, but typically the procedure should be well tolerated by the patient when performed properly. The anoscope consists of the scope itself, an obturator, and a light source. Various sizes and configurations are available, both reusable and disposable (Fig. 4.1). The authors' preference is to use a disposable anoscope with a self-contained internal light source (Fig. 4.2), as opposed to an external light source connected to a reusable anoscope via a fiberoptic cord. An anoscope with a beveled or slotted end is preferred to facilitate hemorrhoidal ligation if indicated.

In most instances, having the patient prep with an enema prior to the procedure is not necessary, and sedation is not required. Once the patient has been properly positioned, and after DRE has been performed, the generously lubricated anoscope is gently inserted, using the thumb of the inserting hand to secure the obturator in place. If resistance is met, the scope should be completely withdrawn and reinserted at a slightly different angle. Once the scope has been fully advanced, the obturator is removed and visual inspection of the mucosa is performed. Prior to rotating the anoscope to inspect a new area, the obturator should be reinserted to avoid pinching or tearing the mucosa. Alternatively, the anoscope can be repeatedly removed and reinserted, moving to sequential quadrants of the anal canal, though this tends to be more uncomfortable for the patient. Pathology such as internal hemorrhoids, polyps, condyloma, mass lesions, mucosal inflammation, and hypertrophied anal papillae can be readily identified. Biopsies of abnormal mucosa or masses can be easily performed at the same setting, as can therapeutic procedures such as hemorrhoid banding or sclerotherapy. Complications of anoscopy are rare and include inadvertent tearing of the anoderm and bleeding, which usually results from a biopsy or therapeutic procedure and not the anoscopy itself.

Proctoscopy

Rigid proctoscopy is utilized for further evaluation of the anorectum up to the distal sigmoid colon and is particularly useful for determining the precise distance of a rectal lesion from the anal verge. Like anoscopy, it requires no sedation and can typically be performed in an office setting, though enemas are generally required to clear the rectum of residual stool. The standard proctoscope is 25 cm long with an outer diameter of 19 mm, though 15 mm and 11 mm scopes are also available (Fig. 4.3). The outer surface of the proctoscope is usually marked at 1 cm intervals to allow for measurements to be taken from the anal verge. An air bladder for insufflation and fiberoptic light source are required; though newer fully disposable proctoscopes have an internal self-contained light source.

Proctoscopy can be used to assess for a number of anorectal conditions, including rectal bleeding not explained by hemorrhoidal disease, proctitis, ulcers, and evaluation of rectal mass lesions. Diagnostic biopsies and simple polypectomies can be performed. Therapeutic procedures, such as topical formalin application for radiation proctitis, can also be performed, though these are typically not done in the office setting. Contraindications to proctoscopy include painful anorectal conditions such as fissure, thrombosed hemorrhoids, anal stenosis, and recent anorectal surgery. Unfortunately, with easier access to flexible endoscopy in recent years, the "art" of rigid proctoscopy has declined, and more recently trained colon and rectal surgeons are less comfortable with rigid proctoscopy.

After the patient is positioned in either the prone jackknife or left lateral decubitus position and DRE has been performed, the well-lubricated proctoscope and inner obturator are gently inserted while holding the obturator in place with the examiner's thumb, aiming the scope posteriorly toward the sacrum. Once the proctoscope passes the sphincter complex, the obturator is removed, the viewing window is closed, and air is gently insufflated to distend the rectal lumen. Direct visualization of the rectal lumen via the viewing window of the proctoscope allows for manipulation and redirection of the scope so that it can be slowly advanced. Deliberate communication with the patient is essential as the procedure is being performed. Withdrawal and redirection of the scope allow for straightening of angles and navigation around mucosal folds. Generally, the scope can be advanced to a distance of approximately 20 cm from the anal verge with minimal patient discomfort. Pain can sometimes be experienced if the tip of the scope gets caught on a mucosal fold, if the rectum becomes overdistended, or when attempting to navigate a sharp angulation. If any point the patient experiences excessive pain, the scope should be withdrawn.

Fig. 4.3 Rigid proctoscopes

Once the proctoscope has been fully inserted, it is then slowly and deliberately withdrawn, sweeping it gently from side to side, using the tip of the scope to flatten out mucosal folds and the valves of Houston to permit thorough mucosal evaluation. Suction can be used via the proctoscope to remove residual stool or mucous. If a polyp or mass is identified, note the distance from the inferior edge of the lesion to the anal verge. Biopsies can be performed, and, with proper instrumentation, smaller lesions can be fulgurated or removed via snare polypectomy. Prior to removal of the proctoscope at the completion of the exam, the viewing window should be opened to allow for the release of any retained air.

Complications resulting from rigid proctoscopy are rare, and usually the result of an unexperienced or overaggressive endoscopist. Minor tears of the anal skin may cause pain and bleeding; mucosal trauma from the edge of the proctoscope can also result in rectal bleeding. Bleeding may occur after biopsy or polypectomy. Perforation is exceedingly rare.

Endoanal/Endorectal Ultrasound

Endoanal ultrasound (EAUS) and endorectal ultrasound (ERUS) are valuable adjuncts to the physical examination and endoscopic mucosal evaluation of the anorectum. This imaging modality allows for detailed evaluation of the anal sphincter complex, the pelvic floor, anorectal disease processes, and anorectal neoplasms. It is particularly useful in the evaluation of fecal incontinence, with sensitivity and specificity of locating a sphincter defect approaching 100% [2]. EAUS can be used to identify and characterize anal abscesses and fistulas, often with the use of hydrogen peroxide instilled via an external fistula opening [3]. ERUS is most commonly used for staging of rectal cancer, with an accuracy of 66–92% for tumor depth and 64–88% for regional nodal status [4]. In recent years, magnetic resonance imaging has largely replaced ERUS in the preoperative staging of rectal cancer [5], though ERUS may still have a role in the staging of superficial neoplasia.

Ultrasound transducers designed for transanal use allow for 360° circumferential assessment of the anal canal and distal rectum. Probes are available for two-dimensional imaging, which is generally used for evaluation of the anal sphincter, or three-dimensional imaging, which is typically used for rectal cancer staging. Transducer frequencies for transanal use range from 3 to 20 MHz. The use of higher frequencies produces a higher-resolution image but cannot penetrate deeper tissues, while lower frequencies allow for a greater depth of penetration, though the resulting image may not have the fine detail of one produced at higher frequencies.

The procedure is generally well tolerated, does not require sedation, and can easily be performed in an office or outpatient setting. An enema should be administered prior to the procedure to clear the rectum of residual waste. The patient is positioned in the left lateral decubitus position, and, after DRE is performed, the well-lubricated ultrasound probe is gently advanced to the desired depth of insertion, then withdrawn to image the distal rectum and anus. Newer transducers are held stationary while the crystal moves within the transducer housing via an automated program for image acquisition.

Highly reflective tissues with higher water content will appear hyperechoic (light) on ultrasonographic imaging, while poorly reflective tissues with less water content will appear hypoechoic (dark). When performing EAUS, the anal canal is divided into three levels based on anatomic landmarks. In the distal anal canal, only the hyperechoic external anal sphincter is visible (Fig. 4.4). In the mid-anal canal, both the hyperechoic external anal sphincter and the hypoechoic internal anal sphincter are present (Fig. 4.5). The upper anal canal is characterized by the U-shaped puborectalis muscle wrapping around the anal canal (Fig. 4.6).

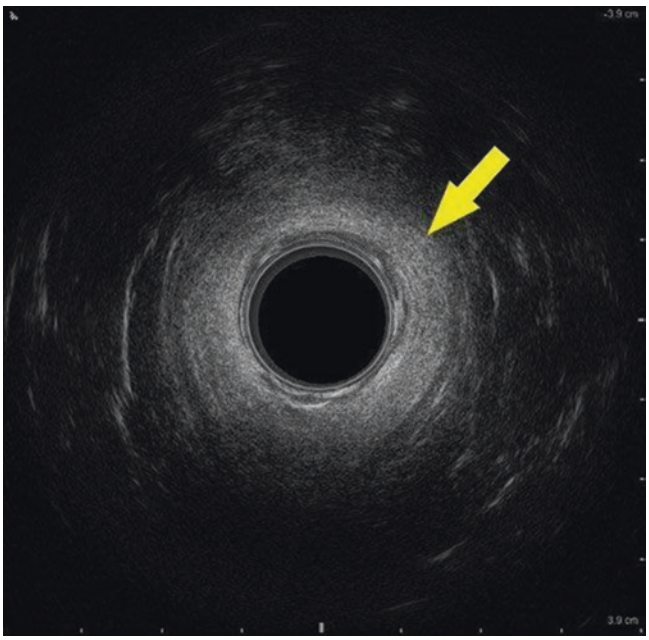

Fig. 4.4 Two-dimensional endoanal ultrasonographic appearance of the lower anal canal, highlighting the external anal sphincter (arrow)

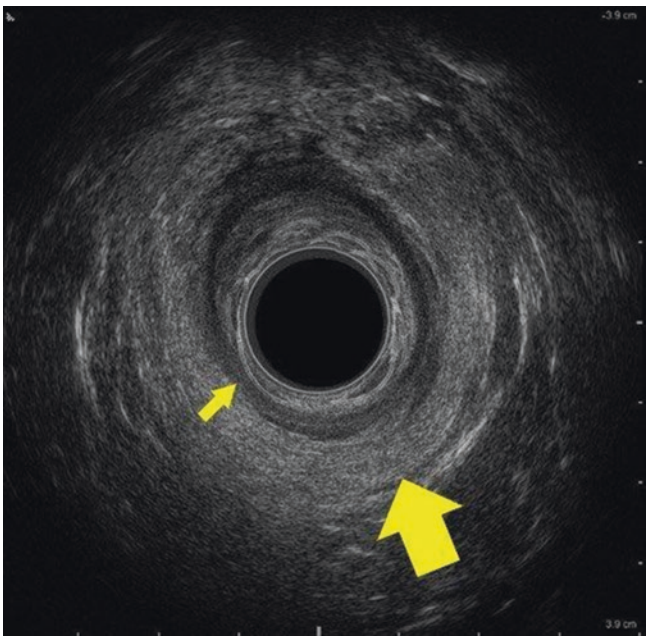

Fig. 4.5 Two-dimensional endoanal ultrasonographic appearance of the mid-anal canal, highlighting the external anal sphincter (large arrow) and the internal anal sphincter (small arrow)

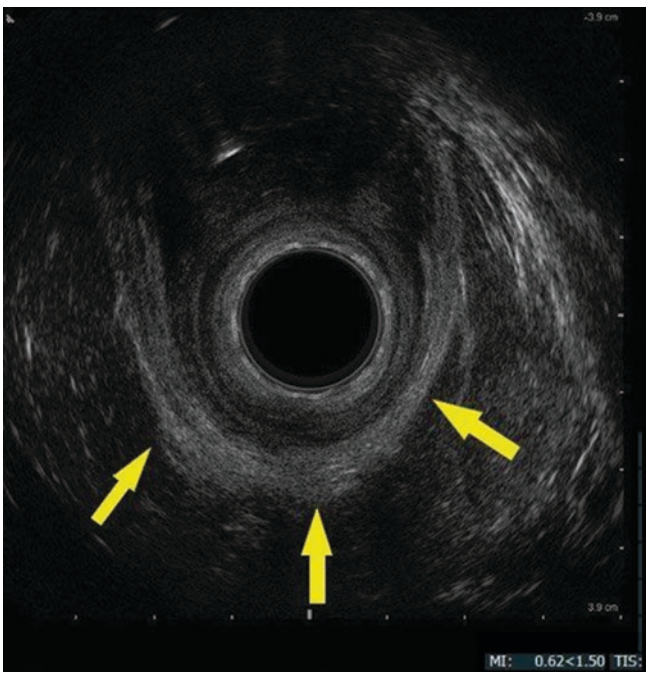

Fig. 4.6 Two-dimensional endoanal ultrasonographic appearance of the upper anal canal, highlighting the U-shaped puborectalis (arrows)

On ERUS, five distinct layers of the rectal wall can typically be seen. The innermost hyperechoic layer is the interface between the ultrasound probe and the mucosa. The next layer moving outward is the hypoechoic mucosal layer. The middle layer is the hyperechoic submucosa, followed by the hypoechoic muscularis propria. The final layer is the hyperechoic interface between the rectal wall and the perirectal fat. When a neoplasm is present, its relationship to the submucosal layer determines the ultrasonographic T-stage (uTx). A uT1 lesion invades the submucosa, whereas a uT2 lesion extends into but not through the muscularis propria. uT3 lesions extend through the muscularis propria into the perirectal fat, producing a characteristic "scalloped" appearance. uT4 lesions directly invade adjacent organs, such as the bladder or vagina.

Relative contraindications to EAUS/ERUS include anal stenosis and painful anorectal conditions. Complications are rare and usually a result of minor trauma to the anorectal mucosa or anoderm. The major advantages of EAUS/ERUS are that it is fast and easy to perform, relatively inexpensive (aside from the cost of acquiring the equipment), does not require sedation, and does not involve exposure to ionizing radiation exposure. The major disadvantage is that it is operator dependent, which raises concerns regarding reliability, reproducibility, and accuracy.

Flexible Endoscopy Techniques

A multitude of technical maneuvers are required to successfully perform flexible endoscopy. Like any invasive procedure, endoscopic technique is best "learned by doing" under the careful supervision of an experienced endoscopist. Mastery of the insertion techniques described below, used for both flexible sigmoidoscopy (FS) and colonoscopy, is essential in order to perform an efficient endoscopic examination while keeping patient discomfort and risk of harm to a minimum.

Torque

The twisting motion applied to the shaft of the scope by the endoscopist's right hand is called torque, an essential technique that allows for stiffening of the scope, changing the direction in which the angulation control knobs orient the tip of the scope. Torque can also increase the resistance of the scope to avoid formation of troublesome loops. "Gentle" torque can be used to keep the scope straight during scope advancement, and more "forceful" torque is used when removing or pushing through a loop.

Tip Deflection

Every effort should be made to keep the tip of the scope in the middle of the bowel lumen. As the scope is advanced and the tip of the scope moves away from the lumen, the endoscopist should return the tip to the center of the bowel lumen, manipulating the inner and outer directional control knobs with the left hand. Ideally, the endoscopist should be able to control and use both control knobs with only the thumb and index finger of the left hand. The goal should be to keep the right hand on the shaft of the scope and the left hand on the scope controls throughout the entire scope insertion.

Dithering/Jiggle

Rapid up-and-down, side-to-side, and to-and-fro movements of the shaft of the scope are often referred to as "dithering" or "jiggle." The objective of these maneuvers is to pleat or "accordion" the colon onto the shaft of the scope in order to shorten the length of the colon and keep the scope straight. This technique is especially useful when combined with rapid torqueing and rapid in-and-out movements of the scope.

Air Aspiration

As insufflated air accumulates in the colon during the procedure, the colon becomes distended and elongates, essentially pushing the "finishing line" further away. Judicious use of air insufflation is important during the procedure, but calculated aspiration/suction of air can be an important adjunct insertion technique. Aspiration of air can "pull" the tip of the scope around a turn of flexure without needing to push the scope forward and form a loop. Once the tip of the scope has passed the turn, advancement should be much easier due to the straightness of the colon.

Slide-By

The slide-by technique involves pushing blindly into a turn or bend with maximum tip deflection and without full visualization of the colon lumen, allowing the curvature of the bowel wall to guide the scope past the turn. This is a controversial maneuver due to the potential risk of bowel wall injury/perforation and should never be performed by unsupervised trainees or novice endoscopists. If significant resistance to forward advancement is experienced or the mucosa becomes blanched at the tip of the scope, the maneuver should be terminated immediately. In the non-sedated/minimally sedated patient, the slide-by maneuver can be very painful due to tension on the bowel mesentery. Once the slide-by maneuver has successfully passed an area of sharp angulation, the scope should be immediately straightened and any loops reduced.

Flexible Sigmoidoscopy

The use of flexible sigmoidoscopy (FS) allows for a greater length of the distal colon and rectum to be evaluated in the office setting and has become more popular due to its ease of use, improved magnification and optics, better patient tolerance, and higher yield of findings over conventional rigid proctoscopy [6]. Depending on the manufacturer, the length of the scope ranges from 60 to 71 cm and the outer diameter ranges from 12 to 14. When performed properly by an experienced endoscopist, FS has been shown to have an average depth of insertion of 40–50 cm, reaching the descending colon in 80% of examinations [7, 8], and is capable of detecting 65–75% of polyps and 50–65% of colorectal cancer [9–11]. It should be noted that FS is not an adequate substitute for screening colonoscopy, as it will not detect colonic polyps and/or neoplasms proximal to the distal transverse colon/splenic flexure.

While the flexible sigmoidoscope is easier to handle than a colonoscope and the technique is easier to learn than colonoscopy, it should only be performed by a properly trained endoscopist or a closely supervised trainee. Given that the patient is not sedated, often anxious, and bowel preparation can be suboptimal, the procedure can occasionally be challenging to perform in the office setting. The indications for FS in the office setting are numerous. FS can be used to evaluate rectal bleeding not explained by findings on anoscopy or to evaluate for suspected proctitis. It can be used to identify the level of a rectal or rectosigmoid tumor, though this is somewhat less reliable than rigid proctoscopy. FS is also an excellent tool in the evaluation of the response to neoadjuvant chemoradiation in patients with rectal cancer. Additionally, postoperative evaluation of distal anastomoses can rapidly be performed to evaluate for stricture or cancer recurrence. FS is also a useful means of monitoring for recurrence after local excision of a rectal neoplasm or in patients with a complete response to neoadjuvant chemoradiation who are in a "watch and wait" protocol.

It is advisable to give the patient one to two enemas prior to the procedure. Sedation is typically not needed, and the patient is best positioned in the left lateral decubitus position. After a proper DRE, the well-lubricated scope is gently inserted, and air should be gently insufflated to distend the rectum. As the scope is advanced, it is navigated around the valves of Houston to the rectosigmoid junction. The scope is then advanced into sigmoid colon, which sometimes requires torqueing of the scope either clockwise or counterclockwise. Care should be taken to clearly visualize the lumen of the bowel before advancing the scope. Blind "slide-by" maneuvers should be avoided in the non-sedated patient to minimize discomfort, and care should be taken to insufflate just enough air to distend the bowel enough for adequate visualization and safe advancement. The scope is then advanced under direct visualization as far as possible, generally to the level of the splenic flexure. Limitations to the depth of scope insertion include the volume of residual stool, patient discomfort, and significant sigmoid diverticular disease. Once the scope has been advanced to its fullest extent, it is then withdrawn carefully and deliberately to evaluate the entire mucosal surface. Any lesions that are identified can be biopsied. Small polyps can be removed with biopsy forceps, though removal of larger polyps may best be done during a subsequent colonoscopy when the patient has performed a full bowel preparation. Identification of polyps in the distal colon during FS should prompt the patient to undergo a full colonoscopy in order to assess for additional polyps in the proximal colon.

The most common complication after FS is abdominal pain and bloating due to overdistention and air trapping. Bleeding may occur after a biopsy or polypectomy. Fortunately, serious complications are exceedingly rare with FS. The perforation rate has been reported to be as low as 0.002% [12]. When perforation does occur, it is typically at the level of the distal sigmoid where it angulates from the fixed rectum at the sacral promontory.

Colonoscopy

Colonoscopy is essential in screening for colorectal cancer, surveillance of patients with history of colorectal neoplasia, and evaluation and management of patients with intestinal complaints. A well-performed colonoscopy allows the physician to evaluate the mucosa of the terminal ileum, colon, and rectum, with biopsy and photodocumentation of abnormal findings, as well as other therapeutic interventions. A survey of American Society of Colon and Rectal Surgeons (ASCRS) members found that more than 90% reported performing colonoscopy as part of their clinical practices, completing an average of 41 procedures per month [13]. The ability to perform a thorough colonoscopy is an essential skill for colorectal surgeons to possess, and training in colonoscopy remains an essential core component of colon and rectal surgery residency programs. The indications for colonoscopy are numerous and covered in the appropriate chapters elsewhere in this book.

Bowel Preparation

The necessity of an adequate bowel preparation prior to colonoscopy cannot be emphasized enough. Removal of all debris from the colonic lumen in order to thoroughly examine the mucosal surface remains a challenge for both the physician and the patient. Most patients describe the bowel prep prior to colonoscopy as the most unpleasant part of the pro-

cedure. The ideal bowel prep is one that is safe, highly effective and reliable, convenient, and tolerable enough that patients are not deterred from completing the prep or undergoing future procedures. Unfortunately, this has not yet been developed [14]. In spite of the development of "better tolerated" bowel preps, approximately one-quarter of colonoscopies performed in the United States and Western Europe are considered to have an inadequate quality preparation [15, 16]. Inadequate bowel preparations lead to lower adenoma detection rates (ADRs), longer colonoscopy times, repeated procedures, shorter surveillance intervals, increased cost of colorectal cancer prevention, and decreased patient satisfaction [17].

A number of commercially available bowel preparations are currently available (Table 4.1), and the choice of which agent is used is often practitioner dependent or directed by which agent a patient's health insurance will cover at the lowest cost. Currently available bowel preps fall into one of three categories: iso-osmotic, hypo-osmotic, and hyperosmotic agents.

Polyethylene glycol (PEG), an inert polymer of ethylene oxide that passes through the gastrointestinal tract without net absorption or secretion, is typically combined with electrolyte solutions to create iso-osmotic preparations. The use of such PEG-electrolyte lavage solutions (PEG-ELS) is one of the most common formulations for precolonoscopy bowel preparation and is the "gold standard" against which other bowel prep formulations are compared. Unfortunately, the large volume required to be ingested (4 L) and poor palatability limit patient compliance; up to 15% of patients are unable to complete the preparation fully [18]. A sulfate-free formulation of PEG-ELS has been developed in an attempt to improve the taste and smell, with similar efficacy and safety when compared with standard PEG-ELS [19]. Additionally, an FDA-approved low-volume (2 L) PEG-ELS prep combined with ascorbic acid has also been shown to have similar efficacy to the standard 4 L PEG-ELS with improved tolerance [20]. The "low-volume" nature of this preparation is misleading, however, as the patient is required to drink an additional 1 L of clear liquids in addition to the 2 L of prep.

The use of PEG-3350 (MiraLax®, Bayer, Whippany, NJ) combined with a commercially available electrolyte solution in the form of a sports drink (PEG-3350-SD) has been widely adopted due to its low cost and better tolerance, though it is not FDA approved for colonoscopy preparation. PEG-3350-SD, often combined with a stimulant laxative such as bisacodyl, results in intestinal catharsis through a hypo-osmotic effect. Studies comparing it with a standard 4 L PEG-ELS prep have shown conflicting results in terms of adenoma detection rates and quality of bowel prep [21–23]. One should also keep in mind that, unlike the electrolyte solutions used for prescription bowel preps, commercially available sports drinks are typically not osmotically balanced, and there have been reports of severe hyponatremia associated with the use of PEG-3350-SD as a bowel prep prior to colonoscopy.

Hyperosmotic agents, such as magnesium citrate, sodium sulfate, and sodium phosphate, are also used as components of oral bowel preparation prior to colonoscopy. Magnesium citrate is not FDA approved as a colonoscopy prep, as data regarding its effectiveness are limited, and there is significant potential for toxicity, especially in the elderly and those with kidney disease. Oral sodium sulfate has been shown to be equivalent to low-volume (2 L) PEG-ELS [24] and superior to 4 L sulfate-free PEG-ELS [25]. A major advantage of oral sodium sulfate is the lack of significant fluid and electrolyte shifts. Sodium phosphate preparations had previously been used widely and were very popular due to the smaller volume of fluid required. However, concern regarding electrolyte disturbance and acute renal failure in certain populations has limited its use. The aqueous formulation of sodium phosphate has been voluntarily withdrawn from the market. A tablet formulation of sodium phosphate is available by prescription, but this requires the patient to take 32 tablets with 2 L of water, which limits its attractiveness. An FDA box warning advises against its use in elderly patients and in those with gastrointestinal motility disorders, renal or liver disease, or congestive heart failure. Sodium phosphate has also been reported to cause mucosal inflammation and ulceration that can mimic the appearance of inflammatory bowel disease, so its use is not recommended in this patient population [26, 27]. Sodium picosulfate combined with magnesium citrate has more recently become a popular alternative as a low-volume bowel prep, combining both osmotic effects and laxative effects to cleanse the colon.

Regardless of the specific bowel preparation chosen, there is overwhelming evidence that a split-dose regimen, administering a portion (usually half) of the prep the day/evening prior to the procedure and the remaining portion of the prep the day of the procedure, results in a higher-quality prep [28–36]. A split-dose prep has also been shown to improve adenoma detection rates [37] as well as patient tolerance [32]. The second dose should be given 3–8 hours prior to the planned start of the procedure, but must be completed at least 2 hours prior to administering sedation to avoid potential aspiration, as recommended by the American Society of Anesthesiologists guidelines [38]. While 4 L PEG-ELS is FDA approved to be used in a single-dose fashion but not in a split-dose fashion, there is sufficient evidence to suggest that split-dose 4 L PEG-ELS produces the highest-quality preparations [39], and, per the Standards of Practice Committee of the American Society for Gastrointestinal Endoscopy (ASGE), is considered the current standard colonoscopy prep [39, 40].

Table 4.1 Partial list of commercially available bowel preparations

	PEG-ELS	SF-PEG-ELS	Low-volume PEG-ELS with ascorbic acid	Low-volume PEG-3350-SD	Oral sodium sulfate	Sodium picosulfate/ magnesium oxide/ anhydrous citric acid	Magnesium citrate	Sodium phosphate tablets
Brand name	GoLTYELY®	NuLYTELY®	Moviprep®	Miralax®	Suprep®	Prepopik®	Generic	Osmoprep®
Company	Braintree Laboratories (Braintree, MA)	Braintree Laboratories (Braintree, MA)	Salix Pharmaceuticals (Raleigh, NC)	Bayer (Whippany, NJ)	Braintree Laboratories (Braintree, MA)	Ferring Pharmaceuticals Inc. (Parsippany, NJ)	OTC	Salix Pharmaceuticals (Raleigh, NC)
Composition	PEG, sodium sulfate, sodium bicarbonate, sodium chloride, potassium chloride	PEG, sodium bicarbonate, sodium chloride, potassium chloride	PEG-3350, sodium sulfate, sodium chloride, ascorbic acid	PEG-3350	Sodium sulfate, potassium sulfate, magnesium sulfate	Sodium picosulfate, magnesium sulfate, anhydrous citric acid	Magnesium citrate	Sodium phosphate
Volume; recommended minimum additional fluid	4 L; None	4 L; None	2 L; 1 L clear fluid	238 g PEG-3350 in 2 L SD	12 oz; 2.5 L water	10 oz; 2 L water	20–30 oz; 2 L water	32 tablets; 2 L water
Dosing regimens[a]	*Split dose*: 2–3 L day before and 1–2 L day of procedure; *Single dose:* 4 L day before procedure	*Split dose:* 2–3 L day before and 1–2 L day of procedure; *Single dose:* 4 L day before procedure	*Split dose:* 1 L day before and 1 L day of procedure; *Single dose:* 2 L day before procedure	*Split dose:* 1 L day before and 1 L day of procedure; *Single dose:* 2 L day before procedure	*Split dose:* 6 oz OSS with 10 oz water + 32 oz water day before and 6 oz OSS with 10 oz water + 32 oz water day of procedure	*Split dose:* 5 oz Prepopik + 40 oz clear liquids day before and 5 oz Prepopik day before + 24 oz clear liquids day of procedure; *Single dose:* 5 oz Prepopik + 40 oz clear liquids the afternoon or early evening before the procedure and 5 oz Prepopik + 24 oz clear liquid 6 hours later	*Split dose:* 1–1.5 10-oz bottles day before and 1–1.5 10-oz bottles day of procedure	*Split dose:* 20 tablets day before and 12 tablets day of procedure
Comments	Poor taste; large volume; poorly tolerated; split-dose not FDA approved but considered criterion standard	More palatable than PEG-ELS	Poor taste; expensive; avoid in patients with glucose-6-phosphate dehydrogenase deficiency	Well tolerated; available OTC; not FDA approved as bowel prep; unbalanced ELS–electrolyte shifts may occur	Pleasant taste; less volume; well tolerated; expensive; avoid in patients with heart failure, renal insufficiency, end-stage liver disease, and electrolyte abnormalities	Less volume; well tolerated; expensive; avoid in patients with renal insufficiency	Avoid in patients with renal insufficiency and elderly; not FDA approved as bowel prep	Avoid in patients with heart or liver failure, renal insufficiency or risk factors for acute phosphate nephropathy, volume depletion, and patients taking ACEi or NSAIDs; not recommended for routine use

PEG-ELS polyethylene glycol electrolyte solution, *SF* sulfate-free, *SD* sports drink, *OTC* over the counter, *OSS* oral sodium sulfate, *FDA* US Food & Drug Administration, *ACEi* Angiotensin-converting enzyme inhibitor, *NSAIDs* nonsteroidal anti-inflammatory drugs

[a]When utilizing split-dose regimen, second dose must be completed at least 2 hours prior to procedure

Special Considerations

Poor/Difficult Prep

It is not uncommon for patients to have a history of poor prior bowel preps for colonoscopy. Patients with a previous experience of inadequate preps or a history of chronic constipation are at particular risk for having a prep insufficient to undergo a thorough colonoscopy. It has been demonstrated that a low-quality bowel prep, defined as the inability to detect lesions <0.5 cm, should be followed up with an early repeat colonoscopy due to the risk of missed lesions [41]. In one study, split-dosage prep was superior to non-split prep in terms of completeness of prep and adenoma detection rates, while there was no difference between the patient having ingested a clear liquid diet and a low-residue diet prior to the prep [42].

Unfortunately, there is a paucity of literature prospectively addressing patients with a history of poor prep, leaving clinicians to individualize their practices based on clinical judgment. Many will start the prep and a clear liquid diet 2 days before the procedure. If the patient does not achieve clear bowel movements with this, then an additional osmotic or cathartic prep can still be administered the day before or the morning of the procedure. Patients with chronic constipation may also have coexisting gastroparesis or intestinal dysmotility, making it difficult to complete the bowel prep; the addition of an antiemetic agent can sometimes be helpful for this subset of patients. As a last resort, the patient can be admitted the day before the procedure to administer the prep through a nasogastric tube or endoscope.

Need for Antibiotics

Outside of scattered case reports, there is little data endorsing the need for routine prophylactic antibiotics in patients undergoing a colonoscopy. The updated 2015 ASGE guidelines recommend against the routine administration of antibiotic prophylaxis solely for prevention of infective endocarditis, as well as before GI endoscopic procedures for patients with synthetic vascular grafts, other nonvalvular cardiovascular devices, or orthopedic prosthesis. The guidelines do make the recommendation, based on low-level evidence, that patients with high-risk cardiac conditions and an established GI tract infection in which enterococci may be part of the infecting bacterial flora should receive antibiotic coverage [43].

Peritonitis in patients undergoing continuous ambulatory peritoneal dialysis can result from translocation across the bowel wall during GI endoscopic procedures. A retrospective study found that the risk of peritonitis after colonoscopy without antibiotic prophylaxis was 6.3% [44]. The ASGE guidelines suggest administration of antibiotic prophylaxis before endoscopy of the lower GI tract in patients undergoing continuous ambulatory peritoneal dialysis, though this is based on very low-level evidence [43]. The International Society for Peritoneal Dialysis (ISPD) recommends ampicillin (1 g) plus a single dose of an aminoglycoside, with or without metronidazole, given intravenously immediately before GI endoscopic procedures to lower the risk of peritonitis [45].

Anticoagulated Patient

The potential risk vs benefit of anticoagulation in a patient undergoing endoscopy can present a challenging situation for the clinician, and clinical decisions should be made in conjunction with the physician managing the anticoagulation. While procedure-related bleeding can be a tangible and often immediate event, therapeutic maneuvers can be utilized to mitigate the risk and manage post-colonoscopy bleeding. Conversely, thromboembolic events can have devastating and irreversible effects. Balancing the risks of bleeding and a thromboembolic event can be difficult.

A screening colonoscopy, even with a biopsy, is considered a low-risk procedure for bleeding and almost all anticoagulant agents can be continued. However, if a polypectomy needs to be performed, the procedure now becomes high risk. Unfortunately, this information is usually not known in advance. The ASGE recommends that for patients receiving anticoagulant therapy, the procedure should be postponed until the patient no longer has a need for anticoagulation, if it can be done safely [46].

Most guidelines do not suggest mandatory discontinuation of aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs) prior to diagnostic or therapeutic endoscopy, especially in patients at high risk for cardiovascular disease. If these agents are to be held, they should be discontinued at least 7 days before the procedure. Thienopyridines, such as clopidogrel, should be stopped 5–7 days before the procedure. Consideration can be given to continuing aspirin for patients on dual platelet therapy [47].

Warfarin should be discontinued 5 days prior to the procedure, and low-molecular-weight heparin should be discontinued 12 hours prior to the procedure. Factor Xa inhibitors and direct thrombin inhibitors should be discontinued 1–5 days prior to the procedure, depending on the half-life of the individual medication. When holding anticoagulant therapy, "bridging" with low-molecular-weight heparin is sometimes practiced, though one double-blinded trial demonstrated that forgoing bridging was noninferior to bridging with low-molecular-weight heparin for prevention of arterial thromboembolism, while bridging inferred a risk of major bleeding events three times that of not bridging [48].

Sedation

While there is ample literature demonstrating that colonoscopy can be performed safely and adequately in non-sedated patients [49–51], most patients who undergo colonoscopy in the Unites States are administered some form of sedation. Sedation is utilized for multiple reasons—patients prefer a favorable experience, endoscopists prefer reasonable technical conditions under which to work, and both prefer optimal patient safety and procedural outcomes [52]. Sedation can be administered by either the endoscopy team or by an anesthesia specialist, though one must keep in mind that adding anesthesia services adds substantially to the cost of these procedures. Historically, most patients received endoscopist-directed moderate sedation. However, a 2017 study using a combination of Medicare and commercial billing data demonstrated a steady increase in the utilization of anesthesia services for gastrointestinal endoscopy, rising from one-third of all patients in 2009 to about one-half of all patients in 2013 [53]. The authors estimated that this may cost as much as $1.5 billion annually in the United States. The main driver of this shift in sedation care is due to the use of propofol deep sedation.

Endoscopist-directed moderate sedation most commonly employs a combination of a benzodiazepine and an opiate. The main disadvantages of this regimen include the length of time needed to achieve adequate sedation, procedural recall, poor intra-procedural sedation, prolonged recovery, and post-procedural emesis. One study evaluating the actual depth of sedation in patients undergoing endoscopic procedures with a targeted moderate level of sedation found that 45% actually were at a level of deep sedation at least once during the procedure [54]. This demonstrates that moderate sedation is inadequate for some patients who are at risk for having a suboptimal experience or receive excessive sedation, leading to the potential for increased adverse effects. When employing moderate sedation, it is essential to have reversal agents readily available—naloxone for opioid reversal and flumazenil for benzodiazepine reversal.

Propofol is a hypnotic alkylphenol derivative that facilitates inhibitory neurotransmission mediated by gamma-aminobutyric acid (GABA), resulting in sedation, amnesia, and hypnosis. The use of propofol has proven to be more advantageous than moderate sedation in a number of variables, including rapid onset, rapid recovery, minimal post-procedural adverse effects, procedural amnesia, good procedural operating conditions, and excellent patient and provider satisfaction [55]. Propofol is traditionally reserved for use by trained anesthesia professionals for a number of reasons. It easily results in deep sedation, and patients often achieve a level of general anesthesia, defined as a lack of response to painful stimulation and frequent need for airway intervention.

Due to the increased cost associated with the requirement of an anesthesia provider to administer propofol, alternative delivery methods have been investigated. A meta-analysis published in 2015 found that the safety of non-anesthesia provider-administered propofol sedation for advanced endoscopic procedures compared favorably with anesthesia provider-administered propofol sedation, though it came at the cost of decreased patient and endoscopist satisfaction [56]. There is rapidly accumulating data to suggest that administration of propofol by registered nurses supervised by endoscopists can be performed safely [57], and there is a substantial evidence base to support the safety of endoscopist-delivered propofol protocols, demonstrating its cost-effectiveness compared with administration of propofol by anesthesia specialists. Although these protocols have been implemented successfully in some European countries, their use in the United States has been limited by financial considerations, medical–legal risk concerns, and what some feel to be nonevidence-based policies of governing organizations [58].

Instrumentation

Depending on the specific manufacturer and product specifications, colonoscopes vary in length from 133 to 170 cm (Fig. 4.7). The typical outer diameter of a standard adult colonoscope is 12.8–13.2 mm, though smaller-diameter pediatric (11.6–11.7 mm) and neonatal (9.7–9.8 mm) colonoscopes are also available. The basic colonoscope houses a suction channel, an air/water insufflation channel, fiberoptic bundles for light transmission, a biopsy port/working channel connected to the suction channel, and cables attached to the angulation control knobs (also called “wheels” or “dials”) used to deflect the tip of the colonoscope for direction change. There are specific models of colonoscopes with a

Fig. 4.7 Colonoscope

second working channel, which can be helpful for more advanced therapeutic procedures. Most modern colonoscopes also have a variable stiffness control that allows the endoscopist to vary the rigidity of the scope.

Colonoscopy Technique

Colonoscopy can be an extremely challenging skill to learn, requiring appropriate training, practice, patience, and attention to detail. A redundant/tortuous colon, angulation created by postoperative or inflammatory adhesions, and altered postoperative anatomy can create technical challenges in navigating the entire length of the colon for even the most experienced of endoscopists.

Once the patient has provided informed consent for the procedure (and separate consent for sedation if anesthesia services are being utilized) and appropriate cardiopulmonary monitoring has been instituted, he or she is positioned in the left lateral decubitus position. The colonoscope is brought from the procedure cart to the bed/stretcher, ensuring that there are no loops or twists in the scope, which will add additional tension to the inner cables. After an appropriate level of sedation is achieved, visual inspection of the anal margin/anal verge is performed, followed by DRE. The well-lubricated colonoscope is then advanced into the anus. It is helpful to double-glove the right hand, removing the outer glove after performing DRE and inserting the colonoscope, in order to avoid getting lubricant on the control body and angulation control knobs, which can make them difficult to maneuver.

Air is gently insufflated to distend the bowel lumen as the colonoscope is advanced into the rectum. There is a tendency for residual liquid to pool in the distal rectum. This should be suctioned prior to advancing the colonoscope to prevent forceful expulsion of the residual bowel contents should the patient begin coughing at any point in the procedure due to airway irritation. One should keep in mind that the suction port is located at the 5:00 position on the tip of the colonoscope. The colonoscope should be rotated so that the fluid being suctioned is located at the inferior aspect of the field of view, and the tip of the scope should be placed just above the air–fluid interface prior to suctioning. The force of suction is dependent upon how far the suction button is depressed. In order to prevent the mucosa from being drawn into the suction port and obstructing it, one should avoid full depression of the suction button for prolonged periods. Instead, repeated short periods of partial depression of the suction button followed by releasing it allows for re-distention of the lumen, preventing luminal collapse around the scope. Simultaneous air insufflation and suction can accomplish the same result.

The colonoscope is then advanced through the rectum, navigating around the valves of Houston (Fig. 4.8) to reach the rectosigmoid junction. Advancing the colonoscope past this point can be one of the more challenging areas of the colonoscopy. There is often an acute angle at this junction, especially if the sigmoid colon is redundant. If the patient has undergone prior pelvic surgery, especially hysterectomy, the sigmoid may become fixed, making negotiation of this angle even more difficult and often painful. As the colonoscope is advanced, it should be kept as straight as possible. A combination of short advancements/withdrawals with slight clockwise torque and appropriate tip deflection can help advance the scope into the sigmoid colon. Slide-by maneuvers should be avoided, if at all possible, as this is one of the most frequent sites of colonoscopic perforation.

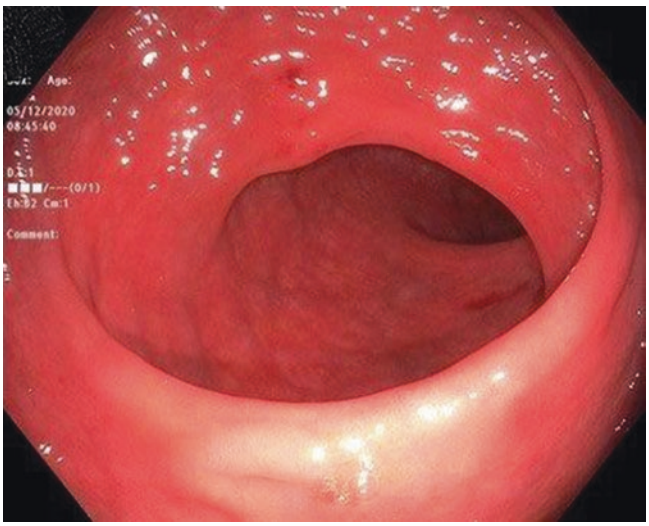

Fig. 4.8 Endoscopic appearance of the rectum, noting the three valves of Houston

Once the colonoscope is advanced into the sigmoid colon, any loops should be reduced, using tip deflection and torque. If loop reduction is not possible, the scope can be carefully inserted farther into the sigmoid, "pushing through the loop," as long as there is minimal resistance and it does not cause the patient excessive discomfort. Keep in mind that this may elicit a vasovagal response with bradycardia—if this occurs, the colonoscope should be withdrawn to reduce the loop.

The sigmoid colon is the most tortuous segment of the colon and is associated with high muscular tone, frequent spasm, and a higher incidence of diverticulosis (Fig. 4.9). The sigmoid colon lacks fixation and can be quite redundant and elongated. A number of techniques can be required to successfully navigate this portion of the colon, including insertion/pull back, jiggle, and torque (usually clockwise), allowing for the sigmoid colon to "accordion" over the scope, advancement of the scope, and prevention of further loop formation.

Large diverticula, when present, can be mistaken for the true bowel lumen. Careful advancement of the colonoscope through a sigmoid colon riddled with diverticula requires patient, frequent use of pull-back techniques to gain a better appreciation of the true colonic lumen. As the scope is

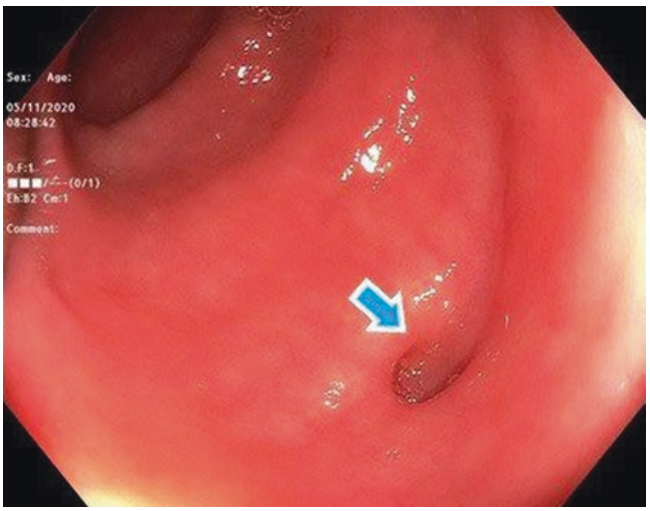

Fig. 4.9 Endoscopic appearance the sigmoid colon, noting diverticulum (arrow)

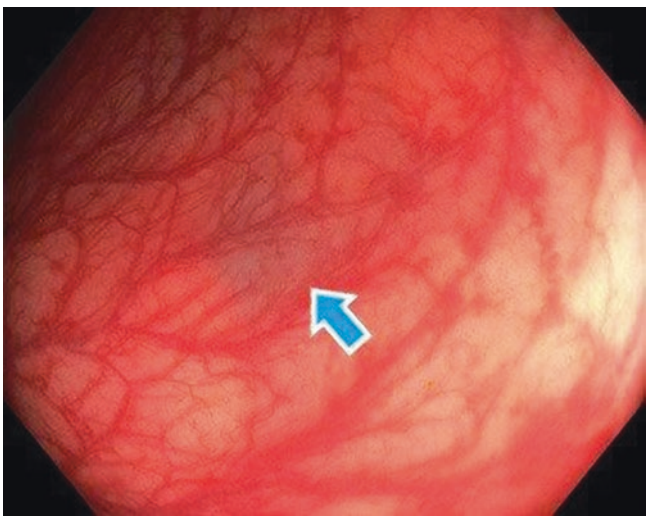

Fig. 4.10 Endoscopic appearance of the spleen (arrow) visible through the colonic wall at the splenic flexure

advanced, one should strive to keep it as straight as possible to prevent loop formation.

Passage of the colonoscope from the sigmoid colon into the descending colon is usually evident, as the descending colon is typically much straighter and less muscular than the sigmoid colon. Once the descending colon is reached, any remaining loops should be reduced with withdrawal and torqueing maneuvers. If there are no loops present, the colonoscope should be easily advanced from this point to the splenic flexure, which can sometimes be identified by the blue shadow of the spleen seen through the wall of the colon (Fig. 4.10) and/or pooling of fluid. Negotiating the splenic flexure is often a simple maneuver, requiring minimal tip deflection and torque. Other times, the splenic flexure may be a complex series of turns and twists in multiple planes, requiring tip deflection, torque, and push/pull techniques.

Once the colonoscope traverses the splenic flexure, the lumen of the transverse colon takes on a characteristic triangular appearance formed by the taenia coli (Fig. 4.11). The transverse colon can also be quite redundant, and the midpoint may descend down into the pelvis where it can become fixed by adhesions, especially following pelvic surgery. Loops are commonly created during this part of the exam, and external pressure on the abdominal wall assists advancement.

As the transverse colon is traversed, the hepatic flexure can be recognized by visualizing the blue shadow from the liver, especially in thinner patients (Fig. 4.12), as well as pooling of liquid. If the hepatic flexure is especially acute,

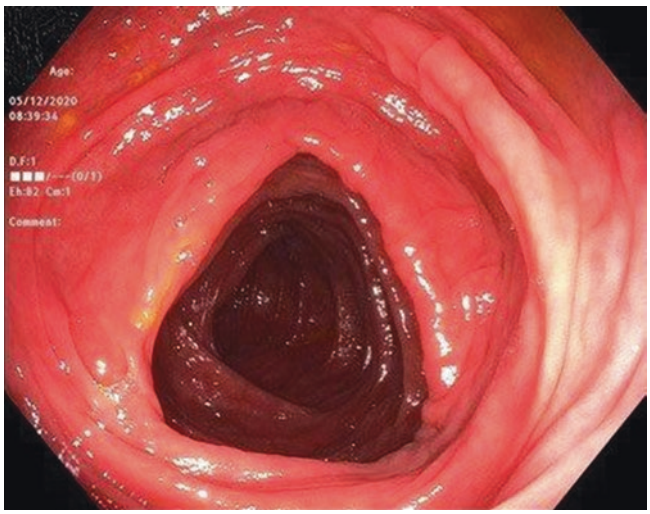

Fig. 4.11 Endoscopic appearance of the transverse colon, noting the triangular lumen

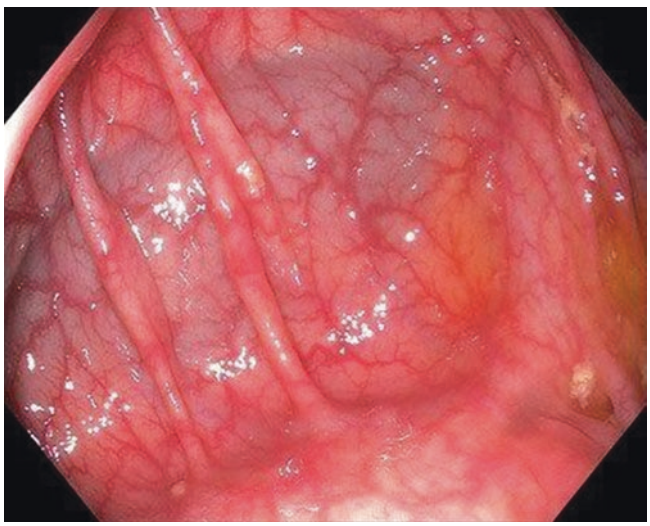

Fig. 4.12 Endoscopic appearance of the liver visible through the colonic wall at the hepatic flexure

the novice endoscopist often mistakes this "fool's cecum" for the true cecum. One should use tip deflection to negotiate this area of particularly sharp angulation. Occasionally, it is necessary to gently push through a loop to advance the colonoscope into the ascending colon and then reduce the loop, at which point withdrawing the scope often will result in paradoxical advancement of the tip of the colonoscope toward the cecum. Another maneuver is to use intermittent suction to draw the tip of the scope down toward the cecum once the colonoscope has made the initial turn around the hepatic flexure. Transitioning the patient from the lateral decubitus position to supine position and the use of external abdominal pressure can also be useful adjuncts in getting the colonoscope to advance to the cecum.

The ileocecal valve marks the junction between the ascending colon and the cecum. The appearance of the valve can be highly variable—it may be visible simply as a fold at the base of the ascending colon, as a polypoid-like yellowish mass with a lipomatous appearance, as a visible lumen opening into the terminal ileum, or it may be completely hidden (Fig. 4.13a–c). When the valve is not easily identified, the presence of gas bubbles or enteric contents flowing from it can assist with its identification.

A complete colonoscopic examination is ensured only when the cecum has been clearly and indisputably cannulated. This base of the cecum is characterized by a "crow's foot" appearance, caused by the muscular arrangement of the colonic wall coalescing around the appendiceal orifice (Fig. 4.14). Identification and photodocumentation of the ileocecal valve and appendiceal orifice (and terminal ileum if intubated) is mandatory for quality assurance of a complete examination. Trans-illumination of the scope through the right-lower-quadrant abdominal wall or endoscopic visualization of external pressure on the right-lower-quadrant abdominal wall is not a reliable indicator that the cecum has been cannulated and should never be used as a substitute for clear visualization of anatomic landmarks. Detailed evaluation of the entire cecum is essential, including the recess behind the ileocecal valve, where it is easy to miss small, flat lesions.

While intubation of the ileocecal valve to visualize the terminal ileum is an essential component of a colonoscopy in patients with inflammatory bowel disease or in a search for obscure gastrointestinal bleeding, the exact role of routine visualization of the terminal ileum during all colonoscopies is not clear. One study in which routine terminal ileal intubation was attempted in over 1300 consecutive patients found that it was successfully performed in 90.2% of cases, but clinically significant findings in asymptomatic patients were found in only 3.3% of cases [59]. Another retrospective study of over 6400 patients who had terminal ileal intubation performed at the time of screening colonoscopy found gross endoscopic abnormalities in 1% and pathologic abnormalities in 0.3%, calling into question the need for routine terminal ileal intubation [60]. Others have argued that, because asymptomatic small bowel lesions with potential for significant consequences such as terminal ileal carcinoid tumors can be identified, routine ileoscopy should be performed with all colonoscopies [61].

While the routine performance of routine ileocecal valve cannulation is somewhat controversial, it is a skill that all endoscopists must possess, and the ability to expertly per-

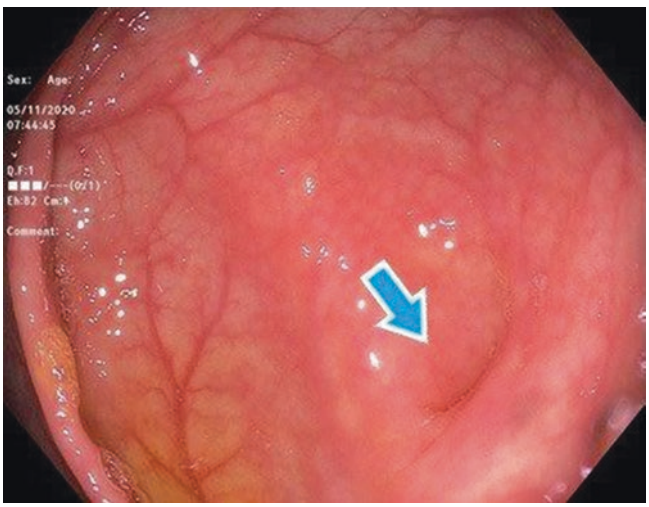

Fig. 4.14 Endoscopic appearance of the appendiceal orifice (arrow)

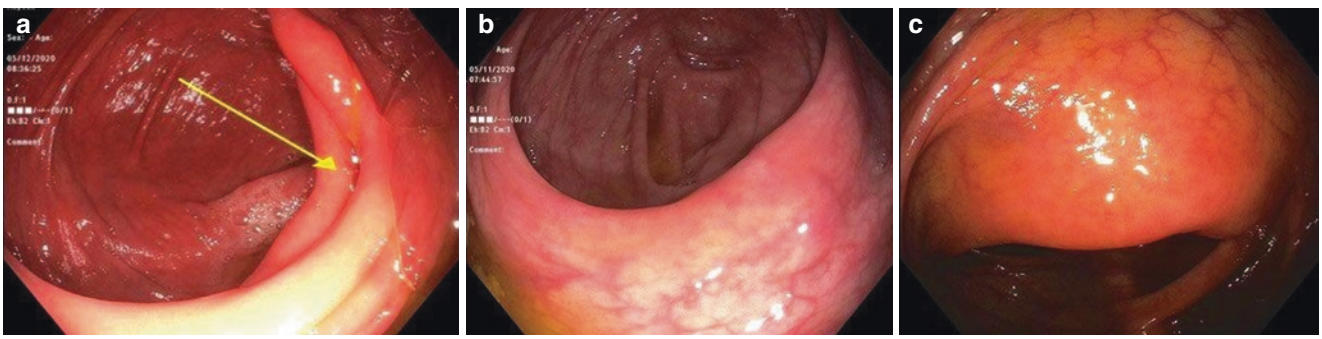

Fig. 4.13 (**a**–**c**) Varied endoscopic appearances of the ileocecal valve

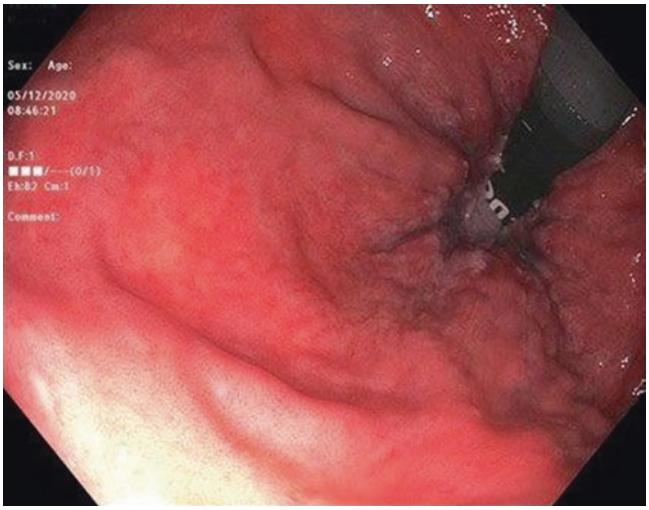

Fig. 4.16 Retroflexed view of the distal rectum

form the maneuver improves with practice. Before attempting to intubate the ileocecal valve, one must first ensure that all loops have been reduced. With a gentle curve in the end of the colonoscope, the edge of the ileocecal valve is then "hooked," and the scope is then gently advanced into the lumen of the terminal ileum. Terminal ileal intubation serves as additional confirmation of a complete colonoscopy in the rare instances where identification of the appendiceal orifice and ileocecal valve is ambiguous.

The terminal ileal mucosa has a much different appearance than colonic mucosa, easily recognizable by its granular appearance and its increased motility (Fig. 4.15). Multiple lymphoid follicles, especially in younger patients, may resemble small polyps. The scope should be advanced as far as it can be without difficulty, taking care to use minimal air insufflation in order to avoid overdistention of the small intestine. Biopsies should be obtained as clinically indicated.

Once the full extent of insertion has been reached, the colonoscope is then slowly and methodically withdrawn, taking care to fully examine the colon for mucosal lesions. It is sometimes helpful to lock one of the angulation control knobs to minimize extraneous movement of the tip of the colonoscope as it is withdrawn. Residual debris should be irrigated and pools of fluid should be suctioned. Care should be taken to evaluate behind mucosal folds when possible; the tip of the colonoscope can often be used to flatten out or splay mucosal folds to look behind them as the scope is withdrawn. There is some controversy as to the practice of routine retroflexion once the colonoscope has been withdrawn into the rectum (Fig. 4.16). Though it has been shown that the use of routine rectal retroflexion does not increase the detection of clinically important neoplasia [62], it can sometimes be helpful in evaluation for sources of anorectal bleeding. Retroflexion of the colonoscope can cause discomfort in incompletely sedated patients, superficial mucosal trauma resulting in post-procedural bleeding, and, in very rare cases, rectal perforation.

Alternative Techniques

Carbon Dioxide Insufflation

Carbon dioxide insufflation has rapidly gained popularity in the setting of endoscopy. Carbon dioxide is absorbed through the gut mucosa much faster than air and expelled through the respiratory system, offering several advantages [63]. Because of rapid absorption, the bowel does not remain distended for long periods of time. If a combined laparoscopic and endoscopic procedure is being performed, insufflated carbon dioxide will be absorbed quickly, allowing for less bowel distention and more working room for the surgical part of the procedure. This is especially evident in surgical procedures performed on patients with incompetent ileocecal valves, who would otherwise be prone to massive small bowel distention, which would limit the field of view during laparoscopy. Additionally, patient comfort during and after colonoscopy has been reported to be improved with the use of carbon dioxide insufflation [64–66].

Water Insufflation

Water insufflation can be another helpful adjunct during difficult colonoscopies. In this technique, water is instilled into the colonic lumen to distend it without the use of air insufflation. This technique has been shown to decrease pain and loop formation. It can also facilitate stabilization of the colon wall during endoscopic resection of large polyps.

However, there is a higher rate of incomplete colonoscopy with the utilization of this technique [67]. While data on water insufflation are mixed, a recent comparative study between carbon dioxide and water insufflation showed that the use of water insufflation was associated with a higher adenoma miss rate [68].

Chromoendoscopy

Chromoendoscopy utilizes a dye (typically 0.5–1% indigo carmine) injected through the colonoscope with the use of a spray catheter to coat the colonic mucosa in order to create more contrast and enhance the visualization of the mucosa [69]. This aids the endoscopist in delineating areas of dysplasia and improves assessment of glandular structure and pit patterns. This technique is especially beneficial in the setting of surveillance in patients with inflammatory bowel disease, where dysplastic lesions tend to be flatter and less conspicuous [70, 71]. The use of chromoendoscopy during screening colonoscopies has also shown improved detection of flat adenomas, though it comes at the expense of a longer procedure time [72].

Narrow Band Imaging

Narrow band imaging (NBI) uses a filter that narrows the green and blue wavelengths and eliminates the red wavelength from standard white light. This enhances the visualization of superficial mucosal structures, especially microcapillaries [73]. Adenomas demonstrate increased vascularity and appear brown against a blue-green background of normal mucosa. Serrated polyps, which are often hypovascular, appear pale against the background of normal mucosa under NBI [74]. The use of NBI has been shown to result in a higher adenoma detection rate when compared to normal white light endoscopy [73]. NBI has also been shown to demonstrate similar yield for detection of ulcerative colitis-associated neoplasia when compared with chromoendoscopy [75, 76].

Full-Spectrum Endoscopy

Full-spectrum endoscopy (FUSE) is a system with coupled lenses mounted to each side of the colonoscope tip, projected externally to multiple viewing screens next to each other. This permits observation up to a 330-angle field of view during colonoscopy in an effort to decrease adenoma miss rate. This was designed to be of particular benefit in areas that are typically difficult to fully visualize. Initial studies demonstrated a decreased adenoma miss rate [76], but subsequent studies have shown mixed results [77]. The cost of the system had been a significant rate-limiting factor in its adoption.

Difficult Exams

Occasionally, even the most experienced of endoscopists will encounter difficult exams that require the use of adjunctive maneuvers, such as abdominal pressure and positional changes. The use of overtubes has mostly ceased due to the advent of adjustable stiffness endoscopes. The most common reason for a difficult examination is the formation of a loop, which makes further advancement of the scope impossible, painful, and potentially harmful, and these adjunctive maneuvers are meant to reduce loop formation or to prevent loops from reforming once they have been reduced. When these techniques fail, one should consider withdrawing the scope back to the rectosigmoid and resuming the procedure.

Changing Patient Position

While colonoscopy typically begins in the left lateral decubitus position, transitioning to a supine position may sometimes ease the navigation of a difficult sigmoid colon. It can also aid in advancing the scope from the ascending colon to the cecum when there is significant backstream looping of the scope. Alternatively, if the patient begins supine, shifting to the left lateral decubitus position can help to achieve the same goal. While done rarely, turning the patient to their right side is another technique that can be useful when the examination has reached the ascending colon and it cannot be advanced into the cecum. Moving to a prone position can also be helpful, though this is difficult to perform in an already sedated patient and requires particular attention to patient safety.

Abdominal Pressure

The technique of applying external pressure via the abdominal wall by an assistant to splint redundant areas of the colon can assist significantly in reduction of loop formation. This technique is most effective when there is a known loop present and the endoscopist can properly guide the assistant to apply pressure at the correct location. The most common areas of looping are the sigmoid and transverse colon, though applying pressure to different areas of the abdominal wall can help determine where the problem lies. A loop in an extremely redundant loop of sigmoid may actually be located on the right side of the abdomen. The effectiveness of abdominal pressure is dependent on the skill of the assistant. Initial pressure aimed at the sigmoid colon should be applied superior and to the right of the umbilicus and directed toward the left lower quadrant. Abdominal pressure should be applied in a gradual fashion to avoid rapid changes in intra-abdominal pressure.

Rotating the Scope

During the navigation of a difficult or acute angulation of the bowel lumen, it may be helpful to change the entire angle of approach of the scope, which can be accomplished by torqueing the shaft and rotating it 180° while keeping the tip of the scope centered in the middle of the bowel lumen using the deflection knobs.

Incomplete Colonoscopy

Every effort should be made to complete a colonoscopy to the cecum to ensure the detection of right-sided lesions. However, rates of incomplete colonoscopy range from 4% to 25%, for a variety of reason [78]. After an incomplete colonoscopy, the patient still needs a complete examination of the portion of the colon that was not visualized, and the strategies for managing incomplete colonoscopies are varied.

Sometimes a colonoscopy cannot be completed simply due to an inadequate prep. If this is the case, the reasons for the poor prep should be elucidated, a strategy to ensure an adequate patient preparation should be formulated as discussed earlier, and repeat colonoscopy should be attempted. If feasible, the patient can be kept on a liquid diet following the failed colonoscopy, given additional prep that evening, and undergo an attempt at repeat colonoscopy the following day. In the setting of a poor prep, the imaging studies below are not likely to be of benefit; if the prep is not good enough to permit a colonoscopy, it certainly will not be sufficient for diagnostic imaging.

For patients who had an incomplete colonoscopy due to inability to achieve cecal intubation, multiple modalities can be applied. The means of sedation can be altered with the help of anesthesia, smaller- or larger-caliber colonoscopes can be used, and carbon dioxide or water insufflation can be utilized. For instances where there are difficult loop formations, fluoroscopy or a scope guidance system can be utilized to aid the endoscopist in the detection and prevention of loop formation [79]. Advancements in balloon endoscopy have been expanded to be used in colonoscopy to assist with difficult procedures [80]. In situations where one unexpectedly encounters an obstruction that cannot be traversed, further evaluation should ensue, understanding that patient will likely need surgery or some other intervention, at which time simultaneous colonoscopy to evaluate the proximal colon can be performed.

Traditionally, double-contrast barium enema (DCBE) was performed for patients who had an incomplete colonoscopy despite utilization of the above measures. The use of DCBE in this setting has been largely replaced by the use of computed tomography (CT) colonography (or "virtual colonoscopy"), which has been shown to be more sensitive than double-contrast barium enema [81]. CT colonography has been shown to have a sensitivity of 96% for detection of colorectal cancer, 67–94% for detection of advanced adenomas ≥1 cm, and 73–98% for detection of advanced adenomas ≥6 mm [82]. Disadvantages of CT colonography include the need for another bowel prep and distention of the colon with insufflated room air or carbon dioxide in a non-sedated patient, which can be uncomfortable. In a patient who is undergoing a difficult colonoscopy, aborting the colonoscopy and proceeding directly with CT colonography, if it is available, is a good strategy to save the patient from re-prepping. However, one recent study suggests that CT colonography for incomplete colonoscopy is suboptimal compared with having the patient undergo a repeat colonoscopy by an "expert endoscopist" [83]. Due to concerns about the risk of radiation exposure in patients who have undergone multiple CT scans, magnetic resonance (MR) colonography, previously used mainly in the evaluation of inflammatory bowel disease, is now also being utilized for polyp detection [84].

Complications

More than 15 million colonoscopies are done each year in the Unites States [85], the vast majority of which occur without complications. However, colonoscopy is an invasive procedure, one that is difficult to master, and complications that can impart significant harm on the patient are possible. Preprocedural discussion with the patient should address the specific risks involved, highlighting the fact that, in the vast majority of cases, the benefit of having the procedure performed far outweighs the risks. Complications can be related to the bowel preparation prior to the procedure, sedation during the procedure, or events that occur during the procedure itself.

Complications Due to Bowel Preparation

In the past, one of the most commonly encountered complications of bowel preparation was nephrocalcinosis and renal failure associated with the use of sodium phosphate preparations, resulting in their removal as an option [86]. The most common complication associated with the more commonly used PEG solutions is nausea and vomiting, which can on occasion be a sign of upper gastrointestinal pathology [87]. Aspiration is a risk in elderly patients and those with gastroparesis. As previously mentioned, electrolyte abnormalities can occur with the use of non-osmotically balanced electrolyte solutions, though these are rarely of clinical significance.

Complications Due to Anesthesia/Sedation

An administrative claims data review published in 2016 revealed that 34% of colonoscopies were conducted with

anesthesia services and that the use of anesthesia services was associated with a 13% risk of any complication within 30 days, including perforation, hemorrhage, abdominal pain, complications specific to anesthesia, and stroke [88]. Procedural sedation should be performed in a closely monitored setting, with continuous pulse oximetry and cardiac monitoring. Oversedation can lead to respiratory depression and hypoxia as well as hypotension. Patients with underlying cardiac conditions may be particularly sensitive. Propofol specifically has been shown to suppress cardiac output and can lead to systemic hypotension [89]. Vasovagal reactions can occur in up to 16% of cases [90], though this is typically due to overdistention of the bowel or traction of the bowel and mesentery due to looping of the colonoscope. Upon recognition of a vasovagal episode, air should be aspirated endoscopically from the colonic lumen, and loops should be reduced. Most vasovagal episodes are self-limited and require no specific pharmacologic management. True cardiac arrhythmias during colonoscopy are quite uncommon and usually result from electrolyte disturbances from bowel preparation and hypovolemia; the vast majority are self-limited and require no specific intervention [91].

While it has been shown that, with good technique, colonoscopy is associated with severe pain in only 10% of examinations [92], there is a tendency to be liberal with procedural sedation due to patient anxiety. Oversedation can mask suboptimal technique, leading to increased risk of procedural complications such as perforation, particularly in patients with redundant or tortuous colons or those who have adhesions from prior surgical intervention. Intra-procedural aspiration can also occur with oversedation due to the patient's inability to protect the airway; applying abdominal pressure or repositioning the patient supine may increase the risk of aspiration, and particular care should be undertaken with patients with known gastroparesis or gastrointestinal dysmotility. A large population-based cohort administrative database study from Canada showed that anesthesia assistance for outpatient colonoscopy was associated with an increased risk of aspiration pneumonia (odds ratio [OR], 1.63; 95% confidence interval [CI], 1.11–2.37) [93].

Procedural Complications

Perforation

While perforation during a colonoscopy is an extremely rare event, most endoscopists will unfortunately encounter this distressing complication at some point in their careers. Colonic perforation is probably the most serious of complications that can occur during colonoscopy and can impart devastating consequences on the patient. The impact on the endoscopist's psyche should not be underestimated as well. The exact incidence of colonoscopic perforation is difficult to estimate. Older studies have reported an incidence of 0.012–0.8% for diagnostic examinations and up to 5% for therapeutic colonoscopies [94, 95]. A more recent systematic review found the pooled prevalence of perforation during all colonoscopies to be 0.05% and the perforation rate of colonoscopy with polypectomy to be 0.08% [96].

Colonoscopic perforation can result from direct trauma from the colonoscope, overdistention and barotrauma, or as a result of a therapeutic intervention, such as polypectomy or dilation. The sigmoid colon is the most common site of perforation from direct trauma, accounting for 64–74% of perforations [97, 98]. Direct trauma rarely occurs from the tip of the scope actually puncturing the colon. This most commonly occurs during "slide-by" maneuvers when attempting to navigate severe angulations of the colon, particularly at the rectosigmoid junction, or if the scope is inadvertently and forcefully advanced through a diverticulum. Direct mechanical trauma from the colonoscope most commonly occurs from "sideways" pressure or "bowing" of the scope on the bowel wall far proximal to the end of the scope while trying to push through a redundant or fixed loop of colon. Risk factors for traumatic perforation during colonoscopy include severe diverticular disease with muscular hypertrophy and luminal narrowing, severe inflammatory bowel disease, colonic ischemia, and a history of prior abdominopelvic surgery. When these risk factors are present, care should be taken to ensure that colonoscope insertion is gentle and not rushed, that the lumen of the colon is clearly visualized before advancing the scope, and that loops are reduced; the use of a pediatric scope can also facilitate safe completion of the exam in high-risk patients.

Perforation due to overdistension and barotrauma accounts for up to 35% of colonoscopic perforations [99] and typically occurs in the more proximal, thin-walled ascending colon and cecum, often after prolonged attempts to navigate a difficult segment of colon. The more recent adoption of carbon dioxide insufflation is thought to be protective in terms of avoiding barotrauma due to its rapid absorption. Proximal barotrauma can also occur following colonoscopic stent placement for a near-obstructing distal lesion. In these instances, the proximal colon is already distended and potentially ischemic prior to the procedure. With attention on addressing the obstructing distal lesion, the endoscopist can easily lose sight of how much additional intraluminal air is being insufflated during a potentially prolonged procedure, putting the patient at risk for perforation.

Abandoning a difficult colonoscopy should not be looked upon as a "failure." While cecal intubation rates are scrutinized and looked upon as a quality measure, the consequences of a colonoscopic perforation cannot be overemphasized. Colonoscopists should have better acceptance of an incomplete examination [94] and not put the patient at unnecessary risk for the sake of pride or ego.

Identification of colonoscopic perforations may be evident during the procedure, as demonstrated by the appearance of a traumatic defect in the wall of the colon or visualization of extracolonic fat. Severe abdominal pain immediately following the procedure is a common presentation of perforation. When perforation is suspected, an upright abdominal film should be obtained immediately to evaluate for pneumoperitoneum, as an overdistended, non-perforated colon with significant air trapping can result in significant abdominal pain that can mimic peritonitis. If plain films are equivocal, computed tomography can be helpful. In general, perforations identified during or immediately after colonoscopy have a better prognosis than those with delayed recognition, less frequently requiring surgical intervention [100–102].

Management of colonoscopic perforation is determined by the etiology of the perforation and the patient's clinical condition. Diffuse peritonitis is clearly an indication for emergent exploration. If the patient requires operative intervention, laparoscopic exploration is generally felt to be safe unless there are specific contraindications. If the bowel prep for the colonoscopy was adequate, there is minimal peritoneal contamination, and the patient is hemodynamically stable intraoperatively, either open or laparoscopic primary repair of a small defect or resection with primary anastomosis is acceptable [97, 103, 104]. In the setting of a perforation complicating a therapeutic colonoscopy in which the patient does not have peritonitis and is clinically stable, attempted nonsurgical management with bowel rest and intravenous (IV) antibiotics is reasonable. Success rates with nonoperative management range from 33% to 90% [105]. Endoscopic treatment via placement of clips is possible when the perforation site is recognized intra-procedurally or in the immediate post-procedural period [106], with a success rate of 59–100% [107–110]. Of note, complication rates and lengths of hospital stay are significantly higher in patients who have undergone delayed surgery after failed conservative management than in patients who were initially treated with surgery [111].

Bleeding

Post-polypectomy bleeding is one of the most common serious complications following colonoscopy, occurring in 0.3–6.1% of cases [112, 113]. Bleeding after diagnostic colonoscopy is quite rare (0.3%) [114] and usually follows biopsy. Immediate post-polypectomy bleeding is usually evident and can typically be immediately managed endoscopically with the use of mechanical clips and/or direct cautery, with or without the use of dilute epinephrine injection [115, 116]. Delayed post-polypectomy bleeding can occur up to a week or longer post-procedure and can be quite alarming to the patient, highlighting the fact that patients should be given instructions outlining how to proceed if they do experience post-polypectomy bleeding.

Risk factors for post-polypectomy bleeding include polyp size (>2 cm), thick stalk, right colon location, resumption of antithrombotic/anticoagulant therapy, cardiovascular disease, and hypertension [116, 117]. Watabe et al. reported that polyps larger than 10 mm were at a 4.5-fold greater risk for post-polypectomy bleeding than smaller ones. They also found that the incidence of post-polypectomy bleeding was 0.4% for polyps smaller than 10 mm, 1.6% for those 10–19 mm, 3.8% for those 20–29 mm, and 5.3% for those larger than 29 mm [118]. Patients on anticoagulant therapy are at a higher risk for post-polypectomy bleeding, though this risk is not seen with aspirin, NSAIDs, or other antiplatelet therapies [119–121]. "Hot biopsy" utilizing electrocautery has been employed in order to minimize the risk of post-polypectomy bleeding. However, hot biopsy is felt to be just as likely, if not more likely, to result in post-polypectomy bleeding [113], as the zone of coagulation produced by hot biopsy cautery is directed downward into the submucosa, where it can damage the wall of submucosal arteries, leading to delayed bleeding [94].

Management of post-polypectomy bleeding begins with resuscitation if the patient has sustained significant hemorrhage and is unstable. If the bleeding continues, the patient should be given a rapid bowel prep and have repeat colonoscopy performed, during which endoscopic maneuvers as described above are typically employed. Alternatively, angiographic embolization may be employed [122]. Surgery is almost never required.

Post-polypectomy Syndrome

Post-polypectomy syndrome refers to a constellation of symptoms, including abdominal pain, fever, and leukocytosis, without radiographic evidence of colonic perforation, that occur following a colonoscopic polypectomy. The symptoms are thought to be caused by a transmural burn to the bowel wall, resulting from the use of electrocautery, with localized peritonitis without radiographic evidence of colonic perforation. The incidence of post-polypectomy syndrome ranges from 0.003% to 0.1% of all colonoscopies [123]. This rate increases to approximately 1% after endoscopic mucosal resection (EMR) and up to 7–8% after endoscopic submucosal dissection (ESD) [124].

Patients typically present 1–5 days following colonoscopy with fever and pain with localized peritoneal signs. The clinical picture often mimics perforation, aside from the absence of free air on radiographic studies. This entity is usually managed with IV fluids, broad-spectrum antibiotics, and bowel rest until symptoms subside [125]; surgical intervention is almost never necessary. In rare instances, the transmural burn can progress to a full-thickness perforation. On CT images, patients with post-polypectomy syndrome demonstrate severe mural thickening with a stratified enhancement pattern, a mural defect filled with fluid, surrounding infiltration, and the absence of extraluminal air [126].

Splenic Injury

Splenic injury during colonoscopy is surprisingly rare, especially given the sharp angulation of the splenic flexure and the close approximation of the colon to the spleen. The reported incidence is estimated at 1 in 100,000 procedures [127], though the true incidence is likely much higher due to unreported cases. A systematic review published in 2016 identified 172 reported cases [128]. This injury typically results from traction on the wall of the colon avulsing the splenocolic ligament. The most typical pattern of injury is a subcapsular hematoma [129], though splenic rupture with frank hemoperitoneum and hemorrhagic shock can be seen as well. In the aforementioned systematic review, splenic injuring during colonoscopy was seen more frequently in females (70.8% of reported cases) and in patients who had undergone prior abdominopelvic surgeries (63.8% of reported cases) [128]. While the tenets of nonsurgical management parallel those for blunt splenic injury in the surgical trauma literature, the majority of patients ultimately require operative intervention, though splenic artery embolization has been successfully employed and seems to be gaining favor in hemodynamically stable patients [128, 130, 131].

Infectious Complications

Colonoscopy has been associated with bacteremia in 2–4% of patients [132] and the risk of infectious complications is felt to be significantly less. Reports of infective endocarditis are exceedingly rare, and prophylaxis for "high-risk" cardiac conditions is recommended at the endoscopist's discretion [133]. The risk of introduction of an infectious agent via a contaminated colonoscope is estimated at 1 in 1.8 million [94]. The most commonly transmitted organisms are *Salmonella*, *Pseudomonas*, and *Mycobacterium* [134]. It is thought that the ability of these organisms to form biofilms on the inner channel surfaces contributes to their ability to persist in spite of decontamination [135]. Transmission of *Klebsiella*, *Enterobacter*, *Serratia*, and hepatitis B and hepatitis C has also been reported [136]. The endoscopist should have a working knowledge of the process of scope cleaning and processing, and endoscopy units should employ vigorous infection control measures.

The Endoscopy Unit

Endoscope Processing

Recent endoscopy-associated outbreaks of multidrug resistant organisms have infected patients and even resulted in death. While these have been associated mostly with contaminated duodenoscopes, it has renewed the focus on endoscope processing and cleaning [137]. In fact, the infection rate of 1 infection per 1.8 million procedures reported by the ASGE in 1993 is now felt to be closer to 1 in 276,000 [138]. Lapses in instrument reprocessing are felt to be one of the main contributing factors.

The Centers for Disease Control and Prevention (CDC) recommends a multistep process for reprocessing scopes. Precleaning should take place immediately after the procedure to prevent biofilm; testing for any leaks in the device should also be done at this time. Manual cleaning with a high-level disinfectant should then be performed to remove any organic debris. This includes brushing and flushing of all ports and channels. A final visual inspection should be completed prior to the instrument being properly stored. This cleaning process is most often facilitated by use of an automated endoscope processor. Surveillance culturing to monitor endoscopes after reprocessing is recommended by a majority of organizations [139].

A recent cost analysis showed that reprocessing and repair costs per colonoscopy range from $101 at high-volume centers to $280 at low-volume centers. Factoring in new infection concerns, repair costs, and high per procedure costs, multiple organizations have begun exploring the finances of disposable flexible endoscopes [140].

Efficiency

Resource allocation and staff scheduling are incredibly complex burdens for every hospital and endoscopy center. Over-utilization and under-utilization both increase lost revenue, patient dissatisfaction, and staff burnout. Managing endoscopy suite efficiency continues to gain importance as health care resources continue to become more strained and limited. Many strategies for assessment of individual endoscopy units have been promoted, but the most important factor appears to be implementation of at least one strategy to increase efficiency of individual units [141].

Discrete event simulation (DES) is a process that was originally developed for the manufacturing industry but is now used by multiple health care centers to evaluate and improve efficiency. One endoscopy center reported utilizing DES to improve efficiency by running multiple software scenarios using patent data from five randomly chosen days and found that for maximum efficiency, they needed eight pre-procedure rooms and nine recovery rooms for their five-suite endoscopy center [142].

DES has also been used to demonstrate the negative financial consequences of "no-show" patients. Berg et al. reported that, for a 24-slot appointment day in an outpatient endoscopy suite, perfect attendance would result in a net gain of $4433.32, while a no-show rate of 18% would contribute to a daily loss of $725.42; the authors suggested implementing a practice of overbooking to offset costs of no-shows [143]. Another study simply added a nursing

phone call to the patient 7 days prior to the procedure, which was found to decrease the no-show rate from 16.5% to 12.8%, saving the institution $43,173 annually after costs were subtracted [144].

Overall endoscopy suite efficiency can also be hampered when other specialists are needed for the procedure, notably anesthesia. It has been shown that scheduling individual blocks for particular cases that require anesthesia increased efficiency over utilization of a standard block for a designated period of the day, in which anesthesia was only utilized as needed [145].

Quality Measures

With the increase in the number of annually performed colonoscopies in the United States and an ever-increasing focus on quality of care, metrics for ensuring the quality of screening colonoscopies has become a topic of increased interest. Ideal quality measurements should include a feasibly measured, clinically significant endpoint that is difficult to artificially manipulate [146]. Current quality measures for colonoscopy include cecal intubation rate, photodocumentation, screening intervals, bowel preparation quality, withdrawal time, and adenoma detection rate (ADR). The majority of data collected regarding colonoscopic quality has been focused on withdrawal time and ADR.

Withdrawal Time

The US Multi-Society Task Force (USMSTF) first recommended withdrawal time as a quality metric in 2002, using a benchmark of at least 6 minutes for screening colonoscopies not requiring biopsy or other maneuvers [147]. More recent studies have suggested that a withdrawal time of 9 minutes increases detection of both adenomas and serrated lesions [148].

The main disadvantage with the use of withdrawal time as a quality metric is that it can be easily manipulated. There can be pressure to artificially prolong the withdrawal time by a number of manipulations so as to not have a quality fallout. These include incorrectly noting the time of cecal intubation and initiation of withdrawal, repeated evaluation of the same section of colon multiple times, or simply "parking" the scope in the rectum until the desired withdrawal time has been documented. These maneuvers clearly do not increase the endpoint of adenoma or malignancy detection, yet on paper maintain an illusion of quality.

Adenoma Detection Rate

Adenoma detection rate (ADR) is the fraction of patients who are 50 years or older undergoing first-time primary screening colonoscopies and who have one or more adenomas detected. It is an excellent quality measure due to lack of confounding factors and ease of data collection. Further, it is a better measure of quality of the actual endoscopist, as patient compliance and pathological disagreements are not a substantial factor. Current ADR benchmarks are ≥30% for male patients, ≥20% for female patients, and ≥25% for a mixed male/female population [149].

The use of ADR as a quality measure provides optimal features when compared to other pathological detection rates. The use of malignancy detection rates as a quality measure negates the screening potential of the colonoscopy and is a much less commonly seen entity on which to collect data. The use of polyp detection rates, which includes all polyps, not just adenomas, can be manipulated by retrieving benign polyps such as hyperplastic polyps or other mucosal abnormalities that do not contribute to colorectal malignancy.

The use of ADR as a quality measure does have some drawbacks. Currently there are strict criteria limiting the data collection to patients over 50 and including only the first colonoscopy. Some argue that expanding the criteria to all screening colonoscopies, regardless of patient age, and including subsequent screening colonoscopies at 10 years would increase the data available to create a better metric.

The use of ADR as a quality measure also can create some incentive to only collect one polyp per colonoscopy and to rush through the remainder of colonoscopy after the first polyp is detected. This, combined with the fact that endoscopists are typically only reimbursed for one polypectomy per colonoscopy, may potentially disincentivize the endoscopist to closely examine the entire colon after the first polypectomy is performed [150]. These drawbacks have pushed some to evaluate the use of adenomas per colonoscopy (APC) as a quality measure. This measurement would reward careful examination of the entire colon and help to eliminate factors that promote the aforementioned "one-and-done" behavior [151].

Leasing vs Purchasing Endoscopy Equipment

Many surgeons and hospital administrators struggle with the decision regarding whether to purchase or lease medical equipment. It is a complex decision that involves credit, cash-on-hand, contraction negotiations, and many other additional factors in addition to the actual equipment and physician preferences.

Purchasing equipment has some advantages. Equity is maintained in the equipment and the value after depreciation belongs to the owner. Over the long term, this can potentially translate to cost-savings. Additionally, the concept of a "one-and-done" negotiation can be much more appealing to unit directors than the prospect of renegotiating contracts every few years. Once the final purchase price has been negotiated

and paid, the transaction is complete. However, a major drawback to this approach is that the cost of expensive repairs will eventually fall upon the endoscopy unit once warrantees expire.

Leasing endoscopic equipment has become an increasingly popular alternative to many physicians and hospital administrators. Leasing contracts can be constructed for variable time periods, allowing endoscopy units to replace older equipment with newer, up-to-date equipment more regularly. For endoscopists just entering practice or newer endoscopy facilities, leasing contracts can also be set up so that there are no payments (or minimal payments) for a set time period to allow cash flow to build up.

While leasing has the distinct disadvantage of not maintaining equity, other advantages can make it an attractive option. Most busy endoscopists cannot afford for their medical equipment to be sent out for repairs, which can be costly, take significant time, and result in lost revenue. Most leasing contracts will bring in replacement equipment while repairs are being made, and maintenance of endoscopy equipment is typically built into the lease and warranty. Even more importantly, with the ever-increasing pace of change in endoscopic technology, the endoscopist can ensure that they are regularly upgrading to the most up-to-date equipment.

Clearly, there are a multitude of factors to consider when making a decision regarding procurement of new equipment. Rapidly changing technology and financial risks should be at the forefront of the thought process. However, long-term financials may not be as clear cut when weighing the two options, as uncertain procedural volumes, varied compensation by third-party payors, warranty lengths, unpredictable costs of repairs, and tax write-off considerations make long-term costs difficult to discern.

Training and Simulation

How to safely and adequately train medical personnel in endoscopy has been a topic of debate for some time. There has been an abundance of literature focused on the training of gastroenterology fellows, but until recently there has been a paucity of studies addressing endoscopy training and surgical residents. When comparing first- and third-year gastroenterology fellows, it has been shown that competence improved throughout training, but an independent completion rate of 90% was not obtained until after 500 colonoscopies were performed [152]. This volume of colonoscopies would be quite burdensome for the average surgical resident. Additionally, making comparisons between gastroenterology and surgery trainees regarding procedural competency volumes can be somewhat misleading, due to underlying differences between baseline procedural comfort and dexterity across the trainees in both specialties.

While colonoscopy has long been a part of the practice of colon and rectal surgeons, according to the American Board of Surgery (ABS), endoscopy is now becoming a much more common procedure for the average general surgeon in practice. An increasing focus has been put on training both general surgery and colon and rectal surgery residents in becoming proficient at endoscopy. It should be obvious to those involved in resident training that performance of an arbitrary number of procedures alone does not translate to proficiency [153]. To improve resident training in endoscopy, the ABS has created a Flexible Endoscopy Curriculum (FEC). Beginning with the 2017–2018 graduating year, before becoming board eligible in General Surgery, graduating residents are required to complete the ABS FEC, which includes Fundamentals of Endoscopic Surgery (FES) certification. The FES program, developed by the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES), is a comprehensive educational and assessment tool designed to teach and evaluate the fundamental knowledge, clinical judgment, and technical skills required in the performance of basic GI endoscopy [154]. Similar in design to the Fundamentals in Laparoscopic Surgery (FLS) Curriculum, it consists of a multiple-choice question exam and a five-part manual skills exam using a Virtual Reality endoscopy platform (GI Mentor II).

The changes in requirements have stimulated residency programs around the country to reevaluate how they provide training in endoscopy. The Accreditation Council for Graduate Medical Education (ACGME) residency review committee's minimum case requirement for colonoscopy for General Surgery is 50, and for colon and rectal surgery is 140, of which 30 must be interventional. Again, it should be emphasized that achieving the minimum case numbers is not synonymous with achieving proficiency.

While the use of simulation may help to add familiarity and comfort with the endoscopic equipment and develop baseline dexterity skills, it will never be able to replace experience on an actual patient. Teaching endoscopy is a challenge for many surgical educators as they are used to being able to "assist" in the operating room and to physically aid a trainee through a difficult step or situation. Teaching in endoscopy does not lend itself well to this type of teaching. When difficulty is encountered or patient safety is threatened, the supervisor must often take over the procedure, resulting in a lost learning opportunity for the trainee.

To combat these difficult hurdles in training, many surgical training programs have created dedicated endoscopic training blocks, comprised of both simulation and clinical experience. A standard scale has also been developed to help with evaluator and training variability. This Global Assessment of Gastrointestinal Endoscopic Skills (GAGES) scale can be used to provide specific feedback to trainees and track their improvement and proficiency throughout the training process (Fig. 4.17) [155].

GAGES - COLONOSCOPY SCORESHEET

GLOBAL **A**SSESSMENT OF **G**ASTROINTESTINAL **E**NDOSCOPIC **S**KILLS

SCOPE NAVIGATION **SCORE** ☐

Reflects navigation of the GI tract using tip deflection, advancement/withdrawal and torque

5 Expertly able to manipulate the scope in the GI tract autonomously
4
3 Requires verbal guidance to completely navigate the lower GI tract
2
1 Not able to achieve goals despite detailed verbal guidance requiring takeover

USE OF STRATEGIES **SCORE** ☐

Examines use of patient positions, abdominal pressure, insufflation, suction and loop reduction to comfortably complete the procedure

5 Expert use of appropriate strategies for advancement of the scope while optimizing patient comfort
4
3 Use of some strategies appropriately, but requires moderate verbal guidance
2
1 Unable to utilize appropriate strategies for scope advancement despite verbal assistance

ABILITY TO KEEP A CLEAR ENDOSCOPIC FIELD **SCORE** ☐

Utilization of insuffilation, suction and/or irrigation to maximize muscosal evaluation

5 Used insufflation, suction, and irrigation optimally to maintain clear view of endoscopic field
4
3 Requires moderate prompting to maintain clear view
2
1 Inability to maintain view despite extensive verbal cues

INSTRUMENTATION (if applicable; leave blank if not applicable) **SCORE** ☐

Random biopsy: targeting is assessed by asking the endoscopist to take another biopsy from the identical site. Targeted instrumentation: evaluation is based on ability to direct the instrument to the target.

5 Expertly directs instrument to desired target
4
3 Requires some guidance and/or multiple attempts to direct instrument to target
2
1 Unable to direct instrument to target despite coaching

QUALITY OF EXAMINATION **SCORE** ☐

Reflects attention to patient comfort, efficiency. and completeness of mucosal evaluation

5 Expertly completes the exam efficiently and comfortably
4
3 Requires moderate assistance to accomplish a complete and comfortable exam
2
1 Could not perform a satisfactory exam despite verbal and manual assistance requiring takeover of the procedure

Fig. 4.17 Global Assessment of Gastrointestinal Endoscopic Skills scoresheet. (Reused with permission from Vassiliou et al. [155])

Summary

The ability to perform a complete and thorough endoscopic evaluation of the patient with colorectal complaints is essential. This should be considered an extension of the physical exam and not a separate entity. The knowledge, techniques, and skills required to perform an endoscopic examination safely and competently should be within the armamentarium of the colon and rectal surgeon, and surgeons should continue to be actively engaged in the testing, training, and advancement of endoscopic techniques and technology.

Key Concepts

- Endolumenal surgery is the forefront of minimally invasive surgery and is rapidly developing.
- Colon and rectal surgeons should be involved in the progression of endolumenal surgery as it will offer benefit to patients.
- New endolumenal techniques can be used to address large polyps that once required resection and treat malignant large bowel obstructions.

Introduction

Colonoscopy was initially described as a way to screen patients for mucosal abnormalities in the colon and has been adopted as the standard for colorectal cancer screening and prevention. However, when retrograde colonoscopy was first described in 1969, "there were some who said it couldn't be done, shortly followed by those who said it couldn't be done safely, followed by those who declared that it required a tricky skill which few would be able to acquire" [1]. Time has proved otherwise. Colonoscopic polypectomy has been demonstrated to decrease the incidence of colorectal cancer and has been widely adopted by the medical community [2]. With advances in technology, colonoscopy has progressed dramatically, and flexible colonoscopy is now used with various platforms that enable advanced endoscopic surgical procedures to be effectively completed. Endolumenal surgery is a rapidly progressive field in gastrointestinal surgery performed by both surgeons and gastroenterologists that offers the benefits of non-invasive surgery done in an outpatient setting. However, endolumenal surgeons are confronted with the challenge of operating through a flexible scope in a confined space that is frequently moving. Similar to opponents of early colonoscopy, there are many physicians in various stages of opposition. Due to the benefits to the patient, endoscopic surgery has the potential to be the next leap forward in minimally invasive surgery. This chapter will discuss the technical aspects of endolumenal surgery, ranging from forceps polypectomy to endoscopic submucosal dissection and colonic stenting.

Forceps

There are three commonly available options for forceps polypectomy: cold biopsy forceps, jumbo cold biopsy forceps, and hot biopsy forceps. For cold biopsy, the standard forceps open to 6 mm, and jumbo cold forceps open to 8.6 mm. Jumbo biopsy forceps have been shown to be superior to standard cold forceps for complete resection [3]. Historically, hot biopsy forceps were commonly used for polyp resection with the theoretical benefit of fulgurating any remaining dysplastic tissue around the polyp. However, this theoretical advantage has been refuted. A retrospective review of 62 hot biopsy polypectomies demonstrated a 17% rate of persistent polypoid tissue on repeat endoscopy 1–2 weeks after the original treatment [4].

Additionally, hot biopsy is associated with an increased risk of delayed hemorrhage compared to cold biopsy [5].

Furthermore, hot biopsy alters the polyp morphology and creates more histological architectural distortion and fragmentation than cold biopsy [6]. For the aforementioned reasons, the European Society of GI Endoscopy (ESGE) has recommended against the use of hot biopsy forceps [7].

Cold biopsy forceps have also been described as an adjunct to difficult to remove large spreading polyps. While these polyps are typically removed with snare (described below), some polyps will not allow snare resection as the snare will slide over the polyp. In these situations, cold forceps are used to methodically avulse all visible polypoid tissue. Following avulsion of the mucosa, the submucosa and margins can be treated with soft coagulation from the tip of a hot snare. This technique, deemed CAST for Cold-forceps Avulsion with adjuvant Snare-Tip soft coagulation, has been reported as an effective and safe strategy for the management of non-lifting large laterally spreading (LST) colonic lesions [8]. CAST is easy to use, does not require additional equipment, and is useful adjunctive technique for organ sparing.

Snare

Endoscopic snare allows resection of larger lesions and more tissue compared to forceps. Incomplete resection of polyps by any method is associated with interval development of colorectal cancer in patients undergoing colonoscopy [9]. In removal of polyps <6 mm, snare excision has a higher rate of complete resection compared to forceps removal (93% for cold snare vs. 76% for cold biopsy forceps, $p < 0.001$) [10].

Snares vary in size, shape, and ability for coagulation. Hot snares are the traditional method for endoscopic snaring but have waned in popularity over recent years due to complications including increased risk of delayed bleeding and thermal injury. Use of a cold snare without electrocautery is associated with lower rate of post-polypectomy hemorrhage and shorter time for polypectomy and colonoscopy [11, 12]. Complete resection rates with cold snare are equivalent to hot snare [13]. Dedicated cold snares have been further improved with use of a thinner wire that more easily cuts tissue. Compared to traditional snares used without cautery, dedicated thin-wire cold snares have a higher rate of complete resection, especially with polyps 8–10 mm in size or sessile polyps [14]. The 2017 guidelines from ESGE recommend cold snare polypectomy as the preferred method for polyps <5 mm in size and strongly favor cold snare polypectomy for polyps 6–9 mm in size [7]. Hot snare polypectomy has been reserved for sessile polyps 10–19 mm in size after submucosal injection has been used to decrease the risk of thermal injury. Hot snare is also recommended for pedunculated polyps to decrease the rate of bleeding.

Bleeding after polypectomy is infrequent but may result in hospitalization, repeat colonoscopy, and poor patient experience. The rate of bleeding after polypectomy is approximately 1–2 per 1000 patients and is 10 times the rate of bleeding compared to colonoscopy without polypectomy [15]. Bleeding after cold snare polypectomy tends to be immediate and can be addressed at the time of initial colonoscopy, while bleeding after hot snare is often delayed and not apparent at the initial colonoscopy. Bleeding after hot snare occurs 0.1–0.7% of polypectomies and can occur up to 30 days after the procedure [16]. Prophylactic clip placement after routine polypectomy does not decrease the risk of delayed bleeding [17], and this practice should be avoided as it drastically increases the cost of the procedure without substantial benefit. Selective use of endoscopic clips is discussed later in the chapter.

Tips for Optimal Snaring

Polypectomy is required in 30–40% of all colonoscopies. To make polypectomy easier, the polyp should be positioned at the bottom half of the screen because the instrument channel on the colonoscope exits the scope at the 5 o'clock position. Occasionally, the lesion cannot be placed in the inferior aspect of the screen due to tortuosity of the colon or location behind a prominent fold. In those situations, working with the scope tip further away from the lesion may facilitate polypectomy by producing a favorable angle of attack to the polyp. Additionally, jumbo forceps removal may be technically easier for polyps in a challenging location if the size is small. If a snare is applicable, lesions are more easily grasped with dedicated cold snares, since they have a thinner wire that can grip the tissue better than an electrocautery compatible snare. If a hot snare is used after a lift for a larger lesion, consideration should be given for use of a non-oval-shaped snare. Snares with some angulation, like a hexagonal snare, tend to grasp tissue better as well as have a greater proximal opening compared to standard oval or round snares. Figure 5.1 shows different type of snares.

Care should be taken during polypectomy to ensure that complete resection of the polyp has been performed. In a prospective study of over 1400 patients, there was a 10% rate of incomplete resection for polyps 5–20 mm. Risk factors for incomplete resection included larger size and sessile serrated polyps vs. adenoma [18]. Any remaining polyp tissue after snare polypectomy can be removed with repeat snare excision or cold forceps avulsion.

Lifting

Flat lesions may require submucosal lift to separate the desired tissue for resection from the underlying colonic muscular wall and decrease the risk of full-thickness mechanical

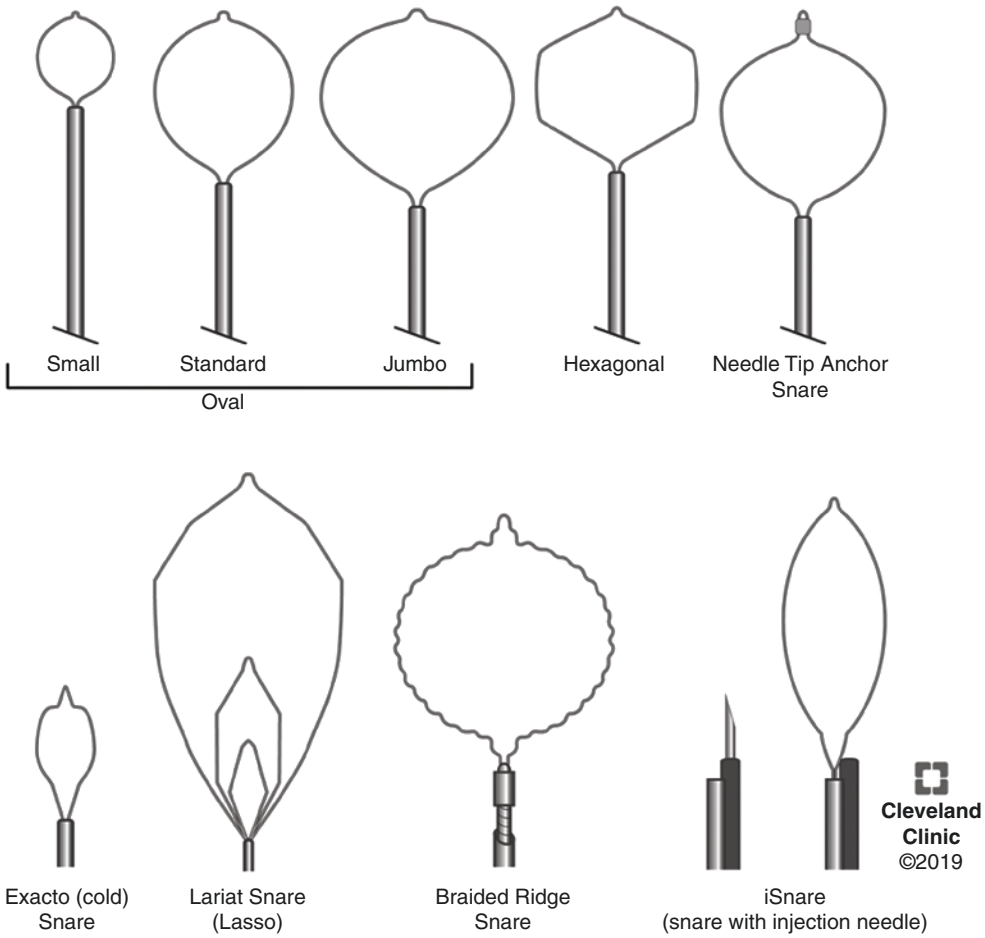

Fig. 5.1 Different types of snares (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography ©2020. All Rights Reserved)

disruption or thermal injury from a hot snare. Common submucosal lifting agents include saline, hyaluronic acid, glycerol, dilute albumin, and proprietary gels. For most polyps, submucosal saline injection suffices and provides a lift that lasts approximately 3 minutes [19]. Normal saline has proven equivalent to other lifting solutions in terms of complete resection rate, post-procedural bleeding, and post-polypectomy syndrome or perforation [20]. For more complex lesions requiring a longer resection time, a more durable solution is desirable. Viscous solutions are often more durable and provide a more localized lift with less lateral diffusion. Multiple solutions exist, ranging from hydroxyethyl starch (hetastarch) to more expensive proprietary solutions like Eleview® (Medtronic, Dublin, Ireland) and ORISE® (Boston Scientific, Marlborough, MA) that can last for over 40 minutes [21].

Adequate lift is critical to allow for advanced endoscopic techniques. Ideal injections are submucosal, but endoscopic injections can be easily misplaced in deeper layers (subserosal or intramuscular). Addition of colored dye to the injected solution can help delineate the submucosal layer as the overlying mucosa is thin and the color of the solution will be readily appreciated. Correctly placed submucosal injections tend to create more focal and taller lifts, while subserosal or intramuscular injections will create a less prominent and broader lift [22]. Submucosal injection can be facilitated by starting to inject solution prior to putting the needle into the mucosa so that the injectant will push away submucosal layers once penetrating the overlying mucosa. Alternatively, the needle can be placed into the colon wall and then gently withdrawn back into the submucosal layer. It is easier to create a lift when injecting in a tangential direction to the bowel wall and avoiding injecting perpendicular to the bowel wall. Techniques for submucosal injection are also applicable to endoscopic tattoo placement to avoid tattoo dispersing throughout the abdomen. If a larger area is needed to lift, injections should be directed at the border of the prior submucosal cushion to stay in the submucosal plane (Fig. 5.2).

Submucosal lift injections can be performed in a dynamic technique to make a taller lift. The needle placement in the submucosa is confirmed with a small amount of injection to demonstrate an adequate lift plane followed by a large-volume rapid injection. During the large-volume injection, the needle and scope can be re-directed within the submucosa to generate a tall and long-lasting lift [23]. For lesions that are on a fold, submucosal injection should start on the

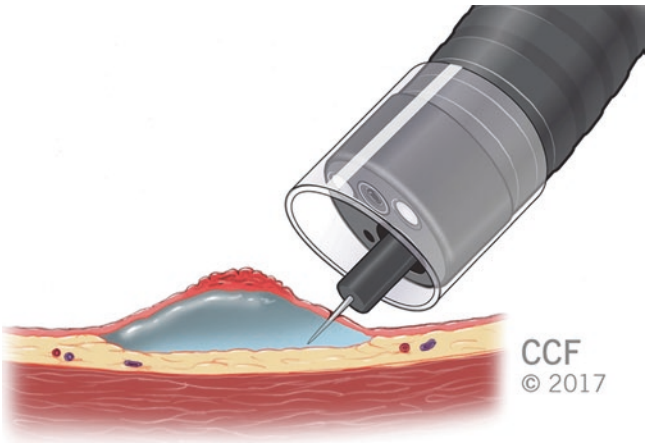

Fig. 5.2 To perform a submucosal injection, the injection needle should be tangential (parallel) to the mucosa. Fluid is injected as the needle is advanced to push away the muscularis and create and submucosal expansion to lift the overlying tissue (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography ©2020. All Rights Reserved)

proximal/oral part of the bowel to lift the lesion toward the scope. Lesions that do not lift may be due to entry into the incorrect plane, scarring from past attempts at injection or polypectomy, or related to more advanced lesions that have invaded into the submucosa.

Endoscopic Mucosal Resection

Lesions that are too large for simple polypectomy can be treated with endoscopic mucosal resection (EMR). EMR is regularly used for polyps ranging from 20 mm to 50 mm in size. EMR is a technique designed for sessile or flat lesions that are confined to the superficial layer of the colon wall. The most common EMR method is the lift and cut technique, in which the lesion is lifted with a submucosal injection followed by snare polypectomy. With expansion of the submucosal space, the polyp can be removed without injury to the muscular layer of the bowel. The goal is to completely remove the polyp with as few snare excisions as possible [7]. EMR is started with a submucosal injection to lift the lesion to create space for resection. Since lesions with EMR are often larger than simple polypectomy, a solution with a longer durability than saline is desired. The ESGE recommends the addition of a staining dye (e.g., methylene blue or indigo carmine) to the submucosal injection to help identify lesion margins and deep tissue injury. The submucosal lift protects the underlying muscularis propria while decreasing resistance in the desired resection plane. The lesion is then resected with snare in as few pieces as possible with care to make sure that the entire lesion is removed. A normal margin of 2–3 mm of healthy-appearing tissue should be included to ensure complete removal. To decrease the risk of leaving islands of polyp tissue, piecemeal snaring should be done sequentially with the snare aligned along the margin of the prior resection. If there are any small remaining amounts of polypoid tissue, these can be ablated with electrocautery or removed with forceps. Following resection, clips can be selectively placed for tissue approximation (Fig. 5.3). Hot snare is commonly used during EMR. However, cold snare has also been shown to be effective for piecemeal resection after submucosal lift for polyps up to 55 mm with a low rate of recurrent disease or complication [24].

The major drawback of EMR is that larger lesions cannot be excised in *en bloc* fashion. EMR has been shown to be safe and effective for lesions smaller than 20 mm [25]. Lesions greater than 2 cm are often excised in piecemeal fashion, which limits the pathologic assessment of the polyp. Piecemeal resection can theoretically allow small amounts of polypoid tissue to remain that would result in recurrent polyp growth. While early experience with EMR indicated recurrent polyp formation on follow-up colonoscopy in 30% of patients [26], a recent prospective multicenter trial of 1000 EMR procedures demonstrated a lower recurrence rate (17% overall). For smaller polyps (20 mm in size), recurrence rate was 5% [27]. Risk factors for recurrence were increased size (OR = 8.2 for polyp >40 mm vs. 20 mm), APC usage (OR = 2.4), and bleeding (OR = 1.6). APC usage likely results in superficial ablation of the polyp, but does not eradicate the polyp tissue. The lack of efficacy of APC has been confirmed with other studies evaluating APC versus avulsion for the treatment of small amounts of residual polyp tissue after EMR. Avulsion with hot biopsy forceps was associated with a significantly lower adenoma recurrence rate compared to ablation with APC (10% recurrence with avulsion vs. 59% recurrence with APC on follow-up colonoscopy in 1 study of 278 patients with EMR of colon lesion >2 cm) [28].

Clip

While routine use of prophylactic clips after polypectomy is discouraged due to cost, endoscopic clips can be used selectively to re-approximate mucosa after EMR or be placed on bleeding vessels in an effort to increase hemostasis. Risk factors for post-polypectomy bleeding include large polyp size, proximal location, use of anticoagulant or antiplatelet agents, and the presence of multiple comorbidities [29]. In a recent multicenter randomized control trial, endoscopic clip application to close the mucosal defects of polypectomies for non-pedunculated polyps larger than 20 mm was associated with a decreased rate of post-polypectomy bleeding [30]. The benefit of clip application was most pronounced in the proximal colon with an absolute risk reduction of 6.3% (9.6% bleed without clips vs. 3.3% bleed with clips, $p < 0.001$). Clip application for large polyps in the distal

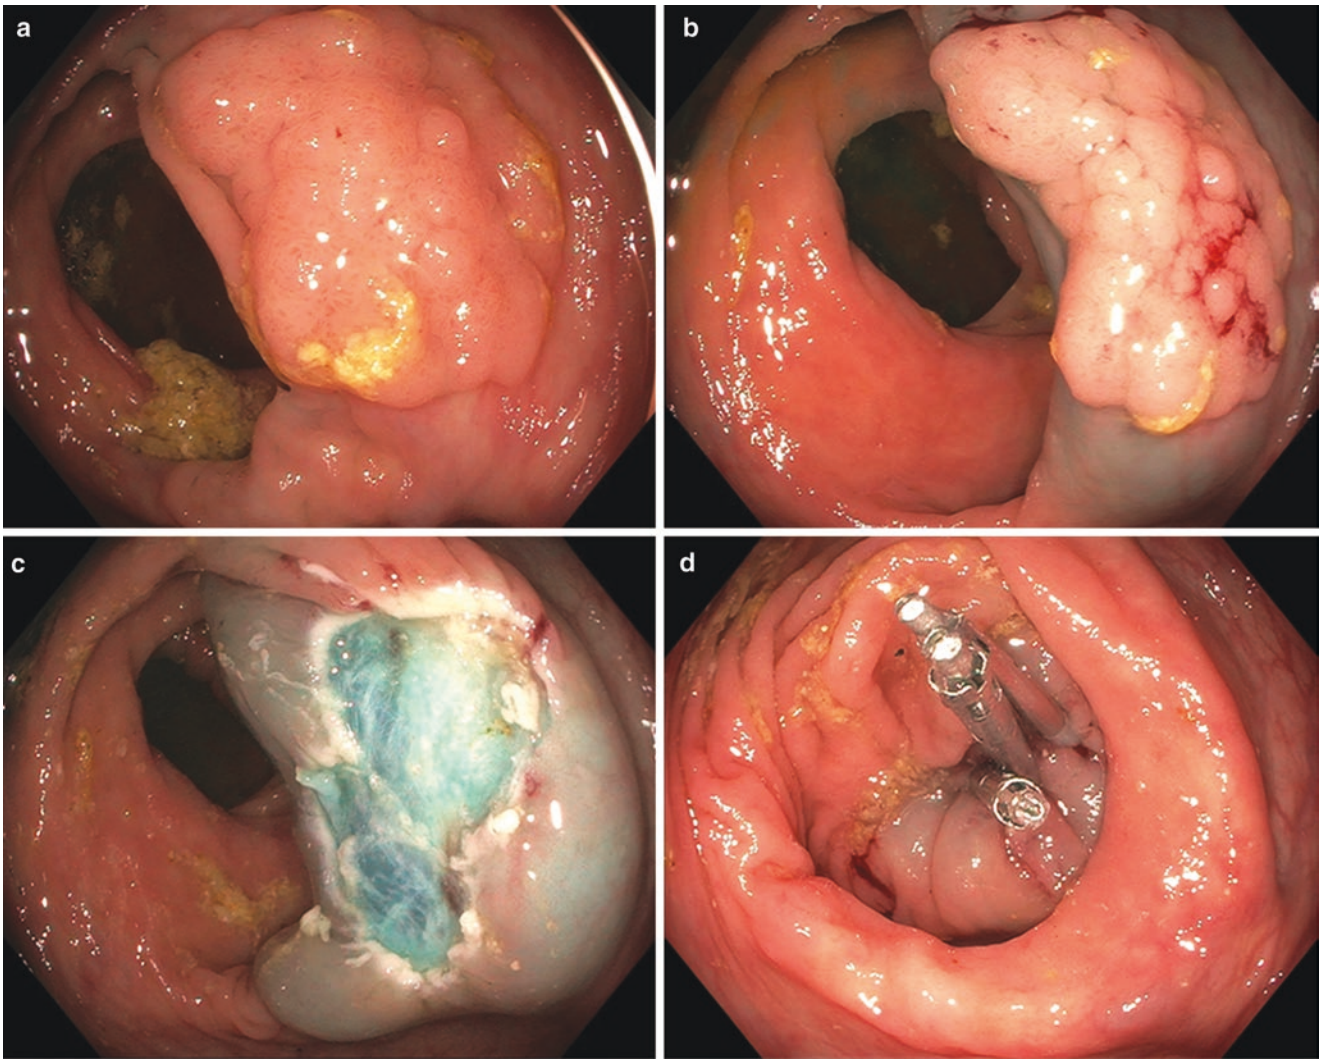

Fig. 5.3 EMR technique. (**a**) Large flat lesion in the right colon. (**b**) Lift with submucosal injection. (**c**) Piecemeal EMR resection with snare. (**d**) Endoscopic clip placement for closure

colon did not affect the rate of post-polypectomy bleeding. Application of clips has also been shown to decrease the rate of delayed bleeding even if complete mucosal re-approximation could not be accomplished [31]. Therefore, consideration should be given for selective use of clips following endoscopic resection of large polyps (>2 cm), particularly in the proximal colon.

Underwater EMR

Underwater EMR was described in 2012 as a method to avoid submucosal injection during resection of large polyps with EMR [32]. As described above, submucosal injection may be in the wrong layer leading to intramuscular injection. Furthermore, submucosal injection may make snare application more challenging as the snare may slip over the distended mucosa and not grasp the polyp. To perform underwater EMR, the air is evacuated and the lumen is filled with 500 mL to 1 L sterile water. The edges of the polyp are marked with APC. The polyp is removed in piecemeal fashion with a snare on cutting current to include all of the prior APC marks. Any small remnant tissue is treated hot biopsy coagulation. It is hypothesized that the water distends and flattens the colon to prevent the muscularis from being brought into the snare excision. When compared to traditional EMR, selective groups have demonstrated that underwater EMR allows increased complete macroscopic resection and decreased recurrence rates [33]. Additionally, underwater EMR has been used to increase rates of salvage endoscopic resection for recurrent polyps after past attempts at endoscopic resection [34].

Underwater techniques have also been applied to endoscopic submucosal dissection (ESD) [35]. Polyp resection while submerged in water can allow the edge of mucosa to float away from the submucosa and therefore improve the

endoscopic view of the dissection plane. Additionally, submerging the process of ESD in fluid allows greater heat dissipation, which theoretically decreases thermal injury. Potential benefits of underwater endoscopic resection must be balanced against the increased time requirement for water instillation.

Endoscopic Submucosal Dissection

Whereas EMR is limited in terms of size of en bloc excision, ESD is useful for larger lesions where complete histological evaluation is desired. ESD was first popularized in Japan in the 1990s for treatment of early gastric cancer. The gastric wall is thick and therefore allows for safe submucosal dissection with a margin for error. Colonic ESD was first described in the early 2000s [36]. The thin wall of the colon makes colonic ESD more challenging due to increased risk of full-thickness injury. However, the benefit of ESD is a more complete resection with lower recurrence rate. In a retrospective study of over 350 patients comparing colonic ESD and EMR, colonic ESD has a sevenfold lower recurrence rate. However, the complete resection of ESD comes at the cost of a nearly fivefold increased rate of perforation (6.2% ESD perforation vs. 1.3% EMR perforation) [37].

Colonic ESD allows resection of large benign lesions that traditionally required surgical resection. Dissection is performed in the submucosal layer under the lesion using a dedicated electrosurgical knife. Recent studies have shown that only 20% of polyps that were deemed endoscopically unresectable and referred to a surgeon for resection have invasive malignancy on final pathology [38, 39]. The rate of malignancy is even lower when carefully evaluating polyp morphology (see patient selection for ESD below). Large polyps that appeared benign to the endoscopist have less than 10% cancer rate [40]. This data suggests that the vast majority of patients with large benign-appearing colonic polyps can be treated adequately with endoscopic resection, saving these patients the morbidity of a larger colon resection. Comparing ESD to laparoscopic formal resection, patients treated with ESD had a significantly shorter hospital stay and decreased hospital financial cost [41]. Complication rates were similar, but the severity of complications was less in the patients treated with ESD compared to surgical resection.

ESD Complications

Prior to considering any intervention, one must be aware of the potential complications. Similar to most endoscopic polypectomy techniques, the most common complications after ESD are abdominal pain, bleeding, perforation, and tumor recurrence. Post-ESD electrocoagulation syndrome is similar to post-polypectomy syndrome and can be seen in up to 40% of patients [42]. Post-ESD bleeding occurs in approximately 2–7% of patients [43, 44]. ESD is also associated with a 5–20% perforation rate [45]. Risk of perforation is associated with increased tumor size and the presence of fibrosis. Perforation during ESD of lesions that are malignant can result in potential tumor seeding of the abdomen, as evidenced from the more robust gastric cancer literature. In a review of 22 perforations during gastric ESD, 2 patients (9%) had peritoneal seeding [46]. Lastly, endoscopic methods at resection carry the potential for recurrence. Local recurrence after ESD is remarkably low (approximately 1%) [43]. Furthermore, none of the recurrences contained invasive cancer and all were adequately managed with repeat endoscopic resection in this series.

Patient Selection for ESD

Careful selection of patients for attempted EMR and ESD is key. Procedural selection is based on the size of the tumor and the risk of underlying carcinoma. If the lesion is <2 cm, EMR is often favored. ESD is typically reserved for lesions >2 cm without features of malignancy. For patients where the diagnosis is unclear, ESD is an acceptable technique for excisional biopsy of lesions that have an increased risk of carcinoma but should be used with caution as the risk of full-thickness injury may be increased due to distortion of the submucosa from malignant invasion or fibrosis.

When doing a colonoscopy or preparing for ESD, the potential for underlying malignancy can be assessed by endoscopic characterization of the polyp appearance. Appearance of the lesion is critical and can be evaluated with one of several available classification systems, including Paris, Kudo pit pattern, or Narrow-band Imaging International Colorectal Endoscopic (NICE) classification. The gross morphology of the lesion is described by the Paris pattern, which divides lesions into polypoid vs. non-polypoid appearance. The non-polypoid superficial lesions are then divided based on their level of protrusion into the lumen (slightly elevated, flat, slightly depressed, and excavated). There is a clear inverse relationship between superficial lesion protrusion and the risk of submucosal invasion [47]. However, there is significant inter-observer variability in the classification of polyps according to the Paris system, suggesting that a simpler three-category classification of pedunculated, elevated, or depressed may be more widely applicable [48]. Depressed lesions have an increased rate of malignancy.

Pit patterns are based on the specific arrangement of glands in different lesions and can help determine hyperplastic vs. adenomatous vs. malignant lesions [49]. Narrow-band imaging (NBI) is commonly available technology that filters light into specific blue and green waveforms that will highlight vessels and mucosal tissue. NBI can be used to

	Type 1	Type 2	Type 3
Color	Same or lighter than background	Browner relative to background (verify color arises from vessels)	Brown to dark brown relative to background; sometimes patchy whiter areas
Vessels	None, or isolated lacy vessels coursing across the lesion	Brown vessels surrounding white structurs**	Has area(s) of disrupted or missing vessels
Surface Pattern	Dark or white spots of uniform size, or homogeneous absence of pattern	Ova, tubular or branched white structure surrounded by brown vessels**	Amorphous or absent surface pattern
Most likely pathology	**Hyperplastic**	**Adenoma*** **	**Deep submucosal invasive cancer**
Examples			

* Can be applied using colonoscopes with or without optical (zoom) magnification

** These structures (regular or irregular) may represent the pits and the epithelium of the crypt opening.

*** Type 2 consists of Vienna classification types 3,4 and superficial 5 (all adenomas with either low or high grade dysplasia, or with superficial submucosal carcinoma). The presence of high grade dyslasia or superficial submucosal carcinoma may be suggested by an irregular vessel or surface pattern, and is often associated with atypical morphology (e.g., depressed area).

Fig. 5.4 NICE classification. NICE, NBI International Colorectal Endoscopic; NBI narrow-band imaging (Reused with permission from Hayashi et al. [50]. Copyright © Elsevier 2013)

classify the polyp as hyperplastic, adenomatous, or malignant based on lesion color, vascular pattern, and surface pattern according to the NICE classification (Fig. 5.4) [50]. Accurate endoscopic assessment allows appropriate selection of polyps for EMR/ESD and avoidance of polyps that are better treated with resection due to concern for underlying malignancy.

The ability of the polyp to lift after submucosal injection has also been used to assess the potential for invasive malignancy. If tumor extends into the submucosa, the submucosa will not expand with injection. In a study of over 270 lesions, non-lifting sign had an overall accuracy of 95% for detecting an invasive malignancy, with a sensitivity of 62%, specificity of 98%, positive predictive value of 80%, and negative predictive value of 95% [51]. Furthermore, inadequate lift dramatically increases the likelihood of full-thickness injury as the submucosal layer is not expanded and there is consequently no buffer. Lesions may not lift well if there is fibrosis from prior attempts at resection or if the injection is too deep in the colon wall. The multiple reasons why a polyp will not adequately lift may explain why endoscopic assessment is more sensitive than the non-lifting sign for detecting invasion in flat or depressed lesions. Thus, in patients where the polyp does not lift well, there remains a role for ESD as long as the polyp has a benign morphologic appearance.

ESD Technique

Ideal polyps for ESD are polyps larger than 2 cm where invasion is not suspected. These are frequently laterally spreading tumors (LST) or polyps. For ESD, the mucosa is first marked outside of the edge of the lesion. This should be done with 2–3 mm normal mucosal margin. Although this step is not critical, it can be helpful for visualizing the borders. Submucosal injection should be performed outside of the coagulation marks so that there is a cushion under the endoscopic knife to decrease the risk of perforation. Once the lift is started, future injections should be directed at the edge of the prior lift to stay in the same plane and avoid the underlying muscularis propria. Once a submucosal lift has been established, the distal (anal) border of the mucosa around the lesion is incised in semicircular fashion with an endoscopic knife (Fig. 5.5). Complete circumferential incision will result in increased leak of submucosal fluid with greater difficulty of subsequent lift. After partial incision, further dissection proceeds tangential (parallel) to the submucosa to prevent injuring the colon wall by getting out of plane. Visualization is aided with a clear cap distal attachment to allow the endoscope to elevate the overlying mucosa and create traction. Additionally, positioning the patient in a manner that uses gravity to allow the polyp tissue to fall away from the colon wall will also improve exposure. Vessels are easily seen from the addition of a blue dye to the injection and are coagulated for hemostasis. As dissection continues, repeat submucosal injection is periodically used to expand the submucosa in front of the dissection.

Occasionally, a hybrid method with ESD and EMR can be useful and time efficient. ESD techniques are used to define the resection borders, perform the lift, and get the dissection started. Afterward, the remaining central dissection can be done with a large snare in an effort to save time. Hybrid ESD can be performed with similar en bloc resection rates and shorter procedural time [52]. However, the recurrence rate following hybrid ESD is higher than conventional ESD alone [53].

Following resection, routine colonoscopic review of the resection bed should be performed to look for any full-thickness defect or exposed vessels. Small defects can be closed with clips or endoscopic suturing techniques (below). Larger perforations can be closed with an over-the-scope clip. Over-the-scope clips involve pulling the defect into a specially designed cap and then releasing a large multi-pronged clip over the defect to approximate the edges. Exposed vessels can be treated with minimum coagulation to decrease the risk of bleeding. The lesion is then placed in a net for removal and stretched onto a board with pins for histology.

As would be expected of any new procedure, there is a learning curve with ESD. ESD has been pioneered out of Japan due to the high incidence of gastric cancer treated with gastric ESD. The infrequency of early gastric cancer in the Western hemisphere limits the training opportunity for ESD

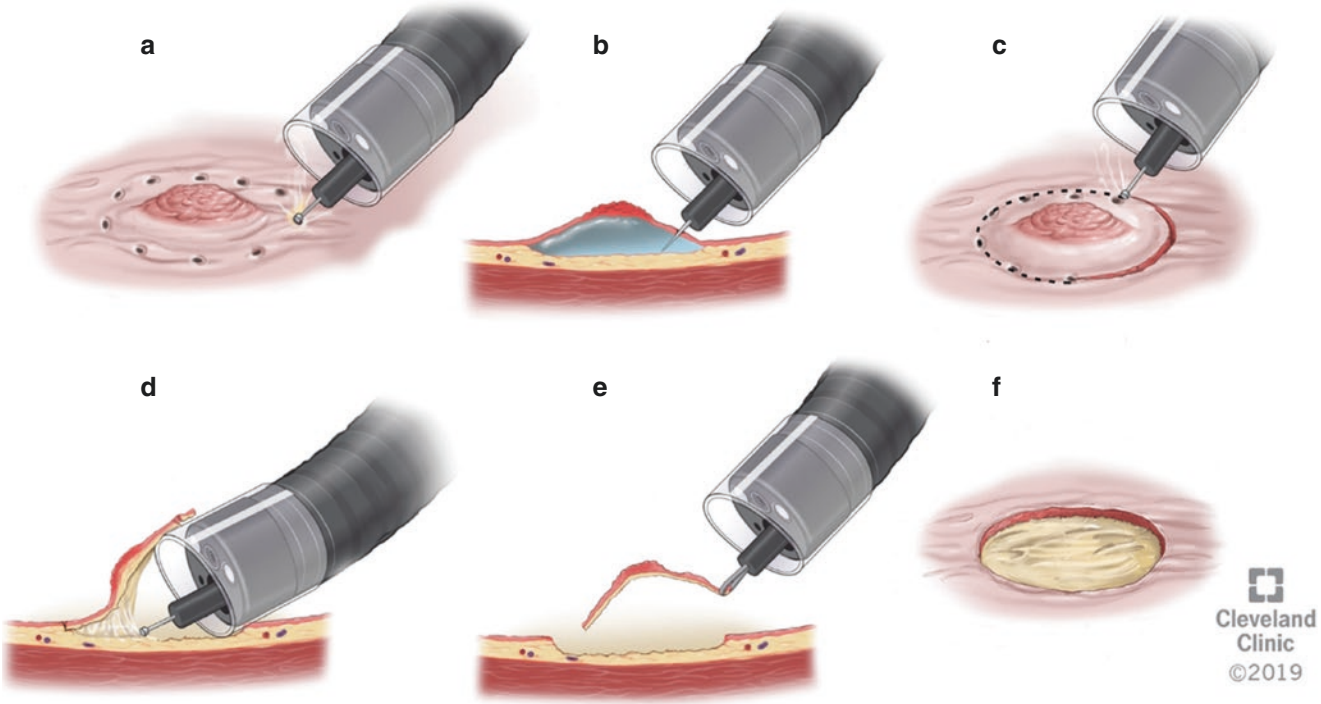

Fig. 5.5 ESD procedural steps (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography ©2020. All Rights Reserved). (**a**) 2-3 mm margin is marked followed by (**b**) submucosal injection. (**c**) Endoscopic knife dissection of the distal (anal) portion of the lesion. (**d**) Careful submucosal dissection with repeated submucosal injection as needed. (**e**) Removal of the polyp intact to allow complete pathologic analysis. Polyp can be pinned on a corkboard for orientation. (**f**) Final dissection. Vessels can be seen and coagulated. Selective closure is used

techniques. Basic skills can be achieved through practice on ex vivo models. When transitioning to patient care, rectal lesions are in a more forgiving location due to the presence of the mesorectum, which will cover inadvertent full-thickness injuries. Even in high-volume centers, endoscopists may require up to 30 supervised cases prior to achieving technical proficiency of colonic ESD [54]. Endoscopists should expect a continued learning curve that may take years to master. In a single-center experience of 200 colonic ESD procedures, the perforation rate decreased from 12% during the first 100 cases to 2% in the second 100 cases [55]. Additionally, the en bloc resection rate increased from 80% to 92% over the 200 cases. Prior to developing an ESD program, one should achieve familiarity with methods of endoscopic closure and hemostasis to develop an arsenal of tools that can alleviate common complications.

Postoperative Care

As with most colonoscopy, patients treated with EMR can go home the same day. Patients treated with ESD may benefit from overnight observation. There is no need for prophylactic antibiotics. Abdominal x-rays are frequently used after a difficult dissection to look for the presence of free air. No dietary restrictions are necessary afterward.

Controversies with ESD Versus EMR

Critics of ESD may argue that en bloc resection of large, endoscopically benign-appearing colonic lesions is unnecessary as the rate of malignancy is <10% and that those lesions can be adequately treated with EMR [40]. Whereas ESD often involves advanced training and greater technical proficiency, EMR techniques are readily available with no specific setup and minimal additional training. Even though EMR has a higher recurrence rate, recurrences are usually detected with follow-up surveillance endoscopy and can be treated with repeat endoscopic interventions [27]. The downside of EMR is the piecemeal excision, which can be detrimental in polyps with carcinoma. In comparison, ESD can be curative for superficial carcinomas that invade upper 1/3 of the submucosa or <1000 μm (Sm1), as these lesions carry a low rate of lymph node metastasis [56]. However, this is a narrow population window for treatment. In comparing ESD and EMR, patients treated with ESD had a similar or higher rate of requiring subsequent surgery as patients treated with EMR [57]. In a study of over 1100 patients treated with colorectal ESD, the prevalence of invasive cancer was 19% [58]. Half of those were Sm2 and required surgical resection. Therefore, only 10% of patients treated with ESD had the benefit of complete resection of a superficial malignancy and avoidance of surgery. However, most would agree that there are certain patients with high-risk tumors that would benefit from en bloc resection to allow complete histologic analysis and potentially avoid major surgery. As a result of this potential benefit, ESD techniques are likely to continue to progress.

Endoscopic Suturing

Closure of large defects after ESD or EMR is challenging with traditional clip placement. In 2006, an over-the-scope endoscopic suturing platform was developed (OverStitch®, Apollo Endosurgery Inc., Austin, TX). The device requires a dual-channel endoscope and employs an endoscopic grasper to hold the oral side of the mucosa to pass the suture. The suture is then passed through the distal (anal) side of the mucosa to close the defect. Partial-thickness or full-thickness bites with the suture can be done to close the defect. The suture can be used in interrupted fashion or run as one long suture for more advanced endoscopists. Once facile with the device, endoscopic suturing is a time-efficient way to close large defects and may prevent the need for overnight observation [59]. Endoscopic suturing has been also used to effectively close full-thickness defects without the need for trans-abdominal operative intervention [60].

Stabilization Platforms

Advanced endoscopy can be challenging due to the lumenal folds and intra-procedural motion of the colon. Multiple stabilization platforms have been developed in an effort to allow more complex endoscopic surgery.

The DiLumen® (Lumendi Ltd., London, UK) is a double-balloon platform that fits over any colonoscope. The device is advanced over the scope to the desired location. The after-balloon is inflated, and then the fore-balloon is advanced beyond the target and inflated to create a therapeutic zone that is flat and smooth. The fore-balloon can also be used to create counter traction during ESD by attaching two small circles with suture to the balloon and then clipping the edge of the polyp resection to the circles [61]. When the fore-balloon is advanced, the edge of the resected mucosa is elevated to provide traction.

The ORISE Tissue Retractor System® (Boston Scientific, Marlborough, MA, USA) platform combines a stabilization cage along with two working channels to pass additional angled graspers to create counter tension. The flexible system is advanced over any colonoscope with a current working length of 40 cm. The lesion is placed at the 6 o'clock position and cage is then expanded to create a stable platform for surgery. Special graspers can be advanced to grasp tissue

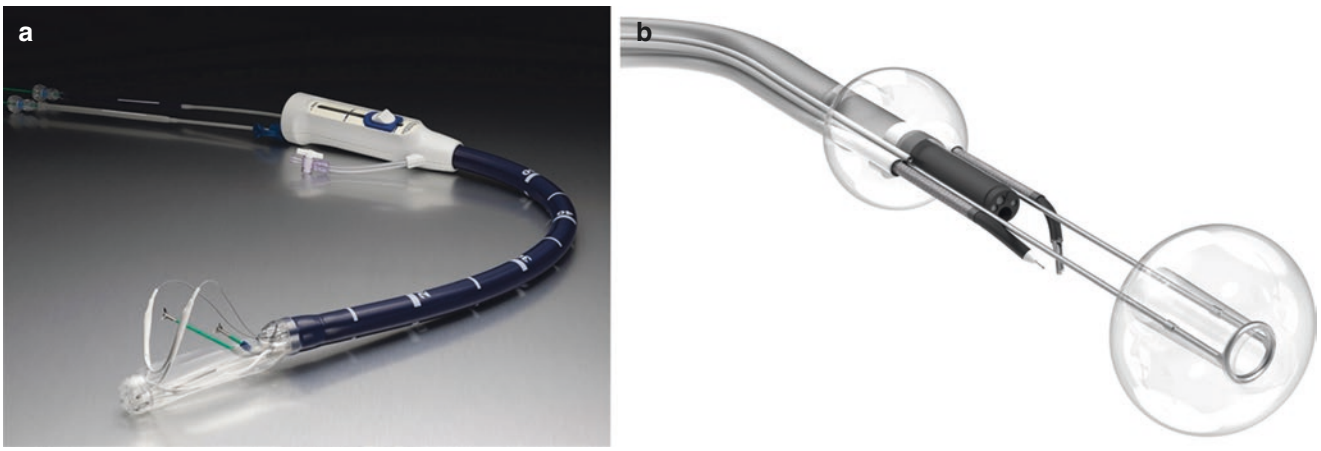

Fig. 5.6 Examples of endoscopic surgical platforms that create a therapeutic working zone with creation of counter traction to aid in dissection. (**a**) The ORISE TRS platform by Boston Scientific (Marlborough, MA) has a stabilization cage with two available retractors to provide counter tension. Image provided by Boston Scientific Corporation. (**b**) The DiLumen C2 platform by Lumendi (Westport, CT) has a fore and aft balloon to straighten and stabilize the colon with two available retractors to create tension (Reused with permission from Lumendi, LLC)

and then elevate the tissue to make dissection easier (Fig. 5.6) [62]. Endolumenal surgical platforms are rapidly progressing to simplify endoscopic resection techniques and allow resection of more complex lesions.

Approach to Referral for Unresectable Polyp

Surgeons are frequently referred large polyps that are considered endoscopically challenging for consideration for colectomy. Historically, colectomy was performed with only a 20% malignancy rate, suggesting that 80% of patients were over-treated with colectomy [38]. Patients often come with photos from their endoscopy, and it is a challenge to determine if the polyp will be endoscopically resectable.

Colored endoscopy photos and the pathology must be closely evaluated. If the photos are good quality, the lesion can be closely evaluated for ulceration, contour of the mucosal surface of the polyp, and vascular pattern. Similar to the above section on patient selection, features of malignancy should prompt colectomy instead of endoscopic attempts at resection. If the photographs are poor, repeat colonoscopy with attempts for ESD or EMR should be performed. If the colonoscopy is done in the operating room, a step-up approach of progressively more invasive techniques can be performmed. Resection can be attempted with endolumenal surgery and if unsuccessful, the patient can have combined endoscopic and laparoscopic surgery (CELS) or laparoscopic colectomy if warranted. The patient is consented for all three procedures prior to starting. The least invasive technique is attempted first followed by progressively more invasive techniques to remove the polyp. The benefit to the patient is that the polyp is removed at one sitting. The downfall of this approach relates to scheduling constraints. However, as one masters the ESD technique and preoperative assessment, selected cases can be easily scheduled in endoscopy units either with conscious sedation or monitored anesthesia care to avoid utilizing an operating room.

Colonic Stenting

Endolumenal advances have also been made in the treatment of large bowel obstruction. Historically, large bowel obstructions have been treated with abdominal surgery and formation of an ostomy due to dilation of the bowel, inability to prep, and emergent indication. Self-expanding metallic stents delivered endoscopically offer a minimally invasive solution to large bowel obstruction. Colonic self-expanding metal stents are uncovered to allow tissue ingrowth and prevent migration. Outcomes following stent placement have been controversial [63]. Colonic stenting is currently utilized in two situations: (1) a bridge to surgery in left-sided colonic obstructions and (2) palliation of malignant large bowel obstruction. There is no role for prophylactic stenting.

As a bridge to surgery in left-sided obstructions, stenting can avoid the need for stoma formation if the obstruction can be relieved and then colonic edema resolves to allow primary anastomosis. Patients treated with colonic stenting as a bridge to resection have a fivefold decreased likelihood of permanent stoma formation with a significant increase in primary anastomosis and decrease in wound infection rates [64]. However, stent placement does have complications, including perforation rate of 5%, migration rate of 4–10%, and repeat obstruction in 30% [65]. Due to stent related complications, two randomized controlled trials of colonic stents were closed early [66, 67]. Concerns about the oncologic safety of stenting as a bridge to surgery exist [68, 69]. The

only published guidelines on intraluminal colonic stents as a bridge to surgery are from the ESGE from 2014 and are based on meta-analyses showing increased rates of local recurrence without differences in overall survival [70]. These guidelines state that colonic stenting should not be the preferred method of treatment for left-sided obstructions in an otherwise healthy patient but could be considered in patients with a higher anesthetic risk (ASA ≥3 or age >70). At least two systematic reviews/meta-analyses published since then have concluded that the use of stenting as a bridge to surgery is oncologically safe with a similar 5-year survival, disease-free survival, and local recurrence rates as emergent surgery [71, 72]. Therefore, the use of stents in this setting is currently at the discretion of the individual surgeon based on experience and an assessment of the risks and benefits for a given patient's unique clinical presentation.

In the palliative setting, endoscopic stenting has been recommended by the ESGE as the preferred method of treatment [70]. According to a recent meta-analysis, stent placement for palliation has a similar mortality rate to emergent surgery with a shorter hospital stay and decreased stoma rate [73]. A separate study showed that long-term stent placement allowed 95% of patients to avoid stoma formation [74].

Prior to considering any colonic stenting, water-soluble contrast enema should be performed to evaluate the relevant anatomy. For obstructions, it is important to map out the location of the tumor, length of stenosis, and the lumen caliber. Alternatively, CT with rectal contrast can provide similar information while also demonstrating potential extrinsic causes and metastatic potential. If no contrast makes it across the lesion, stenting is less likely to be successful as it will be very challenging to pass a guidewire and increase risk of false passage of the guidewire resulting in potential perforation.

Based on personal experience, stenting colonic obstructions secondary to extrinsic causes (i.e., intra-abdominal metastatic disease resulting in colonic luminal narrowing or obstruction) is associated with an increased rate of migration and perforation, likely because the colon wall is not thickened and the mucosa is normal and does not allow stent ingrowth. Therefore, palliative stent placement is usually reserved for intrinsic obstructing lesions. Patients are counseled regarding the risks of stent placement. Either inability to place the stent or procedural complication is followed by emergent surgery with diverting colostomy formation [75].

Stenting Technique

Contrasted enema study is performed (either under fluoroscopy or in CT) to develop a roadmap. Fluoroscopy is used to guide placement. A guidewire is placed across the lesion. Confirmation of location can be done by exchanging the guidewire for a catheter to inject contrast and air to confirm intraluminal location. Haustrations should be seen with double-contrast injection. The appropriate size stent is selected, with favor given to the largest diameter and longest stent available. Shorter stents are chosen for rectal lesions to avoid stent placement within 5 cm of the anus, which may

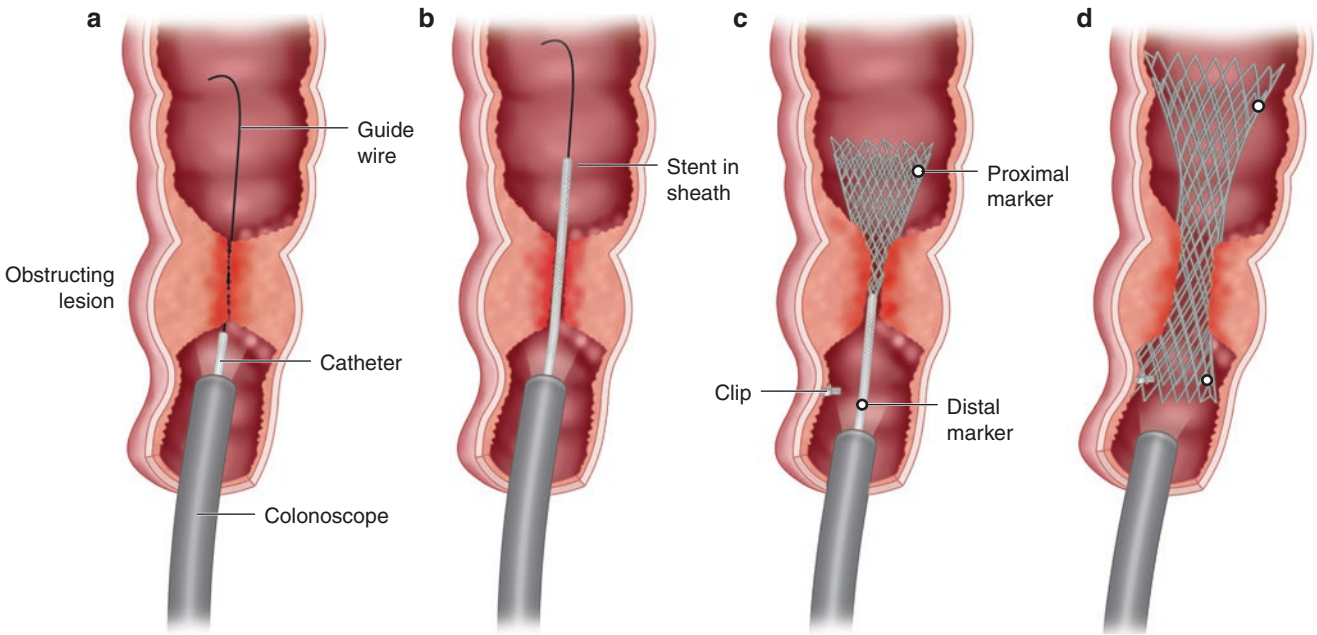

Fig. 5.7 Endoscopic stent placement of obstructing colon lesion. A guidewire is used to cross the lesion (**a**). Catheter can be advanced to instill contrast and air to confirm luminal location proximally. The sheathed stent is then advanced over the guidewire under fluoroscopy guidance (**b**). A clip can be placed 5 cm distal to the lesion to align with the distal marker on the stent, and then the sheath is withdrawn to deploy the stent under fluoroscopy (**c**). The stent will straddle the lesion and expand over the following 48 hours (**d**). Note that the clip and the distal marker are aligned

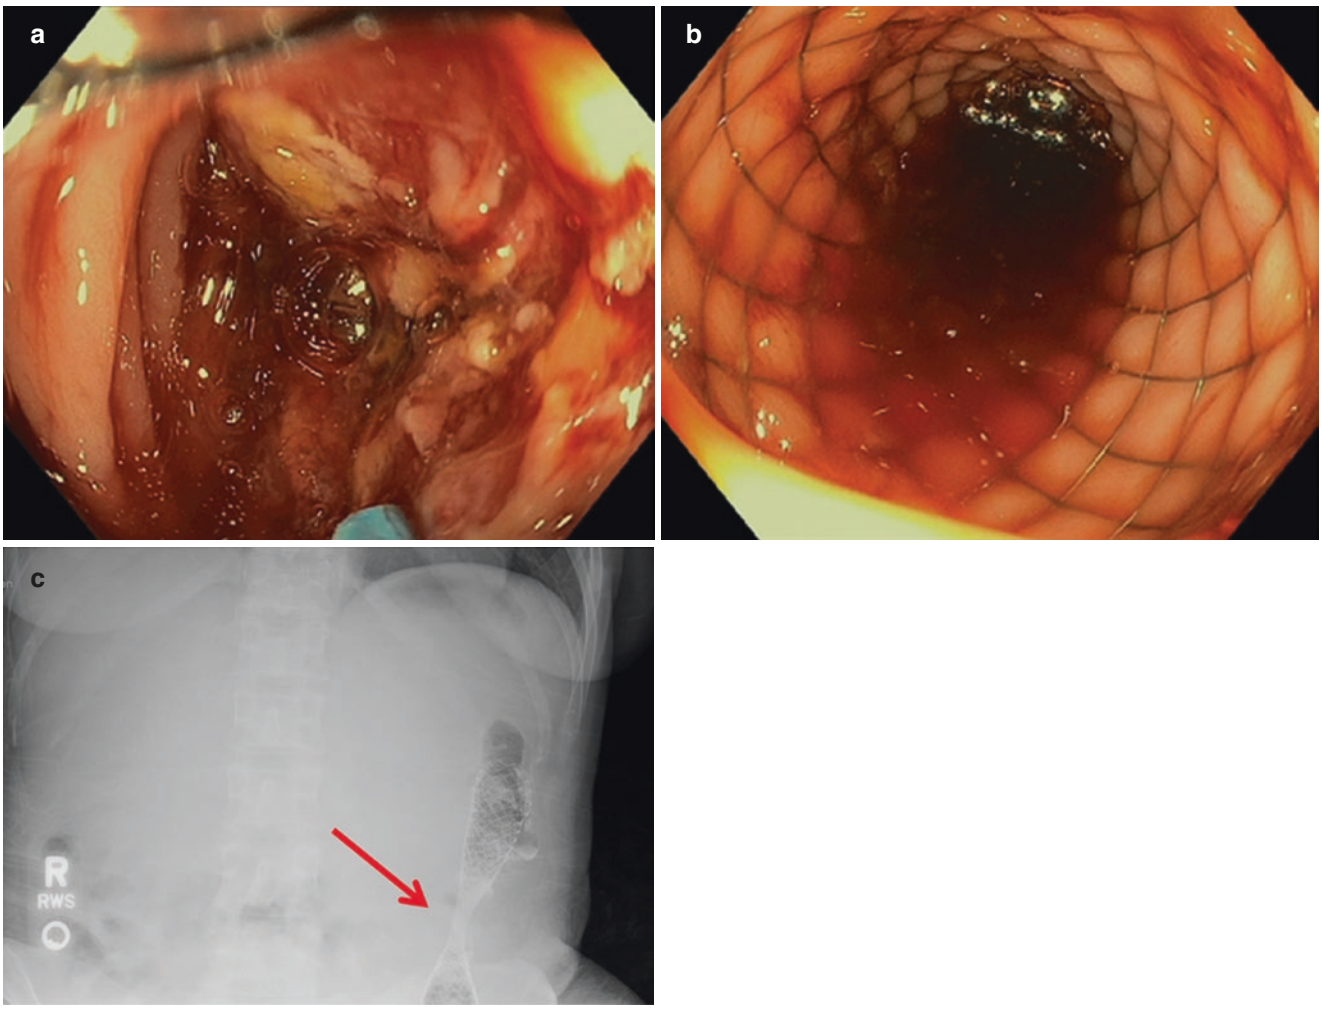

Fig. 5.8 Endoscopic stent placement. (**a**) The lumen in the obstructing mass is carefully selected and a guidewire is passed. Guidewire is exchanged for a catheter to inject contrast and air to confirm location. (**b**) Self-expanding metallic stent is then deployed. (**c**) Postoperative x-ray shows waist (red arrow) in the stent corresponding to the tumor location

result in significant tenesmus. The stent is passed under fluoroscopy guidance. A metallic clip can be placed 5 cm distal to the lesion as a radio-opaque marker for the landing zone of the distal aspect of the stent (Fig. 5.7)**.** Balloon dilation of the stent is not recommended. The scope is not passed through the stent after placement to avoid potential stent dislodgement. Abdominal x-rays are performed in recovery to confirm location and rule out obvious free air (Fig. 5.8)**.** Stent expansion will occur over the next 48 hours and the patient is monitored closely afterward for clinical result. Stool softeners are prescribed to help avoid fecal obstruction of the stent.

Stenting Anastomotic Leaks

Esophageal covered stents have been used in the colon and rectum to treat contained anastomotic leaks with case reports documenting success [76, 77]. The stent will block further extravasation of stool and may allow healing of the sinus. However, there is a high rate of stent migration, which may require stent replacement. In reported small cohort studies, covered stents are left in place without fecal diversion ranging from 20 to 50 days. Following removal, repeat water-soluble enema study is performed. Successful closure was seen in 80–100% of patients.

Conclusion

Endolumenal approaches to surgery are rapidly advancing and offer patients a minimally invasive approach that can result in a shorter hospital stay and more rapid return to normal activity with less morbidity. Surgeons are the ideal provider for endolumenal procedures. Patients can be stepped up from endolumenal surgery to CELS to formal resection based on the nature of the colonic lesions. Additionally, sur-

geons have a firm understanding of the anatomic constraints and the ability to repair potential complications. Although endolumenal surgery is considered challenging at present, it will likely continue to progress and gain more popularity over time with increased patient benefits. Advancing technology and flexible endorobotics will undoubtedly facilitate this evolution.

Preoperative Evaluation in Colorectal Patients

6

Ron G. Landmann and Todd D. Francone

Key Concepts

- Patients undergoing elective abdominal colorectal operations are in the "intermediate" risk group for perioperative morbidity and mortality.
- Recognition and optimization of concomitant patient pathophysiology are paramount in minimizing sepsis (anastomotic leak, surgical site infection), complications, and overall morbidity.
- These include cardiopulmonary, renal, metabolic, and endocrine physiology and other pathophysiologic risk factors and derangements (such as frailty and immunosuppression).
- Implementation of ACC/AHA guidelines and evidence-based medical management leads to improved efficiencies with minimization of extraneous testing and delays, while preserving low complication rates.
- Corticosteroids and immunosuppression remain significant determinants of morbidity in patients undergoing intestinal colorectal surgery.
- Prehabilitation of the frail and elderly patient is critical in optimizing patients for surgery while attempting to mitigate perioperative morbidity and mortality.

Evaluation of the Routine Colorectal Patients

In Office by Surgeon

A detailed history and physical examination are paramount to the evaluation and optimal management of a preoperative patient. A thorough review of the patient's chief complaint as well as associated signs and symptoms and confounding issues or factors is necessary to synthesize an appropriate diagnosis and perioperative plan. Careful attention to the patient's medical comorbidities and past surgical history, as well as review and reconciliation of the patient's medications, is relevant to help coordinate perioperative management and operative planning. In patients who require multidisciplinary care such as inflammatory bowel disease and rectal cancer, it is imperative to ascertain the other specialists' contact information for optimal coordination of care. Similarly, specialist communication should be coordinated for patients who have significant cardiopulmonary disease or other major medical comorbidities. Personal review of source documentation for pertinent pathology, endoscopy, and radiological findings is critical in establishing a diagnosis and individualized plan of care. In many cases, the above may require coordination among more than one physician and more than one healthcare organization to achieve optimal perioperative care and outcomes, while minimizing morbidity.

Abdominal Surgery

In preparation for patients undergoing abdominal surgery, the history should include a reconciliation of active medications, including blood thinners and over-the-counter drugs or topical agents. The history should include complementary or alternative medicine practices and substances, including various legal or illegal drug use. Personal and/or family history of clotting or bleeding disorders (or bleeding complications from prior surgery) should be obtained. Additionally, the surgeon should ask about activity level in order to estimate exercise capacity. Frailty or poor baseline exercise capacity has been shown to adversely correlate with increased risk of perioperative cardiac complications. Can the patient walk up a flight of stairs, do heavy housework, or walk up a hill? A "Yes" to these questions indicates that the patient can perform at least four METs (metabolic equivalents), and if oth-

erwise healthy, the patient does not need a preoperative cardiac workup [1]. Similarly, if patients are unable to get up from a chair and easily and briskly walk to the examination table, this is a surrogate marker for frailty and indicative of perioperative morbidity and need for preoperative optimization with prehabilitation (see "Frailty" below).

The history should also specifically investigate any prior operations that the patient may have had, including those requiring resection and particularly changes and/or alterations in mesenteric vascular anatomy. Knowing this a priori may help with decision-making including the need for preoperative imaging and staging as well as intraoperative assessment and surgical planning.

Anorectal Surgery

Due to the lower acuity and physiological demands placed on the patient during outpatient anorectal surgical procedures, most healthy patients generally do not require extensive preoperative workup. Patients with preexisting common comorbidities of hypertension, hyperlipidemia, or diabetes that are otherwise well controlled, as measured with normal physiological range of values, may not require an additional preoperative evaluation.

Preoperative Testing

Laboratory Studies

Multiple studies have demonstrated that routine preoperative labs have a low yield in identifying abnormalities that require a change in the management of otherwise healthy, asymptomatic patients. A selective approach to preoperative laboratory studies should be taken based on the evidence outlined in this section. A landmark retrospective study of 2000 patients undergoing elective surgery demonstrated that approximately 60% of all preoperative laboratory studies were not indicated and only 0.2% of these non-indicated tests (which occurred in ten patients) revealed abnormalities that could potentially result in a change in management [2]. Further analysis of these ten individual patient charts was performed and it was determined that no further actions were taken in any instance. When laboratory tests are indicated, results from the 3-month timeframe prior to surgery may be used, unless there has been a change in clinical status.

Hemoglobin is recommended for all patients of ages 65 or older who are undergoing abdominal surgery. Younger patients should be tested if there is potential for major blood loss, or if the history is suggestive of anemia. *White blood cell count* as a screening test is of limited utility but is certainly relevant in cases where recent infection has been treated or in the setting of immunosuppression. *Platelet counts* should be checked if the patient will undergo spinal or epidural anesthesia. *Coagulation studies and bleeding time* are not needed in patients with no personal or family history of bleeding disorders. Further, abnormal prothrombin time and bleeding time have not been shown in large studies to correlate with increased risk of intraoperative or postoperative bleeding complications [3, 4]. Pre-transfusion testing consisting of *ABO and Rh typing* ("type and screen") should be performed preoperatively in all patients undergoing major abdominal surgery, including bowel resection. This is particularly important for patients who have a significant transfusion history and who may have multiple alloantibodies.

Serum *creatinine* should be checked in patients 50 years or older, as elevated creatinine is an independent predictor of increased postoperative cardiac complications [5], as well as mortality [6] in elective noncardiac surgery. Further, some anesthetics require dose adjustments for patients with impaired renal function, so this information is vital to our anesthesia colleagues. Routine *electrolytes* are not required unless the patient has a history of prior electrolyte abnormalities, chronic kidney disease, or diuretic use. Routine blood **glucose** measurements are not indicated in nondiabetic patients, as the incidence of asymptomatic hyperglycemia is low [7]. The same logic also applies to *liver function tests*, which also should not be routinely ordered in a healthy, asymptomatic patient [4]. Routine *urinalysis* does not need to be performed in healthy, asymptomatic patients and should be only performed on a more selective basis in patients with history of frequent urinary tract infections or other relevant urinary symptoms. In most instances, asymptomatic patients with positive urinalyses may be treated empirically for urinary tract infection and may proceed with elective abdominal surgery as scheduled. Most studies of the utility of preoperative urinalysis are from the orthopedic surgery literature, and they do not demonstrate a correlation between preoperative positive urinalysis or bacteriuria and postoperative infectious complications [8]. *Pregnancy tests* should be performed on all women of childbearing age if the results would alter management [9]. While serum human chorionic gonadotropin (hCG) assays are the most sensitive in detecting very early pregnancy, most urine pregnancy tests are positive within a week of a missed period and can be processed quickly in the preoperative setting.

Electrocardiogram

Electrocardiograms (ECGs) are quick, noninvasive, and inexpensive; consequently, they are overutilized in the routine preoperative workup of most patients. In asymptomatic patients undergoing low-risk surgery, ECG is unlikely to identify abnormalities that result in a change in management. Further, the incidence of abnormal ECGs is very low in patients under 65 years old. According to the American College of Cardiology/American Heart Association (ACC/AHA) guidelines, preoperative ECG should be performed on patients with known heart disease, peripheral arterial dis-

ease, or cerebrovascular disease [10, 11]. Accordingly, implementation of these ACC/AHA guidelines in a preoperative clinic led to a reduction in exercise stress testing, lower hospital length of stay, increased beta-blocker therapy, and improved preoperative testing appropriateness while preserving a low cardiac complication rate [12].

Chest X-Ray

The American College of Physicians recommends obtaining chest X-ray (CXR) for patients with known cardiopulmonary disease, as well as all patients 50 years or older who require major abdominal surgery [13]. The American Heart Association also recommends CXR (posterior–anterior and lateral views) on obese patients with BMI ≥40 [14]. Despite these recommendations, CXR are low yield in identifying clinically significant abnormalities that necessitate or alter management [15].

Advanced Diagnostic Imaging

Depending on the underlying diagnosis, additional advanced diagnostic imaging may be either beneficial for operative planning or necessary for appropriate staging. In the setting of Crohn's disease, magnetic resonance enterography (MR enterography) is a valuable adjunct to evaluate the small and large intestine and determine if there is any other disease that may require attention intraoperatively. MR enterography has supplanted fluoroscopy or small bowel follow-through examinations. The benefit of MR enterography is its ability to provide objective functional assessment of motility as well as differentiation from active inflammatory disease vs. chronic fibrotic disease of the bowel wall, the former being more amenable to medical therapy and the latter often necessitating surgical intervention. Similarly, MRI of the pelvis is now the standard imaging modality for rectal cancer and is required for appropriate locoregional staging.

In the setting of colon or rectal cancer, CT of the chest, abdomen, and pelvis is recommended for appropriate distant metastatic disease evaluation. In addition, CT scan may benefit operative planning and determining if other organs are involved in the disease process and may require en-bloc resection (i.e., duodenum, pancreas, ureters) secondary to invasive T4 disease. Similarly, for diverticulitis, CT scanning may help with preoperative planning and adjacent structure inflammation. Furthermore, CT may be beneficial and is the preferred method in evaluation for abscess and fistula.

Cardiac Evaluation

Assessment of Cardiac Risk

Appropriate preoperative assessment is essential to identify patients who may be at increased risk. Further preoperative investigation and intervention will help minimize the potential for adverse perioperative cardiac events. In general, surgical risk groups are based on the type of surgery and defined as "low," "intermediate," and "high-risk," with 30-day cardiac event rates (MI and death) of <1%, 1–5%, and >5%, respectively [16]. The highest risk noncardiac procedures include vascular, thoracic, and transplant procedures [17]. All abdominal procedures involving the colon and rectum are included within the "intermediate" risk group (at a minimum) with perforated viscera classified as "high risk" (Table 6.1) [18]. Laparoscopic cases are treated similarly to open cases regarding cardiac risk. Patients presenting in the emergency setting should not be delayed for further cardiac workup such that the benefit of a detailed cardiac assessment is overshadowed by the risk of delaying care of an acute intra-abdominal pathology such as perforated viscus and sepsis.

Table 6.1 Surgical risk estimates according to the type of surgery or intervention [160]

Low risk: <1%	Intermediate risk: 1–5%	High risk: >5%
Superficial surgery	Intraperitoneal: splenectomy, hiatal hernia repair, cholecystectomy	Aortic and major vascular surgeries
Breast	Carotid symptomatic (CEA or CAS)	Open lower limb revascularization or amputation or thromboembolecomy
Dental	Peripheral arterial angioplasty	Duodeno-pancreatic surgery
Endocrine: thyroid	Endovascular aneurysm repair	Liver resection, bile duct injury
Eye	Head and neck injury	Esophagectomy
Reconstructive	Neurological or orthopedic: major (hip and spine injury)	Repair of perforated bowel
Carotid asymptomatic (CEA or CAS)	Urologic or gynecological: major	Adrenal resection
Gynecology: minor	Renal transplant	Total cystectomy
Orthopedic: minor (meniscectomy)	Intra-thoracic: non-major	Pneumonectomy
Urologic: minor (transurethral resection of the prostate)		Pulmonary or liver transplant

Initial Workup

The most common postoperative cardiac events include myocardial infarction, heart failure, arrhythmia, and cardiac arrest. The first step in determining whether a patient is at high risk is to obtain a detailed history and physical during the office consultation. Symptoms requiring further investi-

gation include but are not limited to palpitations, chest pain, syncope, dyspnea, and orthopnea. Not only is a history of cardiac disease important (including valvular or ischemic heart disease, cardiomyopathy, and arrhythmia), but also a history of diabetes, renal impairment, peripheral artery disease, and cerebrovascular disease can be extremely relevant in assessing risk due to their association with coronary artery disease [19]. Clinical cardiac risk factors include angina, prior MI, heart failure, stroke/transient ischemic attack (TIA), renal dysfunction, and Insulin-Dependent Diabetes Mellitus (IDDM). Additionally, exercise tolerance, ambulatory EKG changes, echocardiographic changes demonstrating prior MI, valvular disease or left ventricular diastolic dysfunction, and positive stress test have also been associated with increased risk of perioperative cardiac event [20].

Of specific importance is an assessment of a patient's functional capacity. It is estimated based on patient daily activity or measured with exercise testing. As a reference, 1 MET is an expended metabolic equivalent at rest, 4 METs are equivalent to climbing 2 flights of stairs, and 10 METs represent strenuous sports activities. Patients with greater than 4 METs do not require further cardiac workup, regardless of risk factors. Patients with less than 4 METs are considered to have poor functional capacity in which current guidelines recommend to undergo further cardiac evaluation and risk-benefit analysis (Table 6.2) [16, 21]. A recent study of 12,846 patients undergoing elective resection for colorectal malignancy demonstrated significantly lowered postoperative complications and mortality in patients who had preoperative leisure-time physical activity with MET ≥12 compared to those with an MET <12 (12.1% vs. 14.9%, $p = 0.006$ and 0.3% vs. 0.8%, $p = 0.009$, respectively). Indeed, this increased activity level also was significantly correlated with an increased disease-free and overall survival in these patients undergoing colorectal cancer surgery (62.8% vs. 55.7%, −< 0.0001 and 66.7% vs. 58.7%, $p < 0.0001$) [22]. There are several validated models that can be used by the clinician to predict the risk of peri-cardiac adverse events. The simplest of these models is the Revised Goldman Cardiac Risk Index (RCRI) (Table 6.3) [5]. Other user-friendly models including the American College of Surgeons National Surgical Quality Improvement Program (ACS–NSQIP) risk calculator require more input variables but will also provide procedure-specific quantification of other noncardiac risk factors [23].

Table 6.2 Cardiac risk metabolic equivalents are used to measure functional capacity and are often utilized for preoperative risk assessment in surgical candidates of all ages

Excellent (>7 METs)	Moderate (4–7 METs)	Poor (<4 METs)
Playing squash	Cycling	Vacuuming
Jogging – pace of 10 minutes/mile	Playing golf (no cart)	Activities of daily living
Scrubbing floors	Walking 4 mph	Walking 2 mph
Singles tennis match	Gardening	Writing

One MET = oxygen consumption of a 70 kg, 40-year-old at rest
Adapted from ACC/AHA guidelines

Table 6.3 Goldman Cardiac Risk Index is a tool used to estimate a patient's risk of perioperative cardiac complications [38]

	Points
History	
MI within 6 months	10
Age >70 years	5
Physical examination	
S3 or jugular vein depression	11
Significant aortic stenosis	3
Electrocardiogram	
Rhythm other than sinus or sinus rhythm with or without atrial premature complexes on last ECG	7
Five premature ventricular complexes/min any time before surgery	7
Other factors	
Poor general medical status	3
Intraperitoneal intrathoracic or aortic operation	3
Emergency operation	4
Total points	53

Probability of life-threatening complications based on risk index points

Class	**Points**	**None/minor complications (%)**	**Probability of life-threatening complications (%)**	**Cardiac death (%)**
I	0–5	99	0.7	0.2
II	6–12	93	5	2
III	13–25	86	11	2
IV	>26	22	22	56

Additional Testing

Further testing has been recommended for patients with a greater than 1% risk of perioperative death from cardiac disease as these patients are more likely to have a known history of recent myocardial infarction, unstable angina, heart failure, valvular disease, or arrhythmias [11]. These patients should be evaluated by their cardiologist. Additionally, anything less than 4 METs is considered poor functional capacity but is not strongly associated with worsened cardiac outcomes in abdominal surgery. Current guidelines recommend patients with poor functional capacity to undergo further cardiac evaluation and risk-benefit analysis [16, 21]. Figure 6.1 describes a generalized algorithm for determining the need for further workup in elective noncardiac colorectal surgery patients.

Further testing may include echocardiography, stress test (exercise or pharmacologic), 24-hour ambulatory monitoring, and cardiac catheterization. Patients undergoing medium risk surgery (i.e., abdominal surgery) without risk factors should be considered for an EKG evaluation per recent ACC/

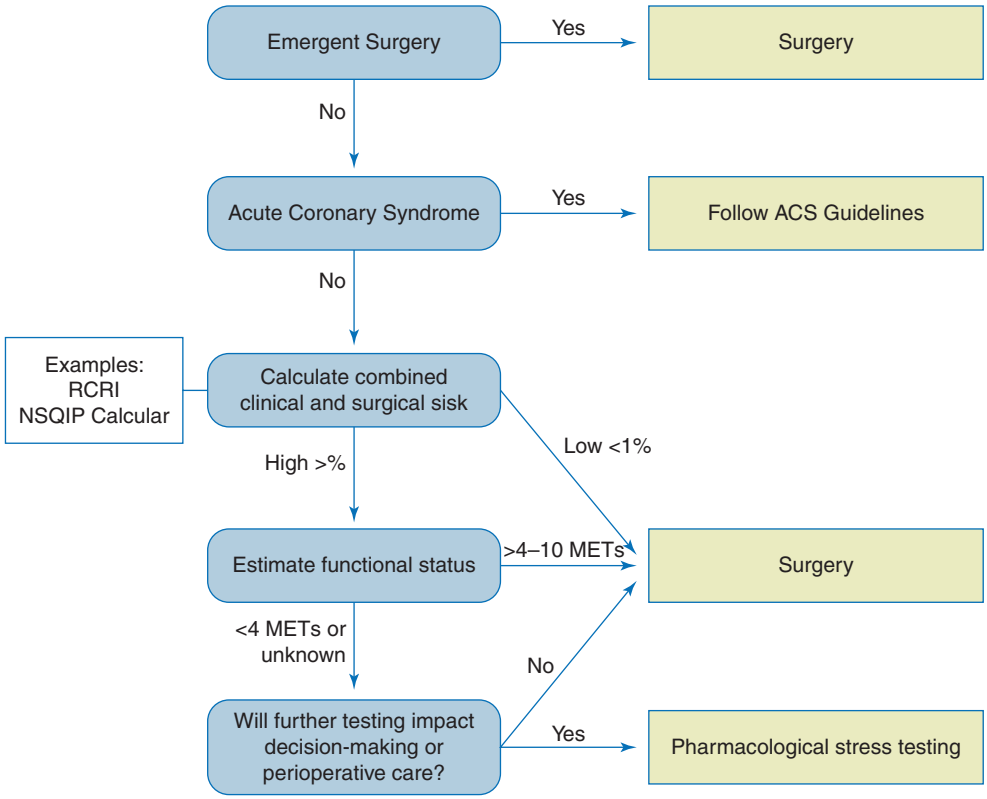

Fig. 6.1 Algorithm to determine the need for further cardiac workup in noncardiac patients undergoing colon and rectal surgeries

AHA guidelines. EKG is required for patients with presence of cardiac risk factors prior to any surgical intervention. Echocardiography is not required for patients free of cardiac symptoms but should be considered in patients undergoing high-risk surgery or who have cardiac risk factors [20, 21]. Image stress testing should be performed in patients with multiple risk factors undergoing medium-to-high risk surgery and poor or unknown functional capacity if it will change management.

Patients with unstable symptoms, a high-risk/abnormal stress test, concern for severe CAD (with or without left ventricle dysfunction), or those refractory to medical therapy, should undergo coronary angiography. Revascularization is indicated only when dictated by other guidelines; however, routine coronary revascularization should not be performed exclusively to reduce perioperative risks [11]. Interestingly, there is minimal evidence to suggest that preoperative revascularization reduces risk in non-cardiac surgery. Instead of cardiac catheterization, beta-blockade and statins pre- and perioperatively are strongly recommended [20].

Preoperative Optimization and Medical Therapy

The need for medical optimization prior to surgery is dictated by the findings of the cardiac evaluation. Patients on longstanding beta-blockers should be continued with their medical regimens. However, beta-blockers should not be initiated *de novo* in the preoperative setting. Multiple studies and meta-analyses have documented a significant increase in the risk of nonfatal stroke and myocardial ischemic events and hypertensive-related morbidity and mortality when beta-blockers are started within 24 hours prior to surgery [24, 25]. Antihypertension medications can be adjusted to avoid perioperative hypotension targeting a systolic blood pressure of 116–130 mmHg at a heart rate of 60–70 bpm. When diagnosed, new dysrhythmias can be controlled with antiarrhythmic agents. Decompensated heart failure increases perioperative risk and this risk may be mitigated by treatment with ACE inhibitors, aldosterone antagonist, and digoxin for at least 1 week preoperatively [26]. Patients may continue to take statins previously prescribed. Preoperative initiation of statins is reasonable in patients undergoing vascular surgery; however, there is no data to support starting statins preemptively in the setting of colorectal surgery [25].

Preoperative Anticoagulation

In recent years, several novel oral anticoagulants have become commercially available and are widely used in patients with atrial fibrillation or history of stroke in addition to placement of coronary or endovascular stents. Table 6.4 summarizes the more commonly seen anticoagulants and recommendations for perioperative management. For all patients taking anticoagulant therapy who are scheduled for a procedure, it is important to carefully review the medical history, medication list, and laboratory test results to identify

Table 6.4 Description and perioperative recommendations for common oral anticoagulant agents

Agent	Pathophysiology	When to interrupt	Temporary interruption recommendations (when to stop/restart)	Management of life-threatening bleed
Warfarin (Coumadin)	Vitamin K antagonist Inhibits the synthesis of vitamin K-dependent clotting factors II, VII, IX, and X as well as the anticoagulant proteins C and S Half-life of approximately 36–42 hours	*Do not interrupt therapy with VKA in patients undergoing procedures with:* No clinically important or low bleed risk; *AND* Absence of patient-related factor(s) that increase the risk of bleeding *Interrupt therapy with a VKA in:* Patients undergoing procedures with intermediate or high bleed risk, *OR* Patients undergoing procedures with uncertain bleed risk and the presence of patient-related factor(s) that increase the risk of bleeding *Consider interrupting a VKA on the basis of both clinical judgment and consultation with the proceduralist and the patient's physician*	When interrupting VKA therapy, the VKA should be stopped: 3–4 days prior to procedure (for INR 1.5–1.9) 5 days prior to procedure (for INR 2.0–3.0) At least 5 days prior to procedure (for INR >3.0) The INR should be re-checked within 24 hours before the procedure Most abdominal procedures are safe to operate with INR <1.4 Provided adequate hemostasis during surgery, warfarin can be restarted as early as 12–24 hours after surgery, although timing will depend on the indication for anticoagulation	For urgent surgery, warfarin can be reversed with vitamin K (2.5–5 mg oral or intravenous) For emergency surgery, warfarin can be rapidly reversed with fresh frozen plasma (FFP)
DOCA 1. Apixaban 2. Dabigatran 3. Edoxaban 4. Rivaroxaban	Factor Xa inhibitor anticoagulant agents Rapid onset of action (1–3 hours) Dose must be decreased for Cr ≥5, age >80 and body weight ≤50 kg Do not require bridging with parenteral anticoagulants No need for routine monitoring of anticoagulation (will prolong PT/PTT/INR)	Interrupt therapy for intermediate, high, or uncertain bleed-risk procedures in: Patients treated with any of the approved DOACs for a duration based on the estimated CrCI	*Duration for withholding is based upon the estimated DOAC half-life* Uncertain, intermediate, or high procedural bleeding risk: 4–5 during half-lives *High-risk procedures:* Typically STOP 3 days prior (Cr CI >50); RESUME 2–3 days postop (provided adequate hemostasis during surgery) *Low-risk procedures:* Typically STOP 2 days prior; RESUME 1 day postop (provided adequate hemostasis during procedure)	*Management of life-threatening bleed:* *Dabigatran* – idarucizumab 2 doses of 2.5 g IV no more than 15 minutes apart; activated charcoal, supportive care; consider 4-component PCC *Apixaban, Edoxaban, Rivaroxaban* – Andexanet alfa (AndexXa), activated charcoal, supportive care, consider 4-component PCC
Clopidrogel	Platelet receptor PY12 blocker Typical maintenance dose 75 mg or orally per day Typically used in patients with history of MI or stroke or coronary stent placement		If discontinued prior to surgery: 5–7 days prior to the procedure Start as soon as possible postoperatively	Platelet transfusion
Heparin (unfractionated)	Binds to and inactivates antithrombin III Half-life of 45 minutes Easier to use, faster to reverse Preferable in patients with renal insufficiency		In preparation for surgery Hold 6 hours prior to surgery	Protamine sulfate

Table 6.4 (continued)

Agent	Pathophysiology	When to interrupt	Temporary interruption recommendations (when to stop/restart)	Management of life-threatening bleed
Heparin (low molecular weight heparin)	Half-life of 3–5 hours Comparable efficacy to unfractionated heparin Administered via subcutaneous injection Does not require monitoring		In preparation for surgery Twice daily dosing – the evening dose should be held on the night prior to surgery Once daily dosing – half dose should be given on the morning of the surgery	Protamine sulfate

factors that may increase the risk for bleeding. Temporary interruption or the omission of more than one dose of an oral anticoagulant in preparation for a procedure is frequently necessary to mitigate the increased bleeding risk with surgical procedures. Based on the clinical history and the type of procedure to be performed, the risks and benefits of temporary interruption should be discussed with the patient and a collaborative discussion should occur between the patient's anticoagulation management team and the surgeon [11].

Two main categories of anticoagulation are utilized for nonvalvular atrial fibrillation. Coumadin remains the most widely used vitamin K antagonist (VKA). More recently, direct oral anticoagulants (DOAC) are being frequently utilized with certain advantages over VKA including rapid onset of action (1–3 hours) and unrequired routine monitoring of anticoagulation, and most of the time bridging is not required. Since the DOACs became clinically available, there has been concern regarding their use due to the lack of a specific reversal agent in case of major bleeding complications. Recently, significant progress has been made in this area, with the approval of the monoclonal antibody fragment idarucizumab for the reversal of dabigatran [27, 28] and the approval of andexanet Alfa for the reversal of apixaban, edoxaban, and rivaroxaban [29]. Table 6.4 summarizes the most recent recommendation from the American College of Cardiology (ACC) for management of anticoagulation in the nonvalvular heart disease patient [11, 28]. When considering these recommendations, the importance of collaborating with the patient's primary care physician or cardiologist cannot be understated, given the complexity of the decision-making. It is worth noting that there remains a boxed warning regarding the association of DOACs and the increased risk of spinal or epidural hematomas with neuroaxial anesthesia. Therefore, DOACs should not be routinely utilized for perioperative anticoagulation if an epidural or spinal anesthesia is planned [28].

Coronary Stent Management

The current recommendation for management of coronary stents in patients with either bare-metal stent or drug-eluting stent is to continue dual antiplatelet therapy (DAPT – aspirin plus an oral antiplatelet agent such as clopidrogel, prasurgel, and ticagrelor) for at least 12 months. The risk of stent thrombosis in the perioperative period for both BMS and DES is highest in the first 4–6 weeks after stent implantation. Discontinuation of DAPT, particularly in this early period, is a strong risk factor for stent thrombosis [30]. Should urgent or emergency noncardiac surgery be required, a decision to continue aspirin or DAPT should be individualized, with the risk weighed against the benefits of continuing therapy. For patients who need to undergo nonemergent noncardiac surgery, the recommendation is to wait at least 30 days for patients with bare-metal stents before discontinuing the anticoagulation therapy. For those patients with drug-eluting stents, it is recommended to continue anticoagulation for more than 6 months after placement of the stent; however, based on an individual case review, 3–6 months of therapy can be considered. During the time of discontinuing the antiplatelet therapy, it is recommended to continue low-dose aspirin and resume the P2Y12 inhibitors as soon as possible. These recommendations are based on data that quantifies the risk of postoperative coronary and cerebrovascular thrombotic events in this patient population (Table 6.4) [28].

In situations where patients with a drug-eluting stent require emergent abdominal surgery within 3 months of stent placement, alternative anticoagulant therapy should be considered. These patients can be safely bridged with IV infusions of short-acting antiplatelet agents such as tirofiban. Tirofiban can be started within 24 hours of the operation, discontinued 4 hours preoperatively, and restarted 2 hours postoperatively until clopidrogel is resumed. It should be emphasized that in these special situations, coordination of the bridging between clopidrogel and short-acting agents requires close coordination between the surgeon, cardiologist, and anesthesiologist. [28]

Bridging

Assessment of a patient's thrombotic and bleeding risk is essential to determine the need for bridging therapy while anticoagulation is being held. For the most part, bridging is used for VKA, given DOACs typically do not require bridging. Several risk scores have been proposed to broadly evalu-

Table 6.5 General recommendation on when to bridge and restart anticoagulation therapy after surgical procedures [28]

When to Bridge
Use of bridging parenteral heparin should only be considered in the following two scenarios:
VKA-treated patients at high risk of stroke or systemic embolism (>10% per year), including those with a CHA_2DS_2-VASc score of 7–9 or a recent (within 3 months) ischemic stroke
Determine the patient's bleed risk to determine the appropriateness of bridging therapy
If increased risk of bleeding, interruption of the VKA without bridging is recommended
If NO significant bleed risk:
(a) In patients with prior stroke, TIA, or SE, consider use of a parenteral anticoagulant for periprocedural bridging (use clinical judgment, likely bridge);
(b) In patients with no prior stroke, TIA, or SE, the use of a parenteral anticoagulant for periprocedural bridging is not advised (use clinical judgment, likely do not bridge)
Low Thrombotic Risk
(<5%/year), with a CHA_2DS_2-VASc score of <4 or/and
No prior history of ischemic stroke, TIA, or SE
Discontinue the VKA prior to the procedure and resume *without* bridging
Moderate Thrombotic Risk
(5–10%/year) with a CHA_2DS_2-VASc score of 5–6 or
History of prior ischemic stroke, TIA, or
Peripheral arterial embolism (3 months previously)
Parenteral bridging anticoagulation should be considered
High Thrombotic Risk
High risk of stroke or systemic embolism (>10% per year) with a CHA_2DS_2-VASc score of 7–9 or
Recent (within 3 months) ischemic stroke, TIA, or SE
Parenteral bridging anticoagulation should be considered
When to Restart
Restarting VAC therapy post-procedure
Before restarting oral anticoagulation therapy, ensure complete hemostasis
VKA therapy can usually be restarted within 24 hours and parenteral heparin bridging (if indicated) within 24–72 hours depending on post-procedure bleeding risk
Restarting DOAC therapy post-procedure
Establish that hemostasis has been achieved
Following procedures with low postprocedural bleed risk, it is reasonable to resume DOAC therapy at full dose on the day following the procedure
Following high postprocedural bleed risk procedures, it is reasonable to wait at least 48–72 hours before resuming DOAC therapy at full dose
DOAC dosing should reflect postprocedural renal function
Bridging therapeutic anticoagulation with a parenteral agent is generally not required

ate bleeding risk in patients with atrial fibrillation, the most widely used of which is the HAS-BLED score (Tables 6.5 and 6.6) [31]. It incorporates hypertension; renal or hepatic impairment; prior stroke, TIA, or systemic embolization (SE); history of a major bleed; a labile INR; and age >65 years. The tool is used to assess 1-year risk of major bleeding in patients taking anticoagulants with a score of ≥3 indicating "high risk." The CHA_2DS_2-VASc score can be used to assess an individual patient's overall thrombotic risk.

Table 6.6 The HAS-BLED score: Used to assess a patient's thrombotic and bleed risk which is essential to determine the need for bridging therapy

HAS-BLED parameters
Hypertension
Abnormal renal function
Abnormal liver function
Prior stroke
History of or predisposition to (anemia) major bleeding
Labile INR (VKA)
Elderly (>65 years)
Concomitant use of an antiplatelet agent or nonsteroidal anti-inflammatory drug
Alcohol or drug usage history (≥ drinks/week)
Additional items included in the periprocedural management algorithm
Prior bleed event within 3 months (including intracranial hemorrhage)
Quantitative or qualitative platelet abnormality
INR above the therapeutic range at the time of the procedure (VKA)
Bleed history from previous bridging
Bleed history with similar procedure

The score incorporates multiple factors including hypertension; renal or hepatic impairment; prior stroke, TIA, or systemic embolization (SE); history of a major bleed; a labile INR; and age >65 years [31]

Table 6.7 CHA_2DS_2-VASc score can be used to assess an individual patient's overall thrombotic risk

Risk factors			Stroke risk per year	
			Score	% Rate per year
C	Congestive heart failure	+1 Point	0	0
H	Hypertension	+1 Point	1	1.3
A_2	Age ≥75	+2 Point	2	2.2
D	Diabetes	+1 Point	3	3.2
S_2	Stroke/TIA history	+2 Point	4	4.0
V	Vascular disease	+1 Point	5	6.7
A	Age 65–74	+1 Point	6	9.8
S	Sex (female)	+1 Point	7	9.6
			8	6.7
			9	15.2

It incorporates the known thrombotic risk factors into a scoring system. As the thrombotic risk increases, the need for bridging becomes more apparent [32]

It incorporates heart failure, hypertension, age, diabetes, stroke, or transient ischemic attack (TIA), vascular disease, and female sex into a scoring system (Table 6.7). The need for bridging correlates directly with thrombotic risk but must be evaluated against the risk of bleeding complications [32, 33]. General recommendations and guidelines for bridging and restarting anticoagulation can be found in Table 6.4 and are in accordance to the America College of Cardiology consensus statement for perioperative management of anticoagulation [28].

Patients who have undergone cardiac valve replacement may have received mechanical or bioprosthetic valves. Mechanical valves require lifelong anticoagulation but are durable and the need for a second surgery is significantly less

than with bioprosthetic valves. Anticoagulation with mechanical valves is achieved using warfarin. Bioprosthetic valves do not require lifelong anticoagulation and thus are associated with fewer bleeding complications but they are less durable and associated with higher morbidity and mortality rates. Bioprostheses require anticoagulation for 3 months unless a transcatheter aortic valve replacement (TAVR) was performed in which aspirin and clopidrogel may be considered an alternative. After 3 months, patients with minimal thrombotic risk may be managed on aspirin alone with additional anticoagulation for higher risk patients. Concomitant low-dose aspirin is recommended for patients with mechanical valves and as sole thromboembolism prophylaxis for patients receiving aortic or mitral bioprosthetic valves [28].

Like coronary stents, the risk of thromboembolism in the first few months after mechanical valve or bioprosthetic valve repair is increased. Therefore, elective noncardiac surgery should be avoided if possible. Evidence-based guidelines exist; however, these decisions should be made in collaboration with the patient's cardiologist and or hematologist. In general, for minor procedures with the ability to easily control bleeding, interruption of warfarin may not be required. If a patient taking warfarin is to undergo a surgical procedure that requires interruption of anticoagulation, bridging therapy with heparin is indicated if the patient has a mechanical aortic valve and any risk of thromboembolism. The warfarin should be held for 5 days. Bridging of anticoagulation with low molecular weight heparin (LMWH) should begin 3–4 days preoperatively or when the INR is <2.0. The last dose should be given 24 hours prior to the operation and an INR should be obtained the day of surgery. Most abdominal surgeries can safely proceed with INR ≤1.4. LMWH or an unfractionated heparin drip should be held during the first 48 hours postoperatively or until hemostasis is assured, while continuing standard DVT prophylaxis. The warfarin should be restarted at the preoperative dose as soon as possible after the procedure when deemed safe by the surgical team. If possible, continue aspirin through the perioperative stay [34].

AICD/Management

Patients with automatic implantable cardioverter defibrillators (AICD) often have underlying ischemic heart disease which should not be overlooked during the preoperative assessment. It is critical for both the surgeon and the anesthesiologist to communicate with the patient's cardiologist and for the anesthesiologist to find out whether the patient is pacemaker-dependent versus independent. Some patients may have pacemaker-dependent atrial, ventricular, or both chambers paced 100% of the time. For these patients, the device may need to be reprogrammed intraoperatively. For those patients who are not pacemaker dependent, the anesthesiologist should place a magnet over the device which will prevent inappropriate delivery of shocks and trigger of arrhythmic events. All AICD patients should have an external defibrillator and transcutaneous pacer immediately available and the electroconductive pad affixed to the patient at the start of the case. In the emergent settings, in which a formal cardiology consult is not feasible, a 12-lead EKG can be used to determine pacemaker dependence. Of note, the AICD activity can be affected by monopolar cautery causing electromagnetic interference. This can result in delivery of a shock to the patient or inadequate or inappropriate pacing. Minimal use of monopolar cautery and preferential use of alternative devices such as bipolar or ultrasonic energy can help decrease the risk of electromagnetic interference [28, 35].

Pulmonary Assessment

Postoperative pulmonary complications contribute significantly to overall morbidity and mortality. Complications may include atelectasis, infection, including bronchitis and pneumonia, hypoxemia, exacerbation of underlying chronic obstructive pulmonary disease (COPD), asthma, or respiratory failure (mechanical ventilation for >48 hours after surgery or unplanned reintubation). The reported frequency of postoperative pulmonary complications in the literature varies from 2% to 70% with one study utilizing the NSQIP database demonstrating a 6% rate of pulmonary complications in 165,196 patients who underwent major abdominal surgery [36]. A more recent multicenter prospective observational study by Fernandez-Bustamante et al. evaluated postoperative pulmonary complications (PPC) in 7 US academic institutions. The study demonstrated that at least one PPC occurred in 401 patients (33.4%), the majority of which included patients requiring prolonged oxygen therapy by nasal cannula (n = 235; 19.6%) and atelectasis (n = 206; 17.1%). Patients with one or more PPCs had significantly increased early postoperative mortality, intensive care unit (ICU) admission, and ICU/hospital length of stay [37].

Preoperative optimization is the best way to minimize risk. Routine pulmonary function tests are NOT indicated for healthy patients prior to surgery. Clinical findings are more predictive of the risk of postoperative pulmonary complications than are spirometric results. These findings include decreased breath sounds, prolonged expiratory phase, rales, rhonchi, or wheezes. Tests generally should be reserved for patients who have dyspnea that remains unexplained after careful clinical evaluation or other high-risk factors. Risk factors for pulmonary complications can be grouped into patient-related and procedure-related risks. Chronic obstructive pulmonary disease (COPD) has been demonstrated to be the single most important risk factor for development of postoperative pulmonary failure. Up to 25% of elderly

patients with COPD have an operative pulmonary complication, with mortality approaching 7% [21]. Other patient-related risk factors include advanced age, American Society of Anesthesiologists class 2 or higher, functional dependence, elevated Goldman Cardiac Risk Index [38], and congestive heart failure. Interestingly, obesity is not a pertinent risk factor [21]. Procedure-related risk factors include aortic aneurysm repair, non-resective thoracic surgery, abdominal surgery, neurosurgery, emergency surgery, general anesthesia, head and neck surgery, vascular surgery, and prolonged surgery [13].

Patients with increased risk factors should be evaluated by their primary care physicians and/or pulmonologists if they see a specialist. Bronchodilators should be continued perioperatively. Glucocorticoid use must be balanced against potential increased risk for complications such as anastomotic leak. In patients with history of tobacco abuse, smoking cessation for more than 6–8 weeks is recommended [20]. If patients pursue smoking cessation, duration needs to be greater than 2 months; otherwise, risk of pulmonary complications is significantly increased. This includes patients who cut down before surgery, with relative risk of 6.7 for individuals undergoing major non-cardiac surgery [39].

Obstructive sleep apnea is one of the most common sleep disorders and is characterized by upper airway obstruction causing apneic episodes. It is important to recognize obstructive sleep apnea preoperatively as it is a risk factor for perioperative cardiopulmonary complications and can be associated with unplanned ICU admissions [40]. Patients undergoing major abdominal surgery should be screened and managed for obstructive sleep apnea, similar to those patients with high BMI and multiple comorbidities. Common symptoms of sleep apnea include loud snoring, daytime sleepiness, and witnessed apnea by a sleep partner; however, other symptoms may include morning headaches, poor concentration, altered mood, vivid or disturbing dreams, restless sleep, GERD, and nocturia. Screening tools are available such as the STOP-Bang questionnaire, in which patients with high scores may be referred to a pulmonologist for formal workup [41].

Perioperative Steroid Management

Colorectal surgeons will often encounter patients on chronic steroid therapy as it is a primary treatment for many conditions such as inflammatory bowel disease, rheumatologic disease, reactive airway disease, and immunosuppression for transplant recipients. Due to the increased physiological stress, patients on chronic steroid therapy are at risk for developing secondary adrenal insufficiency that may manifest as an adrenal crisis in the perioperative period. Signs and symptoms of adrenal crisis may include altered mental status/psychosis, abdominal pain, nausea/vomiting, weakness, and hypotension. In addition to suppression of the hypothalamic-pituitary-adrenal (HPA) axis, the potential adverse effects of perioperative glucocorticoids are numerous. Adverse effects can include impaired wound healing; increased atrophy and tearing of skin, superficial blood vessels, and other tissues; increased risk of fractures, gastrointestinal hemorrhage, ulcer; and increased postoperative infections such as anastomotic leak. The surgeon, in collaboration with anesthesiology, will need to consider whether the benefit of administering perioperative stress dose steroids to mitigate the risk for an adrenal crisis outweighs its potential risks [42].

The decision to administer supplemental exogenous stress glucocorticoids is not always straightforward and there is a lack of data regarding standard protocols. This is in part related to the lack of data demonstrating the dose or duration of exogenous steroids required to cause a dysfunction in the HPA access. Prednisone, 20 mg/day, or its equivalent for more than 3 weeks, has been cited as the most common dose causing suppression. The exact time course of recovery from HPA axis suppression may differ between individuals; however, most agree that suppression does not continue beyond 1 year after cessation of exogenous steroid therapy, except for patients receiving intraarticular glucocorticoid injections [42].

Several approaches to glucocorticoid dosing have been proposed. These protocols categorize patients into high-, intermediate-, and low- risk groups for HPA-axis suppression or stratify based on the anticipated surgical stress associated with a minor, moderate, or major surgery (Table 6.8). Of note, patients who have diagnosed secondary adrenal insufficiency, as demonstrated by the short-acting ACTH test, will require perioperative stress-dose steroids with dosing based on surgical stress risk. Hydrocortisone is the drug of choice for acute stress and rescue-dose steroid coverage [42].

Recent data suggest that stress-dose steroids may not be necessary [43]. Instead, these patients may be maintained on their usual preoperative dose and treated with rescue dose steroids only if refractory hypotension presents in the perioperative period. In 2012, a retrospective cohort study of patients with inflammatory bowel disease undergoing surgery demonstrated that patients who received only low-dose perioperative steroids (the equivalent of their preoperative dose given intravenously) did not require vasopressors for hemodynamic instability or additional steroids for adrenal insufficiency [44]. Similarly, in a randomized trial of patients undergoing major colorectal surgery, no differences in postural hypotension or adrenal insufficiency were seen between those receiving high-dose glucocorticoids (hydrocortisone 100 mg intravenously three times daily) or low-dose glucocorticoids (the equivalent of their preoperative dose given intravenously) [45]. Although this data is promising, perioperative stress-dose steroid administration appears to carry minimal risk compared to the risk of adrenal crisis. Hence, patients who are at risk for HPA-axis suppression should be considered for steroid replacement therapy in the perioperative setting [42].

Diabetes

Diabetic patients represent a complex subset of surgical patients, who often have long-term complications of their

Table 6.8 Several approaches to glucocorticoid dosing have been proposed which categorize patients into high-, intermediate-, and low- risk groups for HPA-axis suppression or the anticipated surgical stress associated with a minor, moderate, or major surgery [42]

Surgery type	Examples	Recommendations
Superficial	Dental surgery Biopsy	Usual daily dose
Minor	Inguinal hernia repair Colonoscopy Anorectal surgery Uterine curettage Hand surgery	Daily dose plus hydrocortisone (25 mg IV)
Moderate	Lower extremity revascularization Total joint replacement Cholecystectomy Colon resection Abdominal hysterectomy	Daily dose plus hydrocortisone (50–75 mg IV; taper 1–2 days)
Major	Esophagectomy Total proctocolectomy Major cardiac/vascular procedures Hepaticojejunostomy Trauma	Daily dose plus hydrocortisone (100–150 mg IV; taper 1–2 days)
Risk for HPAA Suppression		**Recommendations**
Low	Treated with any dose of glucocorticoid for less than 3 weeks Morning doses of prednisone 5 mg/day or less Prednisone 10 mg/day every other day	Perioperative stress-dose steroids are not required unless they exhibit signs of HPAA suppression
High	Patients who have been treated with a glucocorticoid in doses equivalent to at least 20 mg/day of prednisone for more than 3 weeks or who have clinical features of Cushing syndrome	Patients would benefit from perioperative stress-dose steroids with dosing based on surgical stress

disease (neuropathy, visual impairment, peripheral, and mesenteric vascular disease), as well as other related comorbidities, such as chronic renal insufficiency and cardiovascular disease [5, 46] that can significantly impair perioperative outcomes. The initial office consultation with the surgeon should include a detailed history, focusing on the type and duration of diabetes, symptoms, how glucose is monitored at home, baseline glucose range, glycated hemoglobin (Hgb A1c) levels, related symptoms, as well as the contact information of their primary care physician and/or endocrinologist. Diabetic patients undergoing major abdominal surgery should have the following as part of their preoperative workup: ECG, CXR, serum creatinine, serum glucose, and an A1c level (within 4–6 weeks preoperatively). In particular, elevated A1c levels have been shown in cardiac surgery to be associated with increased risk of surgical complications, including infections, myocardial infarction, and death [47]. Close perioperative involvement of the anesthesiologist is also critical, as some patients undergoing major operations will require preoperative intravenous insulin infusion to attain euglycemia prior to initiation of surgery [48]. Additionally, these same patients may require insulin administration intraoperatively. The surgeon should be cognizant that most operations cause a catabolic state with elevated blood sugars. These elevated glycemic levels may be significantly more pronounced in a preexisting diabetic patient and necessitate attention postoperatively. All diabetic patients should be maintained on a postoperative insulin sliding scale regimen, in addition to their home medications. Perioperative elevated blood sugars are concerning as they may lead to perioperative wound infections and anastomotic dehiscence. Due to the cardiac complication rates, as well as increased incidence of septic sequelae, many centers will postpone operations in patients with elevated Hgb A1c levels >6.5 until improved blood sugar control can be achieved [49, 50].

Obesity

More than one-thirds of adults in the USA are obese, which is defined as having body-mass index (BMI) of 30 kg/m^2 or more. One in 20 adults is considered super-obese (BMI of 40 kg/m^2 or more) [51]. BMI is considered a screening tool to identify obesity and is calculated as the patient's weight (in kilograms) divided by square of the height (in meters). The obese patient creates substantial technical challenges for the surgeon. In terms of postoperative morbidity, obese patients undergoing nonbariatric abdominal surgery have been shown to have increased risk of perioperative venous thromboembolism and superficial site infection. A prospective study of over 6000 patients found that the risk of superficial site infection after open abdominal surgery was 4% for obese versus 3% for nonobese patients, $P = 0.03$ [52]. Other studies based on ACS-NSQIP data demonstrated incremental odds of surgical site infection with progressive classes of obesity, as well as increased wound disruption, sepsis, respiratory or renal complication, and urinary tract infection [53]. Studies have demonstrated increased thromboembolism, superficial site infection rates, and inability to create pouches or anastomoses to the lower rectum or anus in obese population [53–56]. Obesity also significantly increases operative time in colorectal procedures [55, 56]. Most importantly, obesity has been demonstrated to increase anastomotic (pouch-anal) leak rate [56].

Obese patients pose significant intraoperative challenges, some of which can be mitigated with appropriate preoperative planning. Much of the difficulty in operating on patients with obesity is due to the visceral adiposity and bulky mesentery, leading to difficult intraabdominal and pelvic exposure as well as manipulation and reach of the visceral contents [56]. For example, if a stoma may be needed, a visit

from the enterostomal therapist is extremely important, as marking on the slightly thinner upper abdomen will be helpful. It is especially important to ensure that these patients can reach their stoma, so they can care for it independently. Both laparoscopic and open surgeries are technically demanding in obese patients; however, if feasible, performance of laparoscopic surgery has the advantage of smaller incisions, less pain, and improved visualization for the surgeon. Avoiding lower midline and Pfannenstiel incisions is helpful in minimizing superficial site infections and other wound-related complications in obese patients with a large pannus. Clear communication with the operating room staff prior to the case is essential to ensure availability of long instruments, deep retractors, appropriate beds, and equipment such as blood pressure cuffs and large pneumatic compression boots. Due to the increased risk associated with operative outcomes in patients with obesity, many have advocated for weight loss preoperatively, and in some cases recommended bariatric surgery, to promote optimal outcomes [57, 58].

As will be discussed later, obesity itself does not predispose a patient from being malnourished. Indeed, the opposite can be quite true, and many patients with obesity demonstrate protein calorie malnutrition and sarcopenia, as demonstrated by low albumin and prealbumin levels as well as muscle wasting on cross-sectional imaging [59, 60]. Methods to reduce visceral and systemic adiposity while improving protein stores preoperatively are imperative to improve operative and postoperative outcomes [61]. Options include very low calorie diets, pharmacotherapy, or metabolic surgery. These allow for reduction in adiposity of the mesentery, shrinkage of the liver, and downsizing of the fat pads in the lower pelvis – all thereby permitting better exposure and visualization of the intraabdominal and pelvic spaces, safer identification of critical structures, and improved mobilization of the colon and/or small bowel for improved reach when required for more distal anastomoses [62].

It should be noted that in the setting of malignancy, increasing length of time to surgery while optimizing the patient status has no effect on disease-specific survival. Indeed, this preoperative management and prehabilitation intervention improve the patient's overall physiological status and subsequently reduce postoperative complications and mortality, while lowering the length of stay [58].

Malnutrition

Colorectal surgeons are commonly faced with challenging patients who are malnourished due to advanced malignancies or inflammatory bowel disease that results in intestinal blockages, intestinal fistulas, poor absorptive capacity, and large volume losses from the GI tract. Nutritional risk tends to be a reflection of the patient's overall health and in oncology has correlated with the Eastern Cooperative Oncology Group score and the presence of anorexia or fatigue [63].

Such nutritional risk is associated with increased postoperative complications, longer length of stay, and higher mortality following elective surgery [64, 65] and is particularly pronounced in patients with colorectal cancer [66]. Incidence remains under-recognized and malnutrition continues to negatively impact postoperative recovery and patient outcomes, as well as mortality [67]. Although logistically challenging, nutritional support can be delivered in the preoperative or postoperative setting and can be administered via the enteral and parenteral routes. Most studies are limited by heterogeneous patient populations, variable study designs, different feeding protocols that often result in parenteral overfeeding, and outdated methodologies. When delivered appropriately, malnourished colorectal patients realize several benefits from perioperative nutritional support including fewer postoperative complications, shorter hospital length of stay, and lower mortality [68].

The evaluation of potentially malnourished patients begins with the history and physical examination. Most patients will complain of some degree of intolerance of oral intake as a result of poor appetite, nausea, abdominal bloating, abdominal pain, and weakness. Patients will relate a recent weight loss, typically over a 1–3 month time period. On physical examination, the patient appears thin, pale, and weak with muscle wasting and loose skin. These variables can be objectified using grading systems such as the relatively intuitive Subjective Global Assessment (SGA) to classify patients as well nourished, moderately malnourished, or severely malnourished [69]. The SGA utilizes five features of the history (weight loss over 6 months, dietary intake change, gastrointestinal symptoms, functional capacity, and the impact of disease on nutritional requirements) and four features of the clinical exam (loss of subcutaneous fat, muscle wasting, ankle edema, sacral edema, ascites) to elicit an SGA rank based on subjective weighting. Serum albumin level has been considered the "classic" test reflecting overall nutritional status, with serum concentration <4.0 g/dL defining the "malnourished state."

Recent groups have recommended that hypoalbuminemia, with levels below 4/dL, serves as a negative prognostic marker for adverse postoperative outcomes including mortality and serious morbidity. These authors have recommended adding hypoalbuminemia as a risk factor when utilizing the ACS-NSQIP Surgical Risk Calculator to improve estimation of surgical risks to patients and surgeons [70]. However, in real practice, its utility and reliability are limited as levels fluctuate for many reasons, including production alterations in the catabolic or anabolic states, external losses, or redistribution between the various fluid compartments of the body [71]. Other short turnover proteins such as prealbumin, transferrin, and retinol-binding protein have similar limitations as nutritional markers as a result of variable half-lives and response to dietary intake and renal/

liver dysfunction, although all these proteins can be useful when followed as trends over time.

Similarly, sarcopenia has been investigated as a factor in preoperatively assessing risk for postoperative morbidity and mortality. This variable is generally measured using psoas muscle cross-sectional area on CT or MRI, generally at the lumbar vertebra (L3) and normalizing for patient height. A recent study evaluated 350 patients undergoing colorectal surgery for malignancy at a tertiary care center. Of these, nearly a third were found to be sarcopenic. Sarcopenia was associated with a significantly increased length of stay (13 days vs. 7 days; $p < 0.01$) and 1-year mortality (13.9% vs. 0.9%, $p < 0.01$). Sarcopenia was also associated with a significant increased risk of any complication (85.2% vs. 34.5%, $p < 0.01$) and of major complications (30.4% vs. 8.9%, $p < 0.01$) [72]. Preoperative identification of these sarcopenic malnourished patients affords the surgical team an opportunity to prehabilitate the patient with improved nutritional support and exercise regimen leading to an improved anabolic state. This is aimed with a goal of improved perioperative physiological status and risk mitigation.

Inflammatory bowel disease, intestinal obstruction, large tumors, fistulizing diseases, and patients with diarrhea are often unable to sustain themselves orally due to a poor appetite or resultant abdominal bloating and pain. This limits the ability to intervene preoperatively, particularly when considering utilizing the enteral route. Options include oral nutritional supplements (standard or immunonutrition) or feeding via nasoenteric feeding tubes. Total parenteral nutrition (TPN) can be used if central intravenous access is obtained, an appropriate formula is prescribed (1.5 g protein per kilogram and 25 kcal per kilogram), and tight glycemic control is maintained (serum blood sugars <150 g/dL).

Unfortunately, the use of preoperative nutrition has not been well studied in the malnourished GI surgery patient populations. A recent Cochrane review [73] highlights this paucity of evidence and the reality that many of the studies are outdated, with only two trials evaluating the administration of enteral nutrition (years 1992 and 2009) including only 120 participants and a high risk of bias. Neither study showed any difference in primary outcomes. The three studies that evaluated preoperative parenteral nutrition (years 1982, 1988, and 1992) showed a significant reduction in postoperative complications, predominantly in malnourished patients.

Solid Organ Transplant Recipients

The introduction of novel, more effective immunosuppression regimens has resulted in improved long-term survival after solid organ transplant. Over 150,000 patients in the USA are living with functional kidney transplants, and this number is on the rise. It is increasingly common for surgeons to encounter transplant patients in their practice, in both the elective and emergency settings. The vast majority of these patients are maintained on chronic immunosuppressive regimens. These agents are generally continued throughout the perioperative and early postoperative period in order to minimize the risk of rejection. Many patients are now on life-long chronic immunosuppressive agents. It is therefore essential that surgeons familiarize themselves with the more commonly used immunosuppressive agents and their effect on wound and anastomotic healing and subsequent impact on perioperative outcomes. Coordination of care with the transplant team is necessary prior to elective surgery.

The newer immunosuppressive agents, sirolimus and everolimus, which belong to the drug class known as inhibitors of the mammalian target of rapamycin (mTOR), have been shown to negatively impact healing of surgical wounds. mTOR is a cytoplasmic kinase that is essential for cell growth and proliferation [74]. Inhibition of lymphocyte proliferation despite stimulation results in immunosuppression. This same mechanism is also responsible for inhibition of the wound healing process. In a prospective trial of 123 patients randomized to receive either sirolimus or tacrolimus on postoperative day 4 after kidney transplant, Dean et al. found a significantly higher rate of wound-related complications (including superficial site infection and incisional hernias) in the sirolimus cohort compared to those receiving tacrolimus (47% vs. 8%, $P < 0.0001$) [75]. This data has prompted clinicians to replace mTOR inhibitors with tacrolimus for 6 weeks prior to elective surgery. Whenever possible, non-operative management may be prudent in patients on chronic immunosuppression. Patients who are on therapy status post-transplant are more likely to require emergency operation and more likely to have a stoma created, whether or not restoration of intestinal continuity is achieved at the index operation. These patients similarly have an increased mortality rate when compared to patients who have not undergone solid organ transplants and are on immunosuppression [76]. Traditionally, patients who were immunocompromised had been recommended to undergo early elective resection for diverticulitis. However, this is no longer the case and should be addressed on an individual basis.

Substance Abuse

All surgical patients should be asked about their use of tobacco, alcohol, and street drugs. A large database study from 2002 determined that 7.6% of Americans had a substance abuse disorder within the prior year (95% CI 6.6–8.6%) [77]. The surgeon must also recognize narcotic dependency and use of prescription opioids that are not medically indicated. It is important for surgeons to make patients feel comfortable in answering these questions honestly and accurately. It is never safe to simply assume that a particular patient does not fit the expected profile of an "alcoholic" or "drug addict." Substance abuse has been shown to affect the elderly [78], as well as

highly functional individuals with families and careers [79]. It is therefore critical to screen *all* patients preoperatively in order to minimize perioperative risk.

Alcohol

Alcoholism has been shown to be associated with a number of different perioperative complications in a dose-dependent manner. Large studies have demonstrated that alcoholism is associated with surgical site and other infections, cardiopulmonary complications, and also correlates with longer hospital stay, increased rates of ICU stay, and increased rates of reoperation [80, 81]. The AUDIT-C questionnaire is a validated screening tool that can be used by the clinician to identify patients at high risk for perioperative complications [82]. A randomized controlled trial of 41 patients with alcoholism (defined as consumption >60 g ethanol per day) undergoing elective colorectal surgery demonstrated that abstinence 1 month preoperatively was associated with fewer cardiac complications, including myocardial ischemia (23% vs. 85%, $P < 0.05$) and arrhythmias (33% vs. 86%, $P < 0.05$), as well as overall decreased complication rate (31% vs. 74%, $P = 0.02$) [83]. It is unknown what the optimal alcohol-free interval is prior to elective surgery, in terms of maximizing risk reduction, although the trial investigators recommend 3–8 weeks, highlighting the importance of intensive counseling and monitoring of these patients during this interval [83].

Tobacco

Smoking has been shown in multiple studies to increase perioperative pulmonary risk, as well as risk of wound infections, neurologic complications, and ICU admission [84]. The best way to minimize this risk is to encourage patients to quit smoking prior to elective surgery. Previously it was felt that smoking cessation less than 8 weeks preoperatively was associated with a paradoxical increase in pulmonary complications, possibly due to a compensatory increase in secretions. This has now been disproven in multiple large studies. A large trial of 522 smokers undergoing gastric cancer surgery compared risk of postoperative pulmonary complications between three groups: (1) active smokers or those who quit less than 2 weeks prior to surgery, (2) those who quit 4–8 weeks prior, and (3) those who quit 8 or more weeks prior to surgery. The odds ratios for postoperative pulmonary complications were 2.92 for group 1 (95% CI 1.45–5.90), 0.98 for group 2 (0.28–3.45), and 1.42 for group 3 (0.66–3.05) [85]. Therefore, the recommendation is to encourage smoking cessation, regardless of the timing of surgery, although ideally surgery can be planned for at least 4 weeks from the "quit date."

Opioids

There are many different types of patients with chronic opioid dependence, including abusers of street drugs such as heroin; abusers of prescription-only opioids; patients with prior history of opioid abuse, maintained on long-acting agents such as methadone; and patients on long-term narcotics prescribed for a chronic medical condition. Overall, prescription opioid use is on the rise in the USA and therefore this is being encountered by the surgeon with increasing frequency [86]. For all patients on narcotics, the surgeon should always ask preoperatively what the indication is, how long they have been taking it, side effects (such as constipation), whether there is a plan to wean off the drug, and who has been prescribing it. The patient's responses should be corroborated with the prescribing physician and/or medical record. Regardless of whether it is warranted for an underlying condition, opioid dependency will result in increased narcotic requirements perioperatively. Whenever possible, it is helpful to involve the acute pain management service preoperatively in order to provide the best perioperative pain management. Non-narcotic adjunct therapies can be considered, including thoracic epidural catheters, transversus abdominus plane (TAP) blocks, and drugs such as ketorolac (Toradol), acetaminophen, and gabapentin (Neurontin). Preoperatively, a clear plan should be made with the patient and the clinician who has been prescribing chronic opioids regarding postoperative pain management following hospital discharge, particularly who will be prescribing and for how long. This is instrumental in avoiding concerns in the outpatient setting with overprescribing and relapse.

Other Illicit Drugs

All patients undergoing elective surgery should be screened for the use of illicit drugs – not just "street drugs" but also other prescription-only drugs, such as benzodiazepines, that are not medically indicated. For patients requiring elective surgery, intensive efforts should be made to encourage cessation prior to planned surgery. This requires clear communication with the patient's primary care physician and/or psychiatrist. Discussion of individual drugs is beyond the scope of this chapter; however, additional information is well summarized in this 2014 reference from the anesthesia literature [87].

Consideration of Specific Perioperative Medication Management

Immunosuppressive Agents

When reviewing the literature on patients with diverticulitis on immunosuppression, there was an increased rate of emergent operation (40%) with index presentation compared to the general population (10–25%). On Biondo's review, the only variable associated with higher risk of surgery was chronic corticosteroid therapy, and this was likely attributed

to the masking of clinical symptoms of sepsis and delay in presentation and diagnosis. Consequently, morbidity was higher in the immunosuppressed patients (30.7%), despite a very high success rate with non-operative management (60.7%) of all patients presenting with acute diverticulitis. Mortality was 6.9% and this was in patients with severe comorbidities that precluded surgical management. Overall, there was a low recurrence rate, and similar to patients not on immunosuppression. Recurrent episodes were primarily related to the initial severity index. Recurrence was significantly higher (5×) and predominantly noted in patients with chronic renal failure or collagen vascular disease (~36%), and for this reason, careful consideration for elective sigmoid resection may be justified in this select cohort [88].

Corticosteroids have been shown to impair wound healing in both animal models and clinical studies. In animal models, corticosteroids have been shown to alter multiple independent signaling pathways, impairing all three phases of wound healing: inflammatory, proliferative, and remodeling. Clinical studies have also demonstrated a higher rate of anastomotic complications in patients on chronic steroids [89]. A prospective study performed in the 1980s specifically evaluated the risk of steroids in Crohn's patients and demonstrated in multivariate analysis that corticosteroids were associated with an increased overall postoperative complication rate in Crohn's patients undergoing surgery involving bowel anastomosis (15.4% vs. 6.7%; $p = 0.03$) [90]. One of the largest studies looking at anastomotic leak (AL) in colorectal patients included 250 left-sided resections with anastomosis. The overall anastomotic leak rate was 7.5%. When patients were administered corticosteroids, either perioperatively or on long term, the multivariate model concluded that corticosteroid use increased the risk for AL by more than seven times (OR, 7.52; standard error, 4.47; $P = 0.001$; 95% CI, 2.35–24.08) [91]. A meta-analysis evaluating the risk of corticosteroids on colorectal anastomotic integrity that included 9564 patients from 12 studies demonstrated an overall leak rate of 6.77% (95% CI 5.48–9.06) compared to 3.26% (95% CI 2.94–3.58) in the non-corticosteroid group [92]. In ulcerative colitis, doses greater than 4 mg/day led to a statistically significant increase in complication. Similarly, in the Crohn's Therapy, Resource, Evaluation and Assessment Tool (TREAT), corticosteroids were shown to slightly increase the infectious complications (OR 2.21) [92].

In addition, corticosteroids impact wound healing and are a risk factor for the development of superficial and deep surgical site infections and have even been shown to impact postoperative mortality [74]. Another more recent meta-analysis on the effect of corticosteriods in the setting of ulcerative colitis and ileal pouch anastomotic complications demonstrated equivocal results [93]. Ultimately, this understanding allows the surgeon to better counsel the patient regarding possible postoperative complications, wean steroids during the preoperative period when possible, and make decisions in the operating room (such as the decision to create diverting stoma and wound closure) to optimize patient outcomes. Current recommendations state that patients who are on greater than 20 mg of prednisone daily, on steroids for greater than 2 months duration, and/or combined immunosuppression with biologics within 12 weeks are at highest risk for septic complications. In these patients, recommendations are to delay pouch creation or other anastomosis (consider modified 2- vs. 3-stage procedures), divert in the setting of, or delay, anastomosis, and wean steroids to less than or equal to 20 mg of prednisone daily for 2 weeks.

Immunomodulators, including azathioprine and 6-mercaptopurine, are used in both Crohn's disease and ulcerative colitis to maintain steroid-induced remission. These drugs often take 3–4 months until clinical benefit is apparent and have infrequent but serious side effects such as leucopenia, liver function abnormalities, pancreatitis, and lymphoma. A retrospective study of 417 operations involving bowel anastomoses for Crohn's disease demonstrated no difference in the rate of anastomotic complications for patients on immunomodulators (10% vs. 14%; $p = 0.263$) [75, 94]. Similar to the studies above, they also found that in multivariate analysis, corticosteroids (preoperative prednisolone 20 mg or more) was a predictor of anastomotic complication (OR 0.355, 95% CI 0.167–0.756; $p = 0.007$). Accordingly, these medications may be continued until surgery in some cases.

Biologic agents, including infliximab (Remicade), adalimumab (Humira), and cetolizumab (Cimzia), are chimeric monoclonal antibodies that target tumor necrosis factor, a proinflammatory cytokine that has been shown to be elevated in inflamed tissue of IBD patients. Biological and immunological agents, including infliximab, have been demonstrated to induce remission and control symptoms in patients with moderate-to-severe Crohn's and Ulcerative Colitis. Other biologic agents are more targeted in their behavior and mechanism of action: ustekinumab – anti-IL12/IL23; natalizumab – selective GI-specific anti-adhesion molecules(MadCAM-1); tofacitinib – JAK (Janus kinase) inhibitors - prevent STAT translocation, gene transcription, and lower cytokine production; vedolizumab – humanized monoclonal antibody to α4β7 integrin specific to GI endothelial cells blocking T-cell migration to inflamed GI tissue, also critical for anastomotic healing. With more widespread use of biologic agents in other inflammatory conditions such as rheumatoid arthritis and psoriasis, surgeons are seeing a larger percentage of patients on these agents perioperatively. Critically, though many of these newer agents are more selective in their mechanism and site of action, they also have the paradoxical effect on inhibiting the pathways necessary for appropriate anastomotic wound healing. Krane et al. performed a retrospective analysis

of 518 patients with IBD undergoing elective laparoscopic bowel resection, of which 142 patients were on preoperative infliximab [95]. There was no difference in the rate of anastomotic leak, which was overall low in both groups (2.1% with infliximab versus 1.3% without; $p = 0.81$). A significantly higher percentage of the patients on infliximab were also on steroids, 73.9% vs. 58.8%, $p = 0.006$, and still this did not impact anastomotic leak rate. A recent meta-analysis by Wong evaluated anti-TNF agents and postoperative outcomes in Crohn's disease. Though there was significant conflicting and controversial results secondary to heterogeneity in the trials, there was a consistent increase in infection complications by approximately 20% (OR 1.5) [96].

Similarly, when evaluating postoperative outcomes with ileal pouch anal anastomoses and the effects that anti-TNF biologic agents have, there was a split on the effect of these agents and adverse pouch-related and infectious complications [93]. Other studies at institutions with high volumes of inflammatory bowel disease and patients on biologics similarly supported an increase in infectious complications, OR 3.5 (anastomotic leaks $p = 0.02$, pouch specific complications $p = 0.01$, other infectious complications $p < 0.01$, and postoperative sepsis, OR 13.8) [97].

A more recent study reviewed 3860 patients undergoing colectomy for Crohn's disease from the NSQIP database. When investigating steroids and/or biologics within 30 days of elective colectomy, multivariate analysis concluded that immunosuppression led to statistically significant increases in infectious complications (OR 1.25; 95% CI 1.03–1.52), overall SSI (OR 1.40; 95% CI 1.13–1.74), organ space SSI (OR 1.47; 95% CI 1.09–1.98), and anastomotic leak (OR 1.41; 95% CI 1.02–2.25) [98].

Vedolizumab is a humanized monoclonal antibody to α4β7 integrin specific to GI endothelial cells. This agent results in blocking of T-cell migration to inflamed GI tissue. This same pathway and migration, however, are also critical for anastomotic healing. When investigating vedolizumab and SSI rate in surgical IBD patients, vedolizumab was demonstrated to increase all postoperative complications more so than when compared to anti-TNF agents or no treatment at all. Vedolizumab use within 12 weeks independently predicted 30-day postoperative SSI [99].

Most recently, the PUCCINI trial investigating risk factors for postoperative infection in patients with IBD was completed and recently published. This group concluded that preoperative use of anti-TNF drugs, as determined by history or by drug levels, was not an independent factor for postoperative infections. When evaluating surgical site infection, there was no statistically significant increase with preoperative TNF use within 12 weeks of surgery ($P = 0.92$) or if there was any detectable TNF level ($p = 0.513$). The results were similar when investigating any infectious complication ($p = 0.80$ and 0.985, respectively). Interestingly, no differences were seen with steroid use or preoperative use of other immunosuppressive agents [100, 101].[1] One of the biggest arguments against the findings in this study was that the group looked at any use within 12 weeks preoperatively. This window was significantly outside the 3× multiple of the biological agents half-life, with only 1.5% of the concentration bioavailable. This concentration would have no effect on any tissue and could not be expected to cause any effect on outcomes. Similarly, the study contradicts many other findings of the deleterious effect of corticosteroids on postoperative complications.

Overall, the current literature is quite conflicting and controversial in their findings. Biologics have significantly improved medical management of IBD, though without a significant reduction in role of surgery. While delaying necessity for surgery (particularly in UC), this comes at a cost of increased malnourishment and chronic illness of patients. Biologics have been shown to adversely impact wound healing and increase the risk of postop infectious and surgical complications. Though newer GI-specific therapies may resolve many of these issues, most surgeons and high-volume IBD centers prefer to hold these agents for the equivalent of 3.5 half-lives (6–8 weeks for most anti-TNFa agents, 12 weeks for vedolizumab) prior to major abdominal surgery [95]. Additionally, steroids should be weaned to 20 mg of prednisone daily and sustained for a minimum of 2 weeks preoperatively. Temporarily diverting stoma should be considered when unable to optimize these medical therapies preoperatively.

Chemotherapy Through a myriad of mechanisms, the final common pathway of cytotoxic chemotherapy is induction of cell death during the otherwise rapid proliferation and growth phase of neoplastic cells. Ideally this effect is minimized in nontumor cells, including healing anastomoses. Large studies have attempted to evaluate the overall effect of neoadjuvant and adjuvant chemotherapy on the rate of anastomotic leak, and there have been conflicting results. In a recent single-center study of 797 patients with a single anastomosis, Lucan et al. determined in multivariate analysis that preoperative chemotherapy was one of the strongest independent risk factors for anastomotic leak, with an odds ratio of 2.85 (95% CI 1.21–6.73, $P = 0.017$) [101]. Morse et al. performed a similar study of 682 patients with intestinal anastomoses over a 5-year period and determined in bivariate analysis that chemotherapy (administered within 6 weeks of the operation) was not a risk factor for anastomotic leak.

Nash published a series of 131 patients with diverticulitis in the setting of chemotherapy. Severity of symptoms was not associated with recent chemotherapy administration.

[1] Cohen et al. [100].

However, chemotherapy patients were more likely to recur with more severe disease, more likely to undergo emergent surgery (75.0% vs. 23.5%, $p = 0.03$), more likely to be diverted (100.0% vs. 25.0%, $p = 0.03$), more likely to incur a postoperative complication (100% vs. 9.1%, $p < 0.01$) following interval resection. These patients also were found to have a significantly increased overall mortality, with a lower median survival (3.4 years) (median survival not reached in non-chemotherapy patients). In summary, the group found that nonoperative management of diverticulitis was very successful in patients receiving chemotherapy and should be pursued. Though recurrent diverticulitis was not more common in cancer patients on chemotherapy, it was more likely to be complicated and led to surgery in the select cohort. The group also concluded that the interval of colon resection after a single episode of diverticulitis was not routinely indicated and that, indeed, chemotherapy can safely be resumed in most patients after acute diverticulitis episodes had resolved with medical management [102].

Biondo also published their review on the effects of immunosuppression in the setting of diverticulitis. Chronic corticosteroid therapy was associated with higher rates of emergency surgery. Recurrence was highest during the first year after the index episode, suggesting the need for appropriate surveillance. The need for emergency surgery for recurrence is comparable to that in the general population, and elective surgery in immunosuppressed patients should be individually indicated according to persistence of symptoms or early recurrences. Contrary to prior guidelines, and appropriately redirecting future practice parameters, Biondo concluded that prophylactic colectomy in immunosuppressed patients with diverticulosis cannot be recommended [88].

Bevacizumab (Avastin) is a humanized monoclonal antibody, which targets vascular endothelial growth factor A (VEGF-A) and is thought to work in solid tumors by restricting neoangiogenesis, which is necessary for tumor growth. It is the first of the antiangiogenic drugs to be approved for first-line treatment of metastatic colorectal cancer and is also used for other solid tumors including breast, kidney, ovarian, and lung cancers. Bevacizumab is associated with increased incidence of postoperative complications, including impaired wound healing and anastomotic leak.

Consequently, phase II and III studies of bevacizumab for colorectal cancer excluded patients who underwent major surgery within the previous 28 days [103–105]. Yoshioka et al. retrospectively evaluated 78 patients with resectable advanced or metastatic colorectal cancer who received neoadjuvant bevacizumab prior to surgical resection (this included 46 rectal resections and 4 colectomies) [106]. Overall median interval from last bevacizumab dose to surgery was 9 weeks; anastomotic leaks occurred in six patients, four of which required re-laparotomy. The mean interval from surgery to diagnosis of anastomotic leak was 15.8 days (range 4–34 days). Although the authors did not document mean in-hospital length of stay, presumably most of the leaks occurred after discharge. In multivariate analysis, primary colorectal anastomosis was the only independent predictive risk factor for major postoperative complications (OR 8.285; $P = 0.013$). Interestingly, the interval from last bevacizumab dose to surgery was not an independent risk factor for postoperative complications. Bevacizumab has also been associated with late anastomotic complications [106]. Unsurprisingly, other newer antiangiogenic drugs have also been implicated in the development of anastomotic leak, including pazopanib and aflibercept in small series and case reports [107]. As with most chemotherapy agents, current recommendations are to hold these antiangiogenic agents for at least 6 weeks before major surgery. Intestinal anastomosis and/or proximal diversion should be carefully considered due to the significant complication and leak rate.

Newer checkpoint inhibitors (anti-PD/PD-L1 immunotherapy) such as prembolizumab, nivolumab, or ipilimumab have been increasingly used in the armamentarium for colorectal and other diseases. In rare instances, urgent intestinal operation may be required. Though no specific intestinal surgical studies have been performed, other studies investigating bladder resections and conduit reconstruction in patients on pembrolizumab found that the morbidity rate was acceptable (69% >= Clavien-Dindo grade 2 complication) with no mortality appreciated [108]. Similarly, when evaluating safety and feasibility of lung surgery following immunotherapy, though the operations were technically challenging, significant morbidity appeared to be rare (32%), with encouraging postoperative disease-free survival [109].

Preoperative Assessment in the Elderly

Historically, advancing age has been utilized as a risk factor in predicting adverse perioperative outcomes in patients like other factors such as emergency surgery, ASA, and preoperative comorbidities, for instance, COPD or morbid obesity. As such, prior risk stratification models such as Colorectal Physiologic and Operative Severity Score for enumeration or Mortality and Morbidity (CR-POSSUM) [110, 111] and National Surgery Quality Improvement Program (NSQIP) Morbidity and Mortality Risk Calculator [112] utilize chronological age as a variant predictor of adverse perioperative outcomes. However, chronologic age has been shown to be a poor reflection of the functional, physical, and cognitive decline a patient may experience in their elder years. This poses a difficult challenge for today's surgeons as most surgeries in the United States are performed on patients older than the age of 65. Thus, most persons facing surgery are elderly, underlying the importance of appropriate preoperative evaluation of this patient population.

Defining the Elderly

The older population is a heterogeneous group with varying levels of health status. Commonly used predictors of postoperative complications are not tailored to the geriatric population. For example, the American Society of Anesthesiology classification is determined by a subjective estimate of organ system disease and likelihood of survival, while the Lee and Eagle Criteria account for cardiac function only. Growing evidence demonstrates that these models are limited in predicting perioperative risk since they do not account for the diverse levels of physiologic reserves in the older surgical patients.

The term "frailty" has been increasingly recognized as a surrogate for decreased physiologic reserve in the elder population. There is a lack of consensus on a standard definition of frailty in the literature, although it continues to evolve. It has been described as several phenotypes associated with the dysregulation of multiple physiologic systems. The two most utilized phenotypes include phenotypic frailty which includes assessment of physical activity, muscle strength, and energy level [113], while deficit-driven phenotype includes assessment of nutrition, cognition, medical condition, and functional decline [114].

Assessing Frailty

A multidimensional comprehensive geriatric assessment (CGA) is considered the gold standard for assessing frailty by geriatricians. The CGA generally includes a compilation of validated tools to assess comorbidity, functional status (including ability to live at home), physical performance, cognitive impairment, psychological status, nutritional status, medication review, and social support (Table 6.9)

Table 6.9 A comprehensive geriatric assessment (CGA) should be a key part of the treatment approach for all older cancer patients [115, 116]

Domain	Measures
Functional status	(1) Activities of Daily Living (Subscale of MOS Physical Health) [161] (2) Instrumental Activities of Daily Living (Subscale of the OARS) [162] (3) Karnofsky Performance [163] (4) Timed Up and Go [164] (5) Number of Falls in Last 6 Months [165]
Comorbidity	Physical Health Section (OARS Subscale) [162]
Cognition	Blessed Orientation-Memory-Concentration Test [166]
Psychological	Hospital Anxiety and Depression Scale [167–169]
Social Functioning	MOS Social Activity Limitations Measure [161]
Social Support	MOS Social Support Survey: Emotional/ Information & Tangible Subscales [161, 170]
Nutrition	(1) Body Mass Index [170] (2) % Unintentional Weight Loss in Last 6 Months [171, 172]

[115, 116]. On the whole, the benefits of a CGA include prolongation of life and prevention of hospitalizations and admissions to adult living facilities [117–120], prevention of geriatric syndromes such as delirium and falls [121, 122], prevention of cognitive decline [123], and detection of unsuspected conditions that may affect cancer treatment in more than 50% of patients aged 70 or over [124].

Complete Geriatric Assessment

Several studies have demonstrated the ability of CGA to predict surgical outcomes in the elder population [125, 126]. Early studies include a Norwegian study by Kristjansson et al. [127] in which the CGA was predictive of surgical morbidity in 178 elderly colorectal cancer patients with a median age of 80. This study is consistent with previous work identifying frailty as a predictor of surgical outcomes. Robinson and colleagues used seven frailty characteristics (Time Up and Go, Katz score, Mini-Cog, Charleston Index, anemia, poor nutrition, and geriatric syndrome of falls) to define frail, pre-frail, and non-frail individuals. Of the 201 patients who underwent major cardiac or colorectal procedures, frailty was independently associated with increased postoperative complications, prolonged hospital stay, and higher 30-day readmission rates [125]. More recently, a 2015 systemic review evaluated six studies on CGA and surgical outcomes in the geriatric oncology population. All studies included were prospective, cohort design and utilized validated questionnaires with data collected prior to surgery. Primary outcomes included 30-day postoperative complications (POC), mortality, and discharged to a non-home institution. Deficiencies in instrumental activities of daily living (iADL), activities of daily living (ADL), fatigue, cognition, frailty, and cognitive impairment were associated with increased postoperative complications. Although there were no CGA predictors for postoperative mortality, frailty, deficiencies in iADL, and depression were found to be predictive of discharge to a non-home institution. Major complications happen more frequently in patients with cognitive impairment, iADL, and activities of daily living (ADL). Interestingly, age was not associated with complication rates [128]. Similarly, a study by Shahrokin et al. evaluating 980 oncogeriatric patients aged 75 years or older demonstrated association between CGA deficits and 6-month mortality after stratification for multiple variables. Of note, ASA classification was not associated with 6-month mortality while each additional impairment identified on the CGA was associated with a 40% increase in the risk of a 6-month postoperative mortality [129].

Frailty Scores

Although comprehensive geriatric assessment is the most consistent in predicting outcomes in the geriatric population, a full CGA can take several hours to complete and may not be feasible in a busy surgical practice. Shorter more efficient

Table 6.10 Frailty score has been described as an age-associated decline in five domains: shrinking, weakness, exhaustion, low physical activity, and slow walking speed [113]

Domain	Definition
Shrinking	Unintentional weight loss ≥10pounds in the last year
Decreased grip strength	Patient squeezed a hand-held dynamometer (strength measurement was adjusted for BMI and gender)
Exhaustion	Response to questions about effort and motivation
Low physical activity	Survey about leisure time activities
Slowed walking speed	Speed at which patient could walk 15 feet

Adapted from Makary 2010 [126]

geriatric assessments have been developed to address the time constraints during acute evaluations, while demonstrating their ability to be as effective as the CGA in predicting postoperative complications [130–132]. In 2001, Fried et al. characterized frailty as an age-associated decline in five domains (Table 6.10): shrinking, weakness, exhaustion, low physical activity, and slow walking speed. The definition was instrumental in providing the framework to help define this challenging population [113]. In 2010, Makary and colleagues used the Fried criteria to establish the Hopkins' Frailty Score, which demonstrated that the frailty was a potentially useful tool in predicting poor outcomes in the elderly surgical population. Frailty was prospectively measured in 594 patents (aged 65 years or older who presented for elective major and minor surgeries). Patients scoring 4–5 were classified as frail, 2–3 were intermediately frail, and 0–1 were non-frail. Utilizing multiple logistic regression, frailty was shown to be independently associated with the development of postoperative complications (OR 2.54; 95% CI 1.12–5.77), length of stay (OR 1.69; 95% CI 1.28–2.23) and discharge to a skilled or assisted living facility after previously living at home (20.48; 95% CI5.54–75.68). In addition, when combined with other current risk assessment models such as ASA and Lee and Eagle scores, assessing frailty improved their predictive power [126].

In 2012, the American College of Surgeons recognized the importance of a CGA in the preoperative evaluation of elder patients. The American College of Surgeons NSQIP and American Geriatric Society collaborated to create best practices guidelines for the perioperative care of geriatric surgical patients. In addition to conducting a complete history and physical, the authors recommended evaluations of preoperative domains which included problems specific to elderly individuals. These domains are very similar if not the same domains included in the CGA discussed above and include cognitive impairment, frailty, poly-pharmacy, risk of malnutrition, and lack of family or social support. A proposed checklist was drafted for surgeons across all specialties to utilize in the evaluation of a surgical geriatric patient; however, translating the information into predicting clinical outcomes remained challenging (Table 6.11) [133].

Table 6.11 Preoperative workup for geriatric patients undergoing colorectal surgery

Cardiac assessment
I. Patients with active cardiac conditions require cardiology assessment and workup
II. Patients with over two clinical risk factors require heart rate management, but do not need cardiac testing unless results will change operative management
III. Patients undergoing low risk surgery, more than 3 METs, or fewer than 3 clinical risk factors may proceed with surgery
Pulmonary assessment
IV. Encourage smoking patients to quit more than 8 weeks postop, although 4 weeks may be long enough in some studies
V. Aggressive management of COPD and asthma
VI. Routine CXR and PFTs not indicated
Diabetes and glucose assessment
VII. Obtain baseline glucose level
VIII. Obtain baseline BUN and creatinine
Nutritional assessment
IX. Patients with BMI <18 or unintentional weight loss over 10% in 6 months require evaluation by a registered dietician
X. Preoperative nutritional
Anemia and hematologic assessment
XI. Obtain baseline hemoglobin and hematocrit
Cognitive assessment
All patients require adequate history from patient and family member
All patients require cognitive assessment (Mini-Cog)
All patients require anxiety/depression assessment
All patients require assessment of alcohol use, identification of possible abuse
All patients require evaluation of decision-making capacity to ensure informed consent
Any new findings, or worsening of existing findings, require further evaluation by appropriate geriatrician or mental health care provider
Laboratory and noninvasive testing
Unless previously indicated above, routine CBC, BMP, PT/PTT, EKG, CXR are not required

Composite indexes obtained from retrospective analysis of large national data spaces are more frequently being utilized to adequately assess the elder population in the preoperative setting, given they are considered quick and simple tools. One example is the modified frailty index (mFI) which was developed utilizing the American College of Surgeons National Surgical Quality Improvement Program (NSQIP) database [134]. This screening tool is favored among multiple surgical disciplines because it is based on easily identifiable relevant patient characteristics which can be extracted using a straightforward history and physical examination. It consists of 11 variables each of which corresponds to one point. The mFI has been shown to predict the 30-day readmission, major complications, wound complications, failure to adhere to enhance recovery protocols, discharge to non-home facilities, and mortality for surgical patients [135–137]. The risk analy-

sis index (RAI) is another composite index frequently used to predict outcomes and surgical patients. It consists of a 14-question survey which evaluates domains such as ADLs and cognitive decline along with more standard factors such as age, sex, and medical comorbidities. Initial studies by Hall et al. demonstrated the RAI to predict prolonged length of stay, out of ICU admission, discharged to nursing home, and mortality [138, 139].

Improving the preoperative evaluation of the elderly surgical patient to assess frailty is the first step in improving surgical outcomes in this heterogeneous, complex population. Preoperative assessments should not only be designed for early detection and treatment of surgical medical complications but should also be aimed at identifying at-risk individuals with modifiable risk factors in which targeted therapy may improve their outcomes. This sets the stage for the increasing interest in evaluating the impact of prehabilitation on the elderly population undergoing surgical intervention.

Table 6.12 Pre- and perioperative risk factors associated with increased risk of postoperative occurrence of delirium

Preoperative
Dementia
Age [20]
Malnutrition [145]
Cognitive impairment [155]
Visual impairment [155]
Dehydration [20]
Immobilization [20]
Polypharmacy [20]
Severe illness [155]
Perioperative
Poor fluid status [145]
Poor glycemic control >150 mg/dL
Metabolic derangements [20, 145]
Uncontrolled pain (PCA necessary to improve delirium in elderly patients) [155]
Addition of more than 4 new medications [145]
Bladder catheters [145]
Serum urea nitrogen to creatinine ratio >17 [155]
Prolonged bed rest
Physical restraints [145]

Cognitive Dysfunction and Delirium

Cognitive dysfunction is common in elderly patients, with rates between 5% and 15% in the general population but as high as 60% in high-risk groups [140]. The degree of dysfunction can vary between severe, otherwise known as dementia, and mild cognitive impairment (MCI). With MCI, the level of impairment is not severe enough to interfere with independent function [141, 142]. Both forms of cognitive dysfunction have been shown to be associated with worse surgical outcomes. Multiple studies have implicated both MCI and dementia as high-risk factors for postoperative delirium.

The American College of Surgeons and American Society of Geriatrics have advocated for the use of the MiniCog preoperatively to detect MCI [143]. The MiniCog screening test is a 3-minute instrument that can increase the detection of cognitive impairment in older adults. It consists of two components: a 3-item recall test for memory and a simply scored clock drawing test. Other tests include the Self-Administered Gerocognitive Examination (SAGE) which was developed by Scharre et al. [144]. It is a 12-item examination that is self-administered to detect MCI and early dementia in geriatric patients.

Delirium is the one of the most common postoperative complications in the elderly. It has been defined as a documented change in mental status characterized by reduced environmental awareness and attention disturbance. In a prospective analysis of patients aged over 70, undergoing abdominal surgery, the overall incidence of delirium was 60% with a 30-day mortality of 20% in those patients. In fact, 40% of patients had three or four risk factors for delirium [145]. In the Hospital Elder Life Program, focus and management of six factors reduced delirium: visual impairment, hearing impairment, cognitive impairment, sleep deprivation, immobility, and dehydration (Table 6.12). Treatment should not utilize medications as first-line therapy. Instead, avoidance of triggers, reorientation, massage, relaxing music, and one-on-one care with family are recommended. If medication is required, Haldol should be initially be considered and the clinician should refrain from restraints except in the most severe cases [146].

Prehabilitation

Increasing utilization of preoperative screening tools, such as mFI, in the geriatric population has resulted in further awareness of elders at risk for functional decline not only from a physical aspect but also from a nutritional and psychological status. These factors may be considered modifiable in which improvement may shift outcomes in a positive direction for this high-risk population. For this reason, there has been a concurrent in interest in developing preventive strategies to restore the functional capacity after surgery, reducing the clinical impact of reduced functional capacity. Prehabilitation is a multidisciplinary intervention focused on utilizing the perioperative period to optimize the patient to prevent or diminish the surgery-related stress leading to functional decline and its consequences. The multimodal approach includes exercise training, nutritional therapy, and anxiety reduction strategies [147].

Although the body of evidence is growing regarding prehabilitation, standardized consensus definition of rehabilitation remains lacking. And as such, there is signifi-

cant variation in the reported types of interventions and the recommended types of interventions, frequency, and duration [148–152]. Duration of intervention may vary between 5 days and 6 weeks and may occur at the patient's home, rehabilitation center, and outpatient or inpatient physiotherapy units. It is no surprise that all trials included exercises and elements of rehabilitation to improve the functional capacity and physiologic reserve.

Exercise

The goal of a prehabilitation program is to identify those with modifiable risk by assessing with screening tools for specific conditions and intervening prior to surgery. Based on the growing body of literature, exercise has been shown to be the main component. Programs focus on the ability of exercise to deliver a physiologic stress that causes an adaptive response in all organs and tissues and as such improve the ability of the body to withstand incoming stress for surgery. Training programs often utilize the three main categories of exercise (aerobic, resistance, and flexibility training) to complement each other and lead to a comprehensive functional outcome improvement [153]. Majority of programs demonstrated improvement in physical performance after undergoing a rehabilitation program. Screening tools that identify patients with decreased performance status include the ACS NSQIP surgical risk calculator along with a revised cardiac risk index. Performance status and functional capacity are often expressed and metabolic equivalents (METs) as described earlier in this chapter [16, 21].

Nutrition

Malnourishment affects between 2% and 32% of elderly, and that's among the "healthy" geriatric population. In hospitalized elderly patients, prevalence of malnourishment is between 1% and 83% [154, 155]. There is a sixfold increased risk of complications in malnourished elderly patients [21], which may be further amplified in the setting of gastrointestinal cancer. Further, poor preoperative nutritional status was independently associated with postoperative delirium and mortality in elderly patients. Therefore, optimization of nutritional status and enhancement of protein metabolism are paramount [145]. Nutritional screening tools can be used to properly identify the presence of undernutrition or the risk of developing undernutrition to select patients for nutritional therapy. Screening tools may include tools such as Subjective Global Assessment (SGA) Nutritional Risk Screening 2002 or Mini Nutritional Assessment (MNA) [154]. The nutritional intervention should be multimodal but individualized to the patient focusing on ensuring the patient (1) meets the energy requirements of daily expenditure, maintains energy stores, and promotes physiologic metabolic processes; (2) maintains a high protein diet; and (3) receives a balanced meal with adequate intake and proportion of all macronutrients.

Psychosocial Therapy

Physiologic stress of surgery is not only entirely related to the trauma of the surgery itself but can also be related to the psychological distress caused to the patient. Preoperative anxiety and depression have been shown to have a negative impact not only in quality life but also in wound healing, infection rates, length of stays, and adherence to medical treatments [153]. The psychological component of a multimodal rehabilitation program is aimed at reducing anxiety symptoms and distress with cognitive behavioral therapy. Interventions may include educational sessions to improve knowledge about surgery, relaxation, and imagery techniques such as passive breathing exercises, meditation skills, and guided imagery [156].

Outcomes

In theory, prehabilitation programs should mitigate surgical complications in high-risk individuals such as elders; however, currently there is little evidence to support this. Several studies have investigated the effect of prehabilitation on postoperative complications with only one study by Waite et al. demonstrating a significant impact on complications with a decrease in overall complications by 30% and severe complications by 20% in those patients awaiting cardiac surgery [157]. Reports vary on the effective prehabilitation with regard to mortality and length of stay. Most of the literature demonstrate no difference in mortality between those who undergo prehab and those who do not, except for the study by Waite et al. who demonstrated significant decrease in both 30-day mortality and 3-month mortality. Majority of the literature also demonstrate no difference between the length of stay and discharged institutionalization with no difference between the two groups. One study by Mazzola et al. demonstrated a trend toward reduced length of stay, while Waite et al. demonstrated a significant decrease in the length of stay for those undergoing prehab [150, 157].

Carli et al. performed a randomized trial evaluating the effectiveness of prehabilitation (versus rehabilitation) specifically on frail patients undergoing colorectal surgery for cancer [158]. In a cohort with a mean age of 78 years and with almost 80% of patients undergoing minimally invasive surgery, there was no difference in the primary outcome measure, 30-day Comprehensive Complications Index, or secondary outcome measures (30-day overall and severe complications, primary and total length of hospital stay, 30-day emergency department visits and hospital readmissions, recovery of walking capacity, and patient-reported outcome measures).

A recent systematic review of 5921 patients undergoing prehabilitation was recently published. Thirty-five studies (n = 3402) on patients undergoing major abdominal surgery were included. Only 45 studies compared the impact of prehabilitation versus no prehabilitation on postoperative outcomes (abdominal, n = 26; cardiothoracic, n = 19), but in those studies, patient's receiving prehabilitation for major abdominal surgery had significantly lower rates of overall complications (n = 10, odds ratio: 0.61, confidence interval 95%: 0.43–0.86, P = 0.005), pulmonary (n = 15, odds ratio: 0.41, confidence interval 95%: 0.25–0.67, P < 0.001), and cardiac complications (n = 4, odds ratio: 0.46, confidence interval 95%: 0.22–0.96, P = 0.044) [159].

Conclusion

Preoperative assessment of the colon and rectal surgical patient remains the first critical step in appropriate decision-making and improving outcomes. A keen understanding of various medical therapies being utilized and their effects on wound and anastomotic healing and resultant septic complications is critical in the timing of and preparation for procedures. Attention to patient's other physiological organ systems (cardiac, pulmonary, renal, endocrine, nutrition and metabolism, and immunologic) and alterations in normal function is necessary for perioperative optimization to enhance the ability of the patients to tolerate the operation and also recover with minimal morbidity and improved long-term function. In some cases, timing of interventions may necessitate judicious delay to optimize the surgical and medical milieu of the patient. Special consideration is necessitated in the elderly, given the multiple domains involved in defining this complex population, particularly as prehabilitation for frailty has demonstrated significant benefits in improving surgical outcomes. Preoperative assessments, with multidisciplinary input, should be designed at early detection, stratification, and optimization to mitigate medical morbidity and minimize or eliminate surgical complications. These should be a component of a robust enhanced recovery protocol that incorporates early mobilization, narcotic-sparing multimodal pain management, and discharge planning.

Optimizing Outcomes with Enhanced Recovery

7

Julie Thacker and Nancy Morin

Key Concepts

- Enhanced recovery is the process of defining modifiable sources of perioperative stress to the surgical patient and applying standardized evidence-based interventions through all phases of care to avoid complications, facilitate faster recovery and discharge (without increasing readmission rates), and reduce hospital costs.
- Champions from surgery, anesthesia, and nursing are essential to the ERAS team, while other members for protocol creation include pharmacy, IT, nutrition, and administration.
- Key elements of patient care delivery can be broken down into five phases, each assigned to and delivered by a different team while certain elements present across phases: preoperative, perioperative, intraoperative, postoperative, and post-discharge.
- Implementation of the Enhanced Recovery Program, ERP, requires order sets, team education, and administrative help as well as databases to facilitate data collection and ensure optimal compliance and quality control.
- ERAS principles are widely applicable and have been proven safe and beneficial in emergency and IBD patients, those with diverting ostomies, and elderly patients, realizing that readiness for discharge rather than length of stay is a more accurate outcome measure.
- Moving forward, technology will assist in gathering patient recovery-centric outcome measures in addition to the traditional audit measures to further quality improvement efforts.

Intrinsic to the personality of a surgeon is the drive toward perfect outcomes. Benchmarking, quality improvement comparisons, and inherent competitiveness all allow surgeons the means to evaluate their performance. Enhanced recovery principles, by contrast, focus on intervention elements. Specifically, enhanced recovery focuses on the surgical stress imposed on unique patient populations. This chapter focuses on enhanced recovery efforts, details, challenges, and future directions in the elective colorectal surgery patient.

Enhanced Recovery, Origins, and Overview

Besides a buzz word on hospital webpages for administrators to publicize adoption of popular care maps for surgical services lines, enhanced recovery has a multi-faceted history and widely diverse definitions. To some, enhanced recovery refers to the patient-focused decrease of surgical stress described in the late 1990s and early 2000s in Scandinavia as "ERAS, enhanced recovery after surgery." To others, "ERAS" is simply an order set or protocolized perioperative care. Enhanced recovery; enhanced recovery programs, "ERP"; and enhanced recovery after surgery, "ERAS" will be used interchangeably in this chapter.

Most clearly, enhanced recovery is the application of evidence-based, perioperative medicine to the care of the surgical patient with a goal of best surgical outcomes. In this chapter we review the thoughtful development of this aspect of perioperative medicine, and, specifically, we discuss the aspects of perioperative medicine that have been defined as enhanced recovery for the colorectal surgery patient.

Building on the understanding of nutrition and stress science from the preceding decades, surgeon scientists began specifically addressing the impact of depleted or supported nutritional reserves at the time of surgical stress on surgical outcomes. After decades of individual work relating operative outcomes to perioperative metabolism, stress, and nutrition, Douglas Wilmore of Boston and Henrik Kehlet of Copenhagen reported the importance of considering the

patient's physiologic reactions, helpful and hurtful, to surgical stress [1–3].

Their work proposed that, with a better understanding of the physiologic stress impact of operations, surgical teams could mitigate this stress. From a background of perioperative nutrition science, these early enhanced recovery efforts began to define modifiable sources of perioperative stress. Wilmore and Kehlet identified several sources of perioperative stress that were worse with traditional perioperative care, and they hypothesized that different care plans might help patients avoid complications [4]. The complexity of physiologic interactions is shown diagrammatically in Fig. 7.1 with representative enhanced recovery interventions to combat these stresses shown in Fig. 7.2.

From modifying perioperative stress to fast-track surgery to enhanced recovery, perioperative care was being revolutionized in Europe in the early 2000s. Simultaneously, in the USA, a trend toward minimally invasive approaches to abdominopelvic operations was taking off. Observed shifts in patient care paradigms followed patient recovery curves

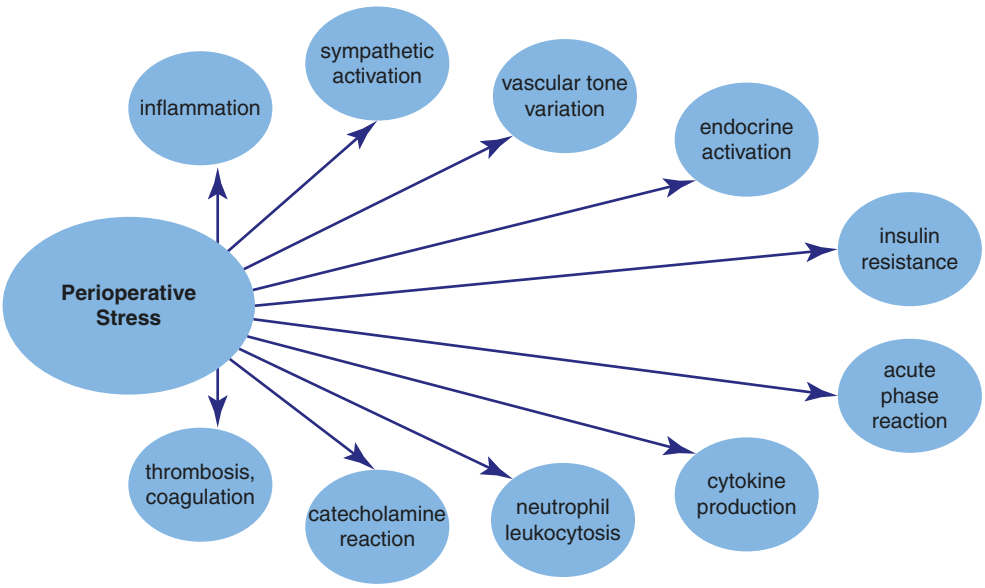

Fig. 7.1 Perioperative stress and reactions

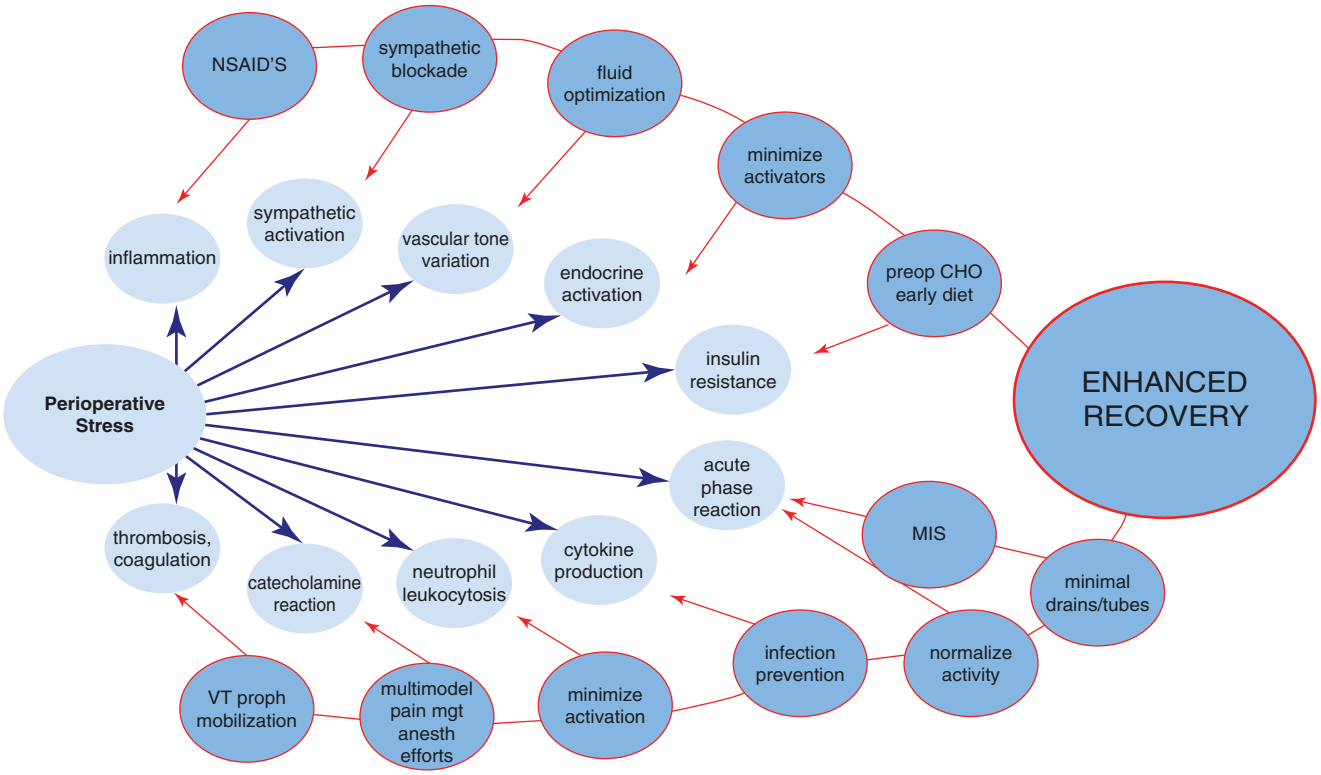

Fig. 7.2 Common ERAS elements to combat perioperative stress

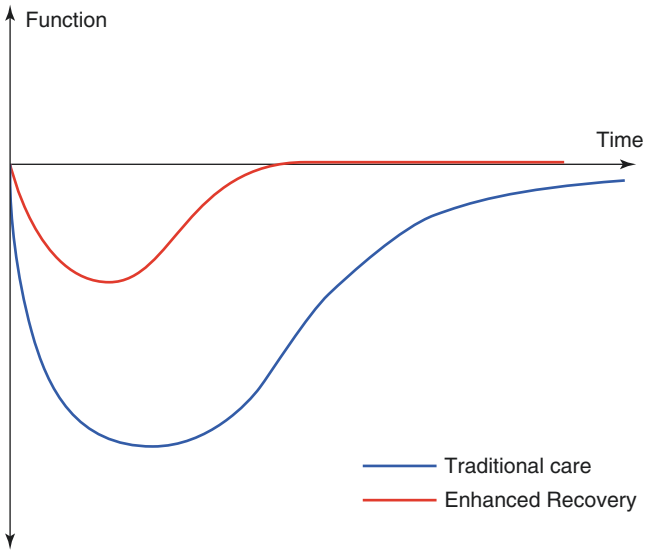

Fig. 7.3 Kehlet and Wilmore's representation of lessened perioperative stress resulting in improved recovery curve

and included earlier postoperative oral intake, earlier mobility, and earlier readiness for discharge from the hospital. Laparoscopic surgeons were responding to patients' decreased surgical stress and facilitating faster recoveries. Through critical review of laparoscopic studies and perioperative care standardization, it became obvious that allowing patients to recover more quickly worked [5]. More directly, Dr. Kehlet's parallel efforts began actively addressing perioperative care elements relative to surgical stress. He reported that an immediate diet and immediate activity, in combination with multimodal analgesia, led to quicker discharge readiness after open operations [6, 7]. He explained that the traditional care paradigms worsened surgical stress and prolonged the amount of recovery below the patient's baseline at time of operation. As demonstrated in Fig. 7.3, and as he simply described, patients did not experience the dip relative to baseline health when they had surgery on his protocol.

Specific to colorectal surgery, the two paradigm shifts collided in the early 2000s. Open operations under this new care paradigm and laparoscopic operations with inherently faster recovery were resulting in decreased narcotic need, earlier diet tolerance, and shortened hospital stays. Surgeons performing predominantly open colorectal operations in Scandinavia adopted Professor Kehlet's perioperative principles, and with the explosion of MIS equipment availability in the USA, more and more surgeons were approaching the colon laparoscopically. In 2004, the American College of Surgeons' Commission on Cancer released the non-inferiority COST trial [8], showing that laparoscopic oncologic resection for colon cancer did not have worse outcomes compared to the open approach. This led to increasing numbers of MIS colon resections in North America, particularly at academic and training centers, where academicians had been reluctant to adopt the technology without reassurance of safety in cancer. In 2005, the first publication of the "ERAS group" shared their attempt to push surgeon-driven adoption of Kehlet's protocols for open colorectal resection patients on their colorectal surgery wards. Admitting that their results were not as amazing as the very confined implementation of Kehlet's single-center and small-sample population, the ERAS group set out to apply implementation science techniques to the idea of changing the perioperative management of colorectal surgery at their centers. Subsequent development and spread of these focused change management strategies has been widely successful [9].

By 2008, worldwide improvement of colorectal surgery outcomes, predominantly in length of stay and decreased wound complications, had been reported by many high-volume laparoscopic centers. Perioperative optimization strategies such as intentional fluid management and opioid stewardship began timely growth from the anesthesia literature. Parallel to the incremental changes happening around the growth of laparoscopic colorectal surgery was the successful effort of the ERAS Society, so named in 2007 [10]. With westerly drift of ideas, US and Canadian centers became aware of the principles of enhanced recovery. This spread was facilitated by the uptake of enhanced recovery in the UK. The 2008 economic recession drove the National Health Service to implement many care changes to improve service and to decrease cost. The implementation of enhanced recovery for surgery patients was mandated across the country, beginning with colorectal surgery. This effort was to save money from decreasing length of stay and complications, and the NICE program was hugely successful at its mission [11]. Enhanced Recovery Partnership Programme in the National Health Service, NHS, of the UK was the first mandated and the first truly multidisciplinary approach to the improving perioperative outcomes reported. Since 2010, the published work of major centers, predominantly shared anesthesia and surgery efforts, has skyrocketed [12–15]. North American efforts have been stimulated by the 2014 creation of American Society for Enhanced Recovery (ASER at www.enhancedrecovery.org) and the American chapter of the ERAS Society, in 2017 (Fig. 7.4).

In short and most holistically, enhanced recovery is the process of considering and implementing the best evidence for each system-patient touch from diagnosis of surgical disease to complete recovery from operative management of that disease. Currently, the best outcomes attributed to enhanced recovery work tend to start with intentional preop-

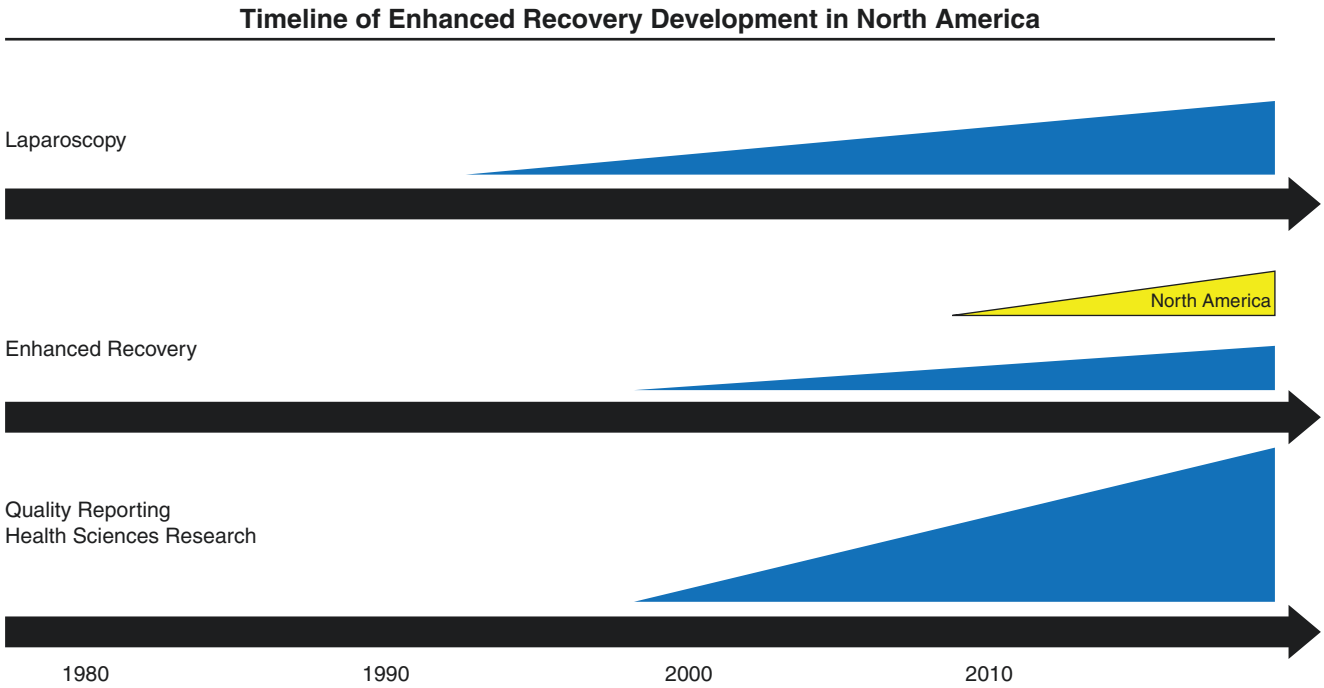

Fig. 7.4 Alignment of improvement strategies in colorectal surgery including laparoscopy, ERAS, and quality improvement research

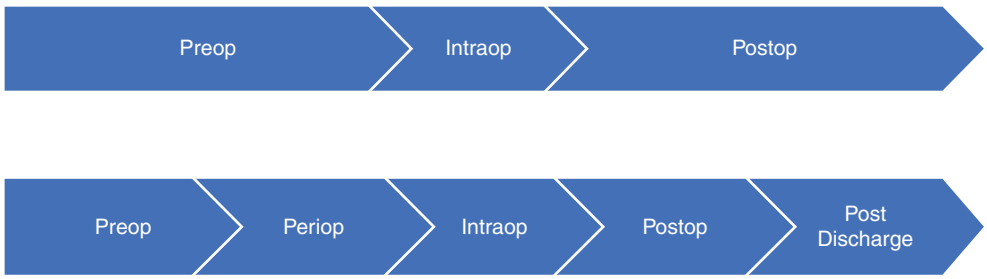

Fig. 7.5 Models of care for change management planning; three phases and five phases

erative education regarding surgical planning, followed by evidence-based management steps via preoperative anesthesia assessment, intraoperative best practices, and intentional postoperative management schemes to minimize perioperative stress and optimize outcomes. Herein, we will discuss the evidence of common care variables of enhanced recovery for colorectal operations, reported implementation schemes, and examples of improved outcomes. In addition to order sets and patient-focused care elements, enhanced recovery efforts frequently lead to continuous improvement platforms. Such platforms, via change management efforts, are tough to create and even harder to maintain. Identification of these barriers and how to break these barriers down is offered. Enhanced recovery has been attractive to administrators and payers because of economic impacts which are discussed toward the end of the chapter. Lastly, next steps and the future of enhanced recovery for colorectal patients are covered.

Enhanced Recovery Models

There are two ways to consider the care elements of most enhanced recovery models. One is to define action in a particular phase of care. Another considers the impact on physiologic stress, allowing for potentially multiple interventions along the surgical continuum.

Dividing the operative experience into phases is somewhat artificial, but it works well when creating an implementation strategy. Care delivery can be divided by time and shown as preoperative → intraoperative → postoperative. Care delivery can also be divided by location, which further defines the team members present in each phase. This five-phase care perioperative scheme is consistent with the Quality Red Book published by the American College of Surgeons (Fig. 7.5) [16].

Preoperatively, the patient is prepared for surgery with information and testing. Intraoperatively, engagement of the

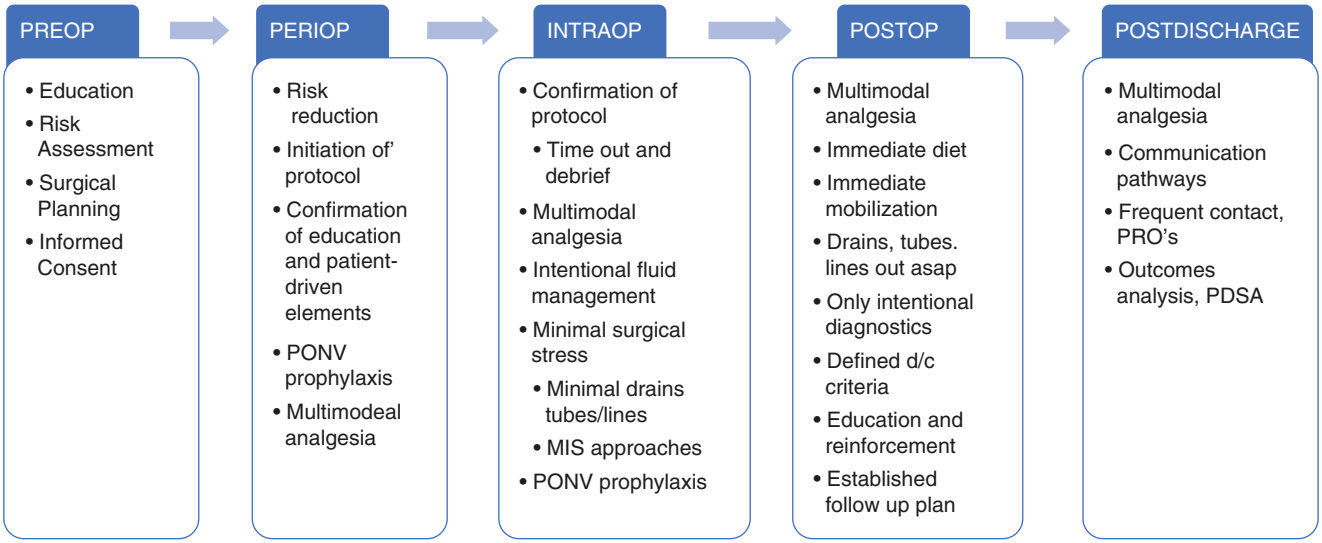

Fig. 7.6 Common enhanced recovery elements; five phases of care model

anesthesia team is key. Important elements in the operating room include intentional fluid management and minimally stressful surgical techniques. Postoperatively, the patient is guided back to baseline health, acutely in the hospital and over the weeks following an operation. Each of these phases is delivered by a different team. The patient and the surgeon are the only two players in each phase. A surgeon's understanding of who does what and when is a key first step to enhanced recovery care. Then key elements in each phase are defined from the evidence. An example of how some elements fall into phases of care is shown (Fig. 7.6).

As is obvious by the repetition of items across the phases, some interventions need to be carried out at multiple time points. Therefore, when creating a protocol, it is important to consider the principles of care and the evidence of interventions.

First Steps to Creating an Enhanced Recovery Program

To start, the ERAS team needs to define what outcomes need to be improved. Seemingly obvious, this initial step is often skipped with teams jumping into building order sets. The second step is to create an evidence library. Once outcomes of interest are defined, and the evidence is collected, the team assigns the elements of impact to phases of care and team members. The lift of implementation often includes an order set, team education, and administrative help. Pearsall et al. detail the team and facilitators nicely in a chapter on implementation in *Surgical Clinics of North America* [17]. Champions from surgery, anesthesia, and nursing are essential. Other team members for protocol creation will be from the pharmacy, IT, administration, and nutrition.

Enhanced Recovery Elements in Colorectal Surgery

This section covers elements common to most protocols for enhanced recovery of the elective colorectal surgery patient. General groupings into phases of care are used to organize the information as one would to create a protocol (Table 7.1).

Preoperative Elements of ERAS in Elective Colorectal Surgery

Education

Patient education is a key element of enhanced recovery. Setting expectations for patients at every phase of care helps to manage stress and encourage participation. Common language and instructions throughout the surgical journey allow the patient to be more relaxed and receptive to the care plan.

Information needs to be at the simplest appropriate literacy level in written, spoken, and, if possible, video versions to reach all learners. Important to every phase of enhanced recovery, the greatest educational effort may be spent at its introduction in the surgery clinic. The anesthesia assessment team, the preoperative holding team, and even the recovery room team – all of these seemingly separate teams – become part of the patient-focused care in enhanced recovery. When this philosophy is adopted, variability decreases.

Preoperative Optimization

The explosion of evidence regarding preoperative optimization outreaches this chapter. There is abundant research ongoing to define readiness for operation. Subjecting patients to exercise-based challenges, evaluating interleukin levels, and reading nutritional parameters on CT scans are just a few of the areas being aggressively studied [18]. This section,

Table 7.1 Common enhanced recovery elements in elective CRS

Phase	Element	Outcomes of interest
Preoperative	Informed consent	Shared decision-making and appropriateness
	Education	Patient participation and decreased stress
	Optimization	Best management of modifiable risk factors
Perioperative	Bowel preparation	Decrease surgical site infection
	Limiting fasting	Encourage euvolemia for safe induction
	Carbohydrate load	Decrease insulin resistance and infection
	Identify/ document	Increase compliance to protocol and audit
	PONV prophylaxis	Optimize early PO tolerance and patient experience
	Multimodal analgesia	Decrease opioid-related complications
Intraoperative	VTE prophylaxis	Decrease thrombotic complications
	Antibiotic prophylaxis	Decrease infectious complications
	Multimodal analgesia	Minimize opioids during general anesthesia
	Goal-directed IVF	Optimize the right fluid relative to needs
	MIS	Decrease surgical stress and optimize recovery
	Minimize drains, tubes, and lines	Decrease foreign body reaction and complication risk without evidence of benefit
	PONV prophylaxis	Optimize early PO tolerance and patient experience
Postoperative	Multimodal activity	Minimize opioids during general anesthesia
	Immediate diet	Encourage return of bowel function, minimize catabolism
	Immediate activity	Minimize complications of inactivity
	VTE prophylaxis and teaching	Decrease thrombotic complications and begin discharge teaching
	Education	Reinforce discharge criteria and goals to minimize unnecessary length of stay and stress
Post-discharge	Multimodal analgesia	Minimize opioid complications and opioids in the community
	Continued activity	Encourage rehabilitation and muscle preservation
	VTE prophylaxis	Decrease thrombotic complications
	Close contact	Decrease stress and recognize problems early to prevent readmissions

PO Per os, *PONV* postoperative nausea and vomiting, *IVF* intravenous fluid, *VTE* venous thromboembolism, *MIS* minimally invasive surgery

though, is a brief review of well-established and feasible recommendations that should be routine in all preoperative preparation programs: smoking cessation, preoperative nutrition, and anemia and diabetes management recommendations. Since acquiring the "Strong for Surgery" program, the best guide for this preparation for surgery elements is the American College of Surgeons webpage, https://www.facs.org/quality-programs/strong-for-surgery, which includes resources for clinicians, preoperative programs, and patients.

Smoking Cessation

The association of smoking with worse operative outcomes is well established [19]. For colorectal surgeons, concerns include increased risk of anastomotic complications, impaired microcirculation, increased postoperative pulmonary complications, and special considerations in inflammatory bowel disease (IBD). Particular recommendations include taking advantage of the life-changing moment of a surgical diagnosis as motivation for patients to quit tobacco use and encouraging even 2–3 weeks of preoperative cessation as beneficial. For many patients, smoking is not their only modifiable risk factor; smoking cessation can be one goal added to increased physical activity, alcohol intake moderation, and improved blood sugar management during even a brief elective case delay. Resources available on Strong for Surgery are thorough. Having a local team with specific addiction focus and training does result in higher success of these efforts [20].

Preoperative Nutrition

The evidence that malnutrition is independently associated with worse colorectal surgery outcomes and increased costs is abundant. The problem is often underestimated, but it is substantial. Work by Wischmeyer et al. [21] produced this infographic defining the impact of inadequate preoperative nutritional status (Fig. 7.7).

However, surgeons' understanding of this has not easily translated to universally applicable recommendations for our patient population. Options to use a diseased gastrointestinal tract to improve nutrition are limited. Making nutritional preparation for CRS more challenging is the difficulty of clinically diagnosing malnutrition. A fast screening plan is proposed by the ASER and PeriOperative Quality Initiative (www.POQI.org) consensus statement by Wischmeyer et al. [21] (https://thepoqi.org/POQI-2-Manuscripts). Detailed discussion of preoperative supplements and the rare indication for parenteral preoperative repletion is available in the online resource linked above. Generally, the recommendations include protein calories, regular mineral and vitamin supplements, and evaluation for nutrient deficiencies and potential directed supplements. Practical implementation is

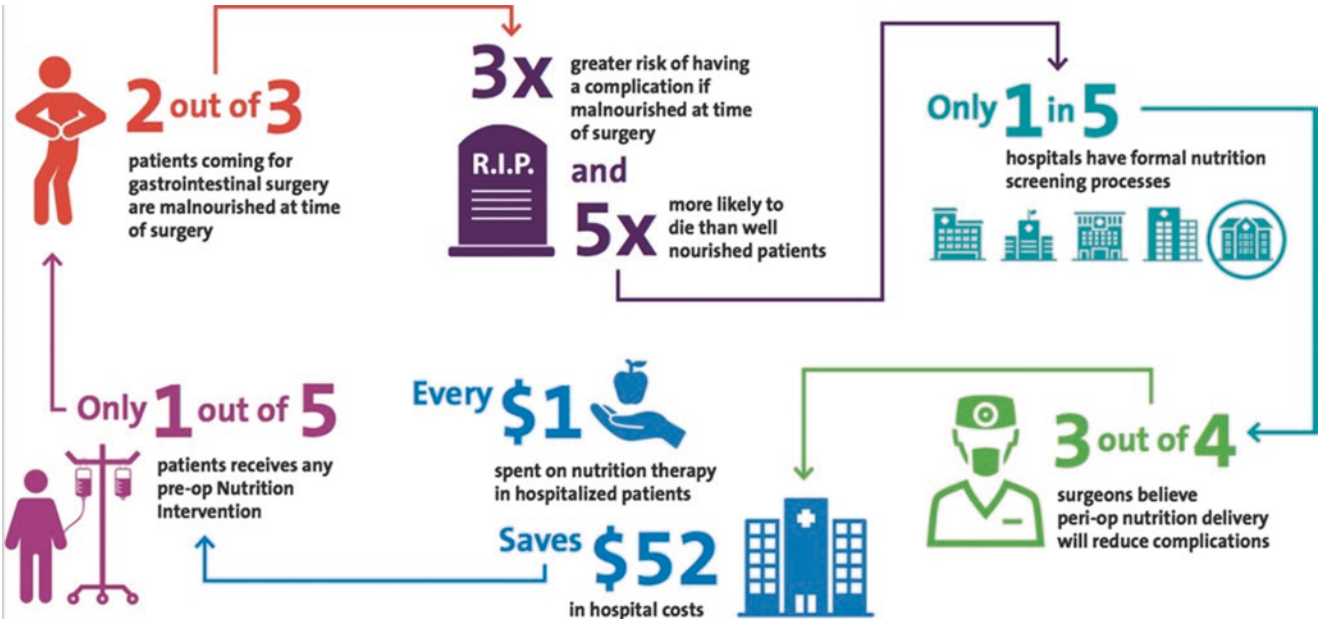

Fig. 7.7 Impact of perioperative malnutrition (Reused with permission from Ref. [21]. Copyright © Wolters Kluwer)

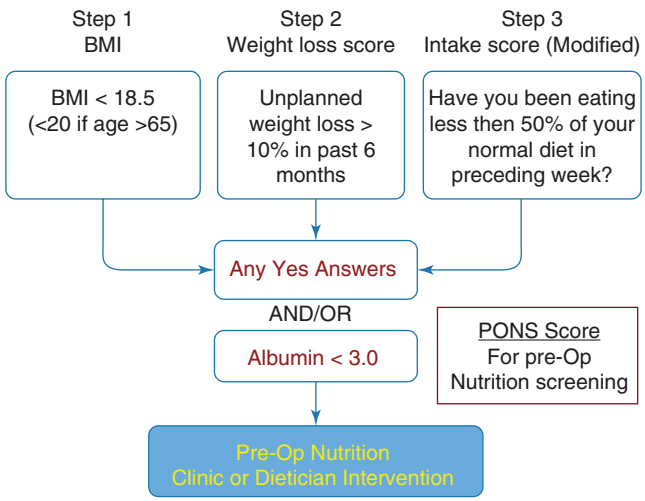

Fig. 7.8 PONS Score for preoperative nutritional assessment (Reused with permission from Ref. [21]. Copyright © Wolters Kluwer)

to wait for uptrending weight and prealbumin to ensure improvement. To minimize complications, prealbumin and other nutritional parameters should be normal before operation (Fig. 7.8).

Preoperative Anemia

Anemia is a significant and modifiable risk factor for worse outcomes from elective operations; however it is not uncommon for surgeons to feel helpless in correcting anemia in the GI surgery patient. Chronic GI losses are often the culprit of preoperative anemia in our patients, and until the operation, the source of bleeding exists. Here, we have created a practical management guide by summarizing recommendations for our patient population (Fig. 7.9) [22–24].

Perioperative Hyperglycemia

Perioperative hyperglycemia is strongly associated with increased infections, reoperations, and death; however, this increased risk is not seen in patients who are well-managed around the time of operation with insulin therapy. This is well described in a review of 11,633 patients in the Surgical Care and Outcomes Assessment Program in Washington State [25]. Good perioperative management of hyperglycemia must start with good preoperative management [26]. Kiren et al. added to our understanding that the degree of hyperglycemia is linearly associated with the severity of complication [27]. Elaborate management of diabetics and non-diabetics with elevated blood sugar in preparation and around the time of surgery has been created. However, most of the recommendations are part of algorithms for preoperative optimization before complete elective operations, such as knee replacements or ventral hernia repairs. Our population of colorectal surgery patients may be able to work on optimization for 2–4 weeks; however longer delays, referral to endocrinology, and documented improvement in HbA_{1C} are not reasonable. As per American Diabetes Association screening guidelines, the following patients meet criteria for HbA^{1C} screening: over 45 years of age; personal history of diabetes (DM1, DM2, or gestational); polycystic ovarian disease; or abnormally high fasting blood glucose. Additionally, a patient with BMI >/= 25 and anyone with inactive lifestyle; HTN; hyperlipidemia; or first-degree relative with diabetes should be tested [28]. The above evidence

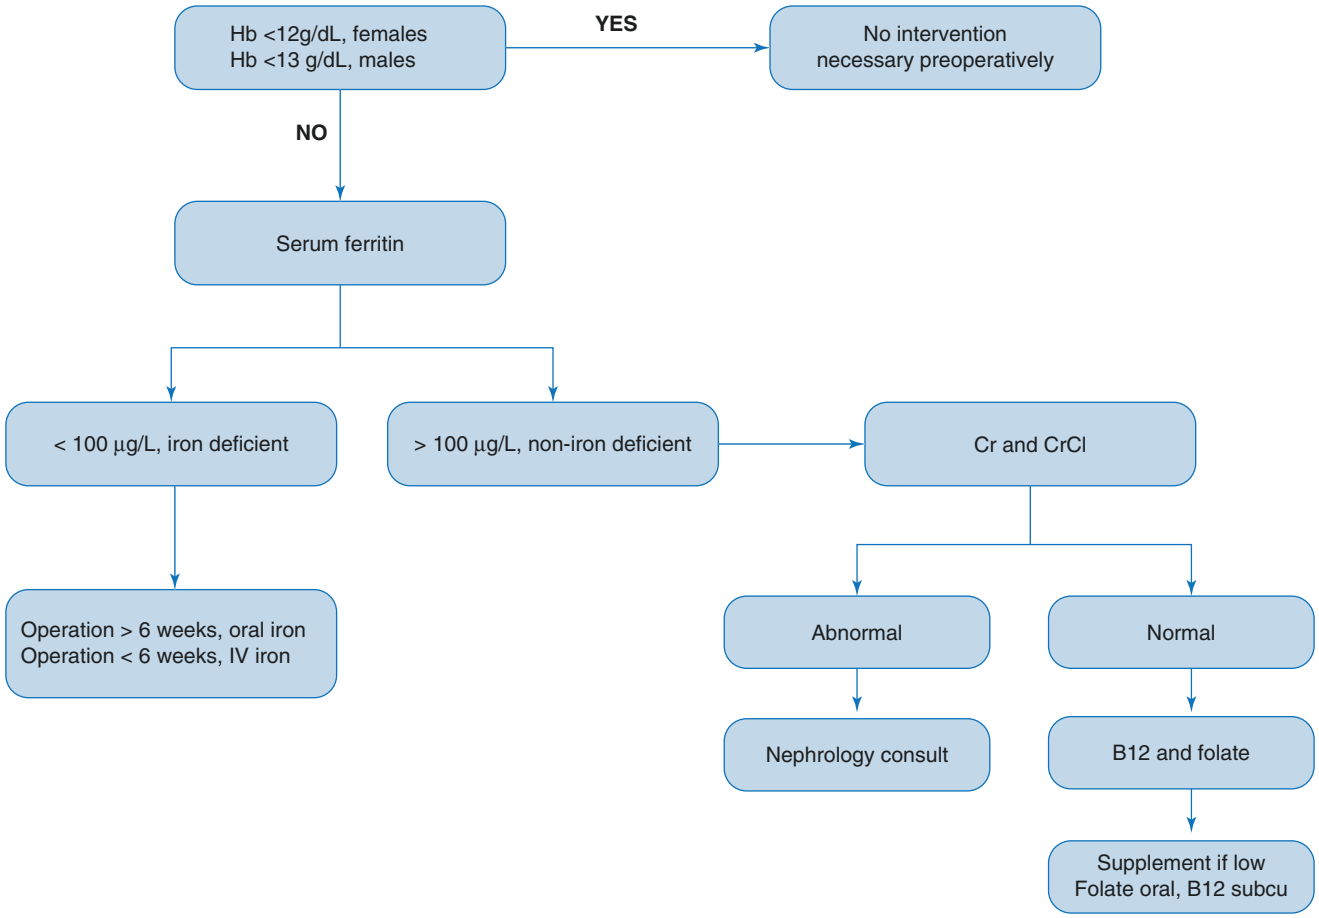

Fig. 7.9 Practical consideration of preoperative anemia in elective CRS

and recommended protocol elements are summarized in functional guide to blood sugar management in elective CRS (Fig. 7.10) [29–31].

Preoperative Fasting Period and Preoperative Carbohydrate Drink

The origins of ERAS Society guidelines date back to work on insulin resistance and the use of preoperative carbohydrate loading by Ljungqvist [32]. In animal trauma models and then in human surgical patients, his lab showed that pre-stress maltodextrin carbohydrate loading decreased postoperative insulin resistance and complications. Currently many products are available commercially and to health systems to fulfill this element. Notably, just carbohydrates, without the studied maltodextrin source, have not been shown to have the same effect. The mechanism of preoperative carbohydrate influence on postoperative insulin resistance has been described as being mediated by AMP-activated protein kinase activation [33]. With this understanding, perhaps more in-depth analysis of the best preop carb drink can be accomplished.

Preoperative carbohydrates and other liberal clear fluids should be encouraged as part of enhanced recovery perioperative preparation. The American Society of Anesthesia guidelines include preoperative clear fluid intake to continue up to 2 hours before induction of general anesthesia [34]. The challenge to institute this recommendation from over 40 years ago is a good reminder of the teamwork that must go into practice changes across phases of care.

Bowel Preparation

Bowel preparation, with antegrade laxative preparation and oral antibiotics, is recommended for operations with a planned lower bowel resection. The literature was recently reviewed, and guidelines were published by the ASCRS Practice Guidelines Committee [35]. Early ERAS Society guidelines did not endorse routine mechanical bowel preparation. However, the evidence of benefit since the earlier ERAS guidelines is robust and clear; most current enhanced recovery programs for CRS include bowel prep.

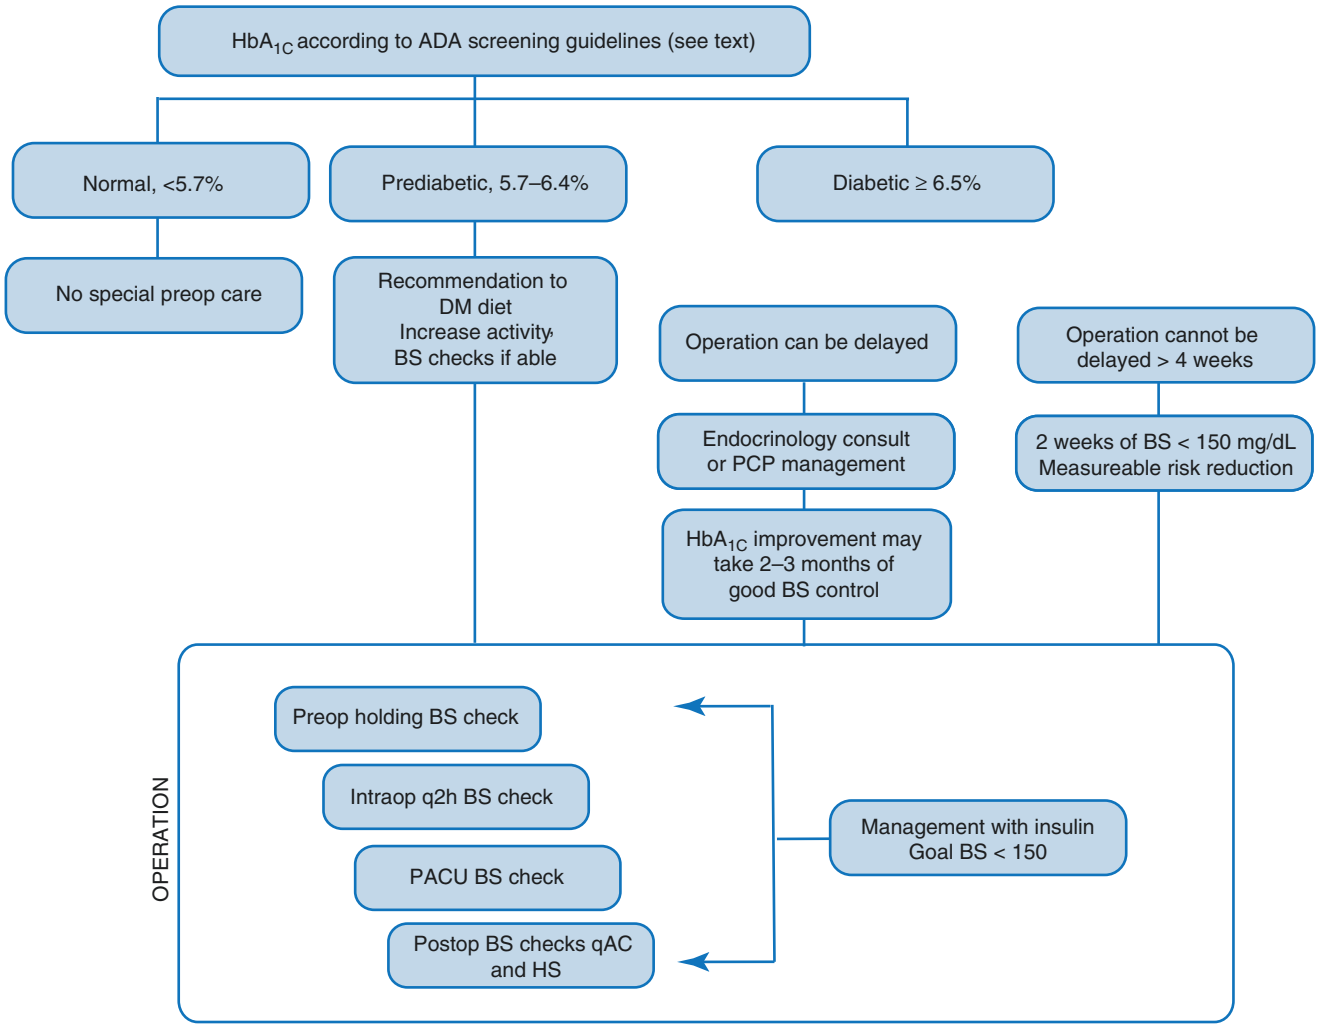

Fig. 7.10 Practical consideration of preoperative hyperglycemia in elective CRS

In-hospital Preoperative Enhanced Recovery Elements

Education and continued, constant messaging are essential for patient participation and stress reduction. At the time of admission, many elements that will continue throughout the hospitalization begin in the preoperative holding area.

Prevention of Postoperative Nausea and Vomiting (PONV)

Combatting the common complication of nausea after general anesthesia must begin in the preoperative space. The role of the surgeon is to identify patients at increased risk and to ensure pre-emptive management by anesthesia. Gan et al. updated the guidelines for the management of PONV; included is an easy cursory scale for PONV risk [36]. Each binary risk factor is 1 point if present: female, non-smoker, history of PONV, or postoperative opioids. These factors are additive, with baseline PONV risk of 10%, any one risk factor correlates to 20%, any two 40%, and any three 60%. If all four risk factors are present, there is an 80% chance of PONV. This prediction model should be applied in preoperative clinic to inform the patient and the anesthesia team before general anesthesia to consider prophylaxis in at-risk patients. Most enhanced recovery protocols include multimodal PONV prophylaxis as per anesthesia recommendations [37].

Multimodal Analgesia (MMA)

Pain receptors and the sensation of pain are mediated by several pathways. Opioids impact a patient's sensation of pain, but opioid-related complications can be minimized or completely avoided by strategies to impact different pain pathways simultaneously [38]. While it might be too stringent to aim for narcotic-free major CRS, the key to MMA is to recognize the cost of each narcotic dose. Even an exposure of as little as ten morphine equivalents has been associated with an increase incidence of postoperative ileus in CRS [39]. A scheme to summarize general MMA approaches is shown (Fig. 7.11).

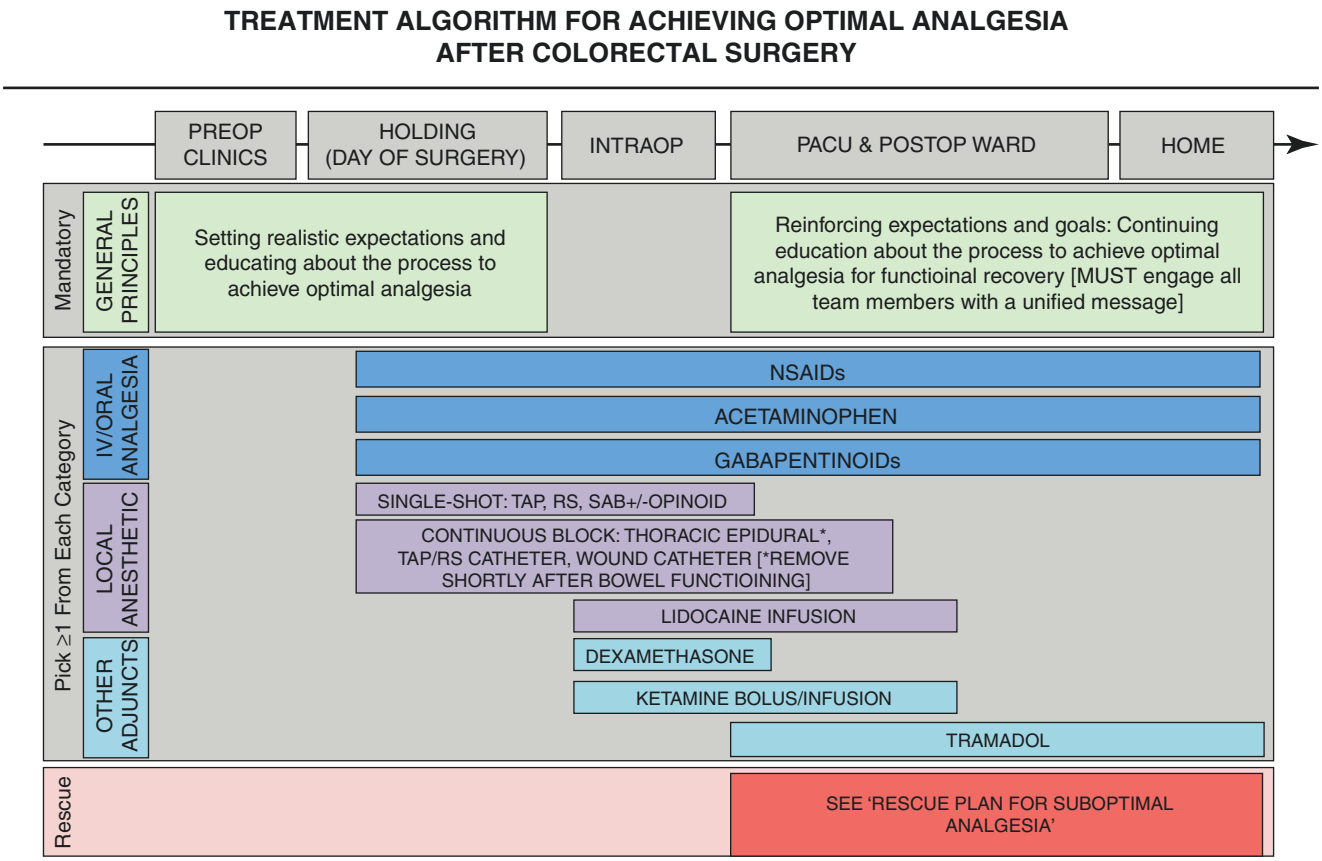

Fig. 7.11 PeriOperative Quality Initiative multimodal analgesia strategy [38]

Multimodal analgesia in enhanced recovery always raises discussion of epidural as a mandatory element. What is often missed in interpretation of earlier ERAS guidelines is the incidence of open operation. Current recommendations for open CRS still include epidural analgesia if the use is supported locally [40, 41]. If inadequate experience and oversight exists, epidurals can increase time to mobility, urinary catheter removal, and discharge. The authors offer experience of expeditiously placed, safely managed epidurals with extremely high success rates and decreased costs [12]. Many other non-catheter blocks are available and in combination with other components of MMA are more appropriate than epidural catheters for MIS cases. They may also be proven to be more appropriate for open cases.

Multimodal analgesia is aggressively studied and re-evaluated with each new pain medicine released. The plan shown above summarized an MMA model with recommendations current to its publication. Some evidence suggests that gabapentin may be related with drowsiness and respiratory depression, and the use oral acetaminophen before placement of gastric decompression may not be as effective as intravenous acetaminophen at fascial closure. Improvement in MMA can be made about every 6–9 months to keep pace with the literature. The pain management scheme for ERAS protocols should be addressed with every interval protocol review. The perception of providers must be that MMA is effective since the implementation of an enhanced recovery protocol was associated with increased use of perioperative MMA in non-ERP patients [42].

VTE Prophylaxis and Antibiotics

Evidence for best VTE strategies and antibiotic coverage for CRS is well established in the literature and elsewhere in this text (Chap. 6). The line item is included here to remind surgeons that not everyone along the continuum of the patient's surgical journey will know these details. The appropriate preoperative antibiotic and the VTE prophylaxis timing, inpatient plan, and plan at discharge with required teaching must be visible to the entire team.

Intraoperative Enhanced Recovery Elements

Surgical outcomes are impacted by every aspect of care while the patient is in the operating room – every dose of narcotic, every liter of fluid, every tube or drain, every incision. While it is impossible to study any one intraop care element independent of the rest of the operation, general principles have been investigated. Including the anesthesiology team throughout the creation of an enhanced recovery pathway is essential for success.

Multimodal Analgesia

MMA must continue during general anesthesia. The details of medication combinations, available blocks and neuraxial approaches, as well as intraop and postop infusional choices are all subject to local formularies and anesthesiologists' talents and preferences. The anesthesia team's knowledge of ERAS and their expertise relative to narcotic-sparing management has to be garnered during the creation of any enhanced recovery pathway. Infusional lidocaine has been shown to be effective in center reports, but Cochrane review failed to find convincing evidence for recommendation [43].

Intentional Fluid Management

The evidence supporting the safest fluid management for intraoperative enhanced recovery is still evolving. There was little discussion of fluid management in the first colorectal ERAS guidelines, as this was developing in the anesthesiology literature simultaneously. Studies and opinions about this are now abundant; most are anesthesiologist designed and directed.

Specifically, trial design often includes a statement such as "an enhanced recovery pathway was in place," and a diversity of patient populations are included to ensure power. In the larger trials, from which the anesthesiology community is defining their understanding of best fluid management, surgical outcomes, such as length of stay in the hospital, readmissions, surgical complications, and ileus, are recorded. However, the postoperative fluid management is not reviewed. As has been proven, excessive or inadequate fluid management postoperative also impacts these same outcomes. The data can be difficult to interpret.

Contradiction between "restrictive and liberal" protocols can be clarified by analysis of the details. Myles et al. claimed higher incidences of acute kidney injury (AKI), in enhanced recovery protocol patients who randomized to the restrictive fluid arm of a multinational study of over 3000 [44]. Given there was no analysis of the enhanced recovery elements or preoperative fluid allowance, this study also lacked direction for perioperative fluid management. The thoughtful comments of a surgeon in Denmark who has studied perioperative fluid management since the 1990s are helpful describing the benefits of intentional fluid management and limitations of the Myles study [45]. Evidence for best fluid management is still accruing; therefore watching for studies with a defined perioperative protocol and deeper evaluation than just high-level, reported surgical outcomes is prudent. Though the Myles study showed association with AKI, a careful observational study out of Mayo failed to show increased AKI in ERAS. Their chief finding, however, was potential increase of ileus in patients receiving greater volumes of fluid on their protocol [46].

As we await further science behind patient responses to fluid and associated surgical outcomes with well-defined care protocols [47], safest and cheapest management of fluid around the time of colorectal operations has three tenets [48, 50]:

1. Liberal fluid encouraged during bowel prep and until 2 hours before induction of general anesthesia.
2. Zero-balance intraoperative fluid management based on weight.
3. Normotension and urine output should be maintained with reactive intravenous fluid until oral intake is adequate.

Minimally Invasive Surgical Approaches

Discussed previously and covered thoroughly elsewhere in this text, minimally invasive approaches decrease surgical stress and improve outcomes. These benefits are additive when combined with enhanced recovery care plans [51].

Minimal Use for Drains, Tubes, and Lines

Early in literature for enhanced recovery, the promotion of minimizing the use of intra-abdominal drains, nasogastric tubes (NGT), and central venous access lines (CVL) was promoted. These recommendations persist with evidence of no benefit to abdominal drains; harm with NGT except in obstruction; and increased infection and complication with CVL [51, 52].

Postoperative Enhanced Recovery

Aarts et al. reported a review by the iERAS group in Canada that postoperative ERAS interventions have the greatest impact on optimal recovery [53]. Confounded by the fact that postoperative elements are more successful if earlier occurring elements show high compliance, the postoperative phase is, indeed, the longest of the in-patient phases and the most impactful on outcomes.

Early Diet, Early Mobilization, and Early Oral Medications

The success of postoperative elements of enhanced recovery often demonstrates the success of earlier elements. Education leads the patient toward a low stress discharge plan. A minimally stressful operation results in faster return to regular diet and oral management of fluid needs. Well-managed, opioid-sparing analgesia is less likely to result in ileus. The elements of immediate diet and mobilization are well supported as safe and beneficial. Low residue diet is better than clear liquid diet at promoting earlier return of bowel function and earlier discharge with fewer complications [54]. However, Clough et al. showed persistent reluctance to adopt early feeding in a comparative cohort study. Lack of adoption of these well-founded elements further represents the need for evidence-based care protocol implementation, such as enhanced recovery [55].

Multimodal Analgesia

Details of MMA are discussed above. Important aspects of MMA in the postop period include rescue therapy and education. Not all patients will be well-managed with the prescribed MMA. Anxiety and pre-existing pain conditions make postop analgesia challenging. ASER-POQI 2 addressed this with the rescue plan shown in Fig. 7.12 [38].

Postoperative reiteration of the goals of MMA, medication names, and an opioid-sparing plan is essential. This message needs to be consistent from the first dose of medication in the postoperative experience, through discharge instructions, and with the clinic contacts after discharge.

Standard Discharge Criteria

An international consensus to determine readiness for discharge criteria created a simple five-item list [56]. GI function and general recovery are well assessed by solid diet tolerance, adequate liquid intake, oral pain management, and activity. Objective readiness is confirmed with ward data, such as blood pressure, heart rate, urine output, temperature, and spontaneous voiding. A rigorous and well-known enhanced recovery program demonstrated that the delays typical of discharge after a patient meets discharge criteria are minimized with standard practice. In the review at McGill, readiness for discharge and actual discharge most often were at the expected 3 days after colorectal resection [57].

Considerations in Special ERAS Populations

Enhanced Recovery in Stoma Creation and Reversal

Diverting ileostomy is a frequent source of delayed discharge and readmission. High ileostomy output and dehydration readmission rates are reported in up to 15% of these patients. Index admission length of stay among diverted patients has been shown to be prolonged significantly, mitigating the effects of laparoscopy on LOS [58], even in the context of an ERP [59]. With the expected expedited recovery on an ERAS protocol, new ileostomy patients leave the hospital sooner, leaving little time for a patient with a newly formed stoma to learn the practical skills of caring for the stoma. In fact, many studies looking at the impact of ERAS exclude patients undergoing stoma creations. This section discusses the application of ERAS to even these patients and the special considerations necessary.

A controlled randomized study [60] out of Norway investigated whether an ERAS program with a dedicated ERAS and stoma nurse specialist could reduce the length of hospital stay, readmission, and stoma-related complications, compared to standard of care pathways in patients undergoing planned stoma. Preoperative and postoperative stoma education in the context of an ERAS program was associated with a significantly shorter hospital stay with no difference in

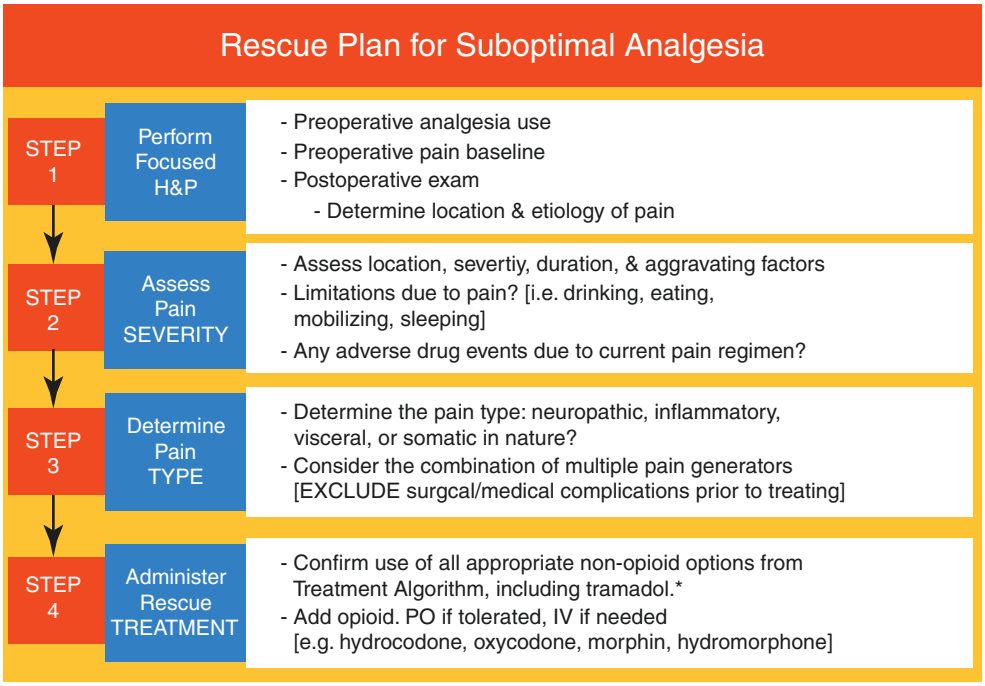

Fig. 7.12 Rescue plan in MMA breakthrough. *MMA* Multimodal analgesia [38]

readmission rate or early stoma-related complications. In a UK-based pre-/post-ERAS study of anterior resection patients with ileostomy, Younis et al. [61] showed significant reductions in average LOS (nearly half) with preoperative stoma management teaching as part of an ERP. The readmission rates in both groups were low (2.5% pre-ERP vs. 0% post-ERP), and none was due to stoma management issues. Patients were closely monitored in the community by stoma care specialist nurses and any stoma complications managed promptly in conjunction with GPs. This is in line with other studies that confirm that length of hospital stay need not to be prolonged among patients with a stoma if adequate patient education is provided [62], particularly in the context of ERAS [63, 64]. The Ontario Provincial ERAS Enterostomal Therapy Nurse Network recently published best practice guidelines for care of patients with fecal diversion [65], addressing coordinated preoperative, postoperative, as well as discharge phases of care in the community, in order to improve outcomes, decrease complications, and reduce hospital costs.

ERAS in Emergency Surgery and Trauma

ERAS is well established in elective colorectal surgery; however the feasibility and benefit of ERAS in emergency colorectal surgery has only been reviewed more recently. In 2019, Lohsiriwat et al. [66] reviewed six retrospective observational studies [67–72] on patients undergoing emergency operations managed by enhanced recovery principles. The authors concluded the following: (1) Compared to ERAS-CRS for elective cases, ERAS after emergency colorectal surgeries is associated with a longer length of stay and a higher rate of unplanned reoperation without a difference in rates of anastomotic leak or readmission. Overall compliance with ERAS protocol was lower, with comparable compliance to elective cases in the operating room. (2) Compared to emergency surgeries performed without ERAS programs, ERAS is safely applicable in emergency colorectal surgery and confers similar beneficial effects seen in the elective setting.

A recent meta-analysis of 6 ERAS protocols in 1334 total emergency abdominal surgery patients [73] confirms these findings. The authors conclude that ERAS protocols favorably resulted in reduced postoperative complications, accelerated recovery of bowel function, and shorter length of stay without increased readmission in emergency abdominal surgery patients. As in all patient populations, ERAS in emergency colorectal surgery should be guided by the concept of reducing stress responses to surgery [74].

Enhanced Recovery in the Elderly

ERAS pathways in the elderly are safe and effective. Bagnall et al. [75] performed a systematic review that included 16 studies involving 5965 patients who underwent colorectal surgery. Two randomized controlled trials demonstrated shorter hospital stay and fewer complications in elderly patients >65 and >70 years of age who were on an ERAS pathway compared with an age-matched group receiving standard perioperative care. There are no significant differences in morbidity and mortality between the elderly and younger patients on ERAS pathways, although older patients tended to have a longer length of stay compared to the younger patients. Only two studies in the systematic review above reported any data on adherence to the ERAS pathway: Rumstadt et al. [76] found lower compliance among patients >79 years of age (not the group of patients age 70–79 years). Feroci et al. [77] showed that patients age >75 years had poor adherence to many postoperative items. In this study, poor compliance in this age group was the greatest predictor of poor outcomes. However, two later studies [78, 79] did not show any effect of age on adherence to ERAS pathway, and they did not demonstrate a difference in morbidity or mortality. Interestingly, Baek et al. found that there was no difference among older versus younger patients in return of bowel function, diet advancement, urinary catheter removal, complications, or length of hospital stay, but there were increased rates of emergency room visits and readmission in older patients [80]. The most recent study by Owodunni et al. [81] evaluating compliance to ERAS pathway in patients age ≥ 65 years did not show any significant difference in overall compliance rates compared to younger patients. While ERAS intervention in the older patients resulted in significant decrease in length of hospital stay, a further reduction in length of stay occurred in ERAS patients undergoing laparoscopy. In all studies, the greatest benefit was seen in older patients achieving high compliance with the ERAS variables.

A recent Italian study confirmed the feasibility, safety, and benefit of a tailored ERAS program in octogenarian patients undergoing minimally invasive surgery for colorectal cancer [82]. The majority of patients met release criteria in a median of 5 days, which was significantly shorter than the actual days of dismissal (6+/−4.2). The authors commented that a consideration should be made for the very elderly for whom length of hospital stay could be a misleading outcome; readiness to discharge might be a more accurate measure. They speculate that several factors may explain the discordance between these variables including social and geographical isolation, unavailability of nursing assistance, and limitation of communication with caregivers.

Management on an ERAS pathway appears to be safe and beneficial in the elderly, though with slightly lower rates of adherence to certain aspects of the protocol and increased length of hospital stay and readmission compared to the younger patients. These differences in adherence and outcome in the elderly are likely due to their comorbidities and baseline functional status [74]. Caution must be taken to not overinterpret "lower compliance," when compliance is considered across a population. Enhanced recovery, at its best, is patient-focused. The geriatric patient on anticoagulation, who does not qualify for an epidural, is not non-compliant for that element. The patient is not eligible, and should not be considered non-compliant. However, that ineligibility may, indeed, portend a slower recovery.

Enhanced Recovery and Inflammatory Bowel Disease

Patients with inflammatory bowel disease (IBD) frequently present with malnutrition, immunosuppression, anemia, as well as intra-abdominal abscesses, fistulas, and bowel obstruction placing them at higher risk for significant postoperative morbidity. As such, patients undergoing surgery for IBD, as a group, have prolonged hospitalizations and increased readmissions and hospital costs. In addition, many IBD operations are less suitable for laparoscopy. This drives the question whether enhanced recovery would be able to achieve similar benefits in IBD patients as in patients with colorectal cancer or other benign conditions.

Ban et al. [83] investigating the American College of Surgeons National Surgical Quality Improvement Program (NSQIP) database for patients with enhanced recovery variable data undergoing elective colectomy have shown that a preoperative diagnosis of IBD is associated with prolonged length of stay and higher odds of readmissions and morbidity/mortality when compared with patients who had undergone colectomies for non-IBD diagnoses. In a single-institution ERAS retrospective analysis, Dai et al. [84] demonstrated that IBD patients had higher incidence of postoperative ileus compared to colorectal cancer patients (28.8% vs. 14.8% ($P < 0.001$), respectively). The results from these two studies do in fact question whether there is any benefit in ERAS protocols for IBD patients in the first place.

Enhanced recovery pathways do improve outcomes after bowel resection for IBD. D'Andrea et al. [85] analyzed pre-/post-ERP implementation IBD patients undergoing elective bowel resection. The ERAS group had significantly reduced rates of SSI, ileus, and anastomotic leak with a decreasing trend in the LOS, readmission, reoperation, sepsis, and wound disruption. Another pre-/post-ERAS study showed ERAS-managed IBD patients had reduced LOS and hospital costs without an associated increase in complications or readmissions. In addition, MIS was independently associated with reduced LOS, while ERP within the MIS group was associated with an even shorter LOS. Crohn's disease (CD) diagnosis was associated with a longer LOS. However, the post-ERP group still had a shorter LOS despite having a higher rate of CD. Patients with IBD undergoing major abdominal and pelvic surgery, despite being a complex patient population, benefit from the implementation of an ERP, at least with respect to LOS and in-hospital costs.

Clearly ERAS principles are widely applicable and beneficial to these unique patient populations. Increased physician and nursing training to promote widespread implementation and adherence to ERAS principles (as many as feasibly possible) can further improve the quality and cost of healthcare administered. Modified programs are appropriate for different patient populations, with the common goal of decreasing surgical stress and its effects and costs.

Economic Impact and Value of Enhanced Recovery to the Healthcare System

In the most recent systematic review and meta-analysis on cost analysis of ERPs in colorectal surgery, ERP induced mean saving costs of $3101 USD per patient [86]. It is generally accepted that ERPs reduce healthcare costs by virtue of shorter duration of hospital stay and decreased rate of complications without increasing readmission rates, as demonstrated in several systematic reviews [87–89]. These pathways achieve such cost savings by using defined evidence-based processes that are monitored to allow optimal resource management and minimal variability. Roulin et al. [90] found specific gains in medication, laboratory, and radiology costs. Standardization not only ensures that patients receive routine care items that might otherwise be forgotten, it also prevents unnecessary diagnostics without increasing the complication rate.

However, there are many limitations when examining the mechanisms of impact of ERPs on cost using these traditional audit measures [70, 91, 92]. The true costs and systemic values need to be considered. Future economic models of ERP costs need to incorporate societal costs and patient, as well as recovery-centric outcomes, in addition to the traditional audit measures. In fact, ERAS can and should fulfill what is now referred to as the "Quadruple Aim": achieving not only better patient outcomes, at a lower cost, and improved patient satisfaction but also medical, nursing, and provider satisfaction [93–96]. A recent review of the literature by Li et al. [97] confirms that the application of ERAS pathways following colorectal surgery does not lead to worse outcomes in patient satisfaction, quality of life, fatigue, and return to activities: however, no publications have assessed surgeon or care provider satisfaction with ERAS pathways.

Current Directions and the Future of ERAS

Societies and Governments Assist Implementation Across Canada and the USA

ERAS is quickly becoming the standard of care in colorectal surgery. In North America, adoption of enhanced recovery has been mostly driven by individual providers or healthcare systems, without government collaboration or incentive. At our training centers, adoption has been occurring insidiously via substantive, unfunded academic effort and inculcating trainees by incorporation of ERAS principles in training and on certification exams [98]. Nonetheless, barriers to implementation remain a challenge. Results from a Canadian qualitative study suggest that although clinicians see the value in implementing an ERAS program, lack of nursing staff, lack of financial resources, resistance to change, and poor communication and collaboration are perceived as barriers to its adoption [99]. There is no unified enhanced recovery assessment program or compensation program in the USA, but the American Society for Enhanced Recovery (ASER) promotes best practice via multidisciplinary collaboration between surgical, anesthesia, certified registered nurse anesthetists, and nursing societies. In addition, quality initiatives and protocols that arise from ASER are undertaken with an understanding of US healthcare strategies – cost structures, interactions of siloed stakeholders, and shared outcomes without shared inflow of resources [98]. In an exceptional effort to expand the implementation of ERAS pathways across the USA, a multimillion-dollar grant was awarded by the US Agency for Healthcare Research and Quality (2017–2020). The "Safety Program for Improving Surgical Care and Recovery" team plans to introduce enhanced recovery in approximately 750 US hospitals [98, 99]. Similarly, in Canada, the Canadian Patient Safety Institute's Integrated Patient Safety Action Plan for Surgical Care Safety, with support from numerous partner organizations from across the country, formed Enhanced Recovery Canada (ERC) in 2017.

Future Directions

Innovation of technology provides opportunities to overcome challenges with ERAS [100–102]. Databases facilitate core data collection, ensure optimal adherence to protocols, and reduce variability in clinical care. More robust data collection is particularly useful for ERAS clinical studies [103]. In the future, such dataset will also allow us to investigate the impact of the perioperative period on long-term patient outcomes such as cancer survival or disease recurrence in IBD [100]. Wearable sensors measure, store, and transmit large amounts of patient and environmental data and have been used to objectively and continuously monitor physical activity (an important indicator of functional recovery) within the hospital setting and at home following discharge [104–106]. To provide a complete recovery picture beyond activity tracking, smart devices will also be ready to collect patient-reported outcome data concerning other relevant aspects of postoperative recovery [107, 108]. In recent years, the role of telemedicine (TM) in postoperative care, implemented by way of smart devices with text messaging or mobile health applications, including pictures and videos, has grown. TM has demonstrated excellent clinical outcomes, a high degree of patient satisfaction, decreased driving distance and wait times, and cost savings to both the patient and healthcare systems, particularly for surveillance after ambulatory surgery [109, 110]. A prospective multicenter study in France confirmed the feasibility of home surveillance by TM after major surgery, in colorectal patients within an ERP. TM with automatic alerts led to early, timely detection of postoperative complication and less time spent answering phone calls by the surgical team and avoided ER visits. A more recent cohort study [111] looked at an active post-discharge surveillance (APDS) program as part of an ERAS protocol in colorectal patients in the USA. The program's interface is also centered on a text messaging paradigm with automatic alerts and is accessible via any smart device or desktop. It employs automated protocols (defined by the surgery team) to automatically communicate with patients not only after discharge but also before and after surgery to ensure compliance with protocol perioperatively. Patients, physicians, office staff, nurses, care coordinators, and extended care nurses are all able to communicate and coordinate care via the APDS. The study also concluded that APDS allows many postoperative issues to be resolved in an outpatient setting without ER visits or readmissions. The biggest limitation in this study was attrition bias as patients enrolled in the APDS and engaging with the program initially would stop responding. It is unclear if this was due to technical difficulties or that patients were simply overwhelmed by the frequent reminders and checks. Future studies should look further into the difficulties of TM technology. Integrating patient-centered recovery data in electronic health records [112] will provide an opportunity for recovery auditing and further database-driven research aimed at quality improvement [107].

Summary

The principles of enhanced recovery require thoughtful analysis of the perioperative literature and application of the evidence to everyday care. This process has fit the practice of colorectal surgery as we are always striving for better outcomes in our patients with known risks having operations

with known complication profiles. Our specialty encompasses a significant portion of elective operations, providing us with research opportunities and volume to merit quality improvement efforts. The change management of enhanced recovery requires the development of a team that is then in place for whatever the next, best thing is. This deliverable, from working through the implementation phase of enhanced recovery, sets up colorectal practices and their hospitals for continuous, efficient improvement. The enhanced recovery process brings as much to the surgeon and system, as it does to our patient population. The authors' hope is that we as individuals and as change management agents keep an open mind to all possible future care improvement strategies and that we encourage an open platform for continuous improvement.

General Postoperative Complications

8

Daniel I. Chu and David J. Maron

Key Concepts

- Complications following colorectal surgery are not infrequent, making recognition and treatment an important component of the care of postoperative patients.
- Assessment of risk factors (particularly modifiable factors) can help to estimate and reduce the risk of postoperative complications.
- Gastrointestinal complications are the most frequent complications after major abdominal operations and range from minor nausea/vomiting to ileus and bowel obstruction.
- Postoperative bleeding and transfusions are the second most common complication following colorectal surgery, and additional complications such as venous thromboembolism can have major impacts on patients and healthcare systems.
- Infectious complications following colorectal surgery include surgical site infections (SSIs) – which include both incisional and organ space infections, as well as postoperative urinary tract infections and pseudomembranous colitis.
- Pulmonary complications in colorectal surgical patients include pneumonia, aspiration, and postoperative respiratory failure requiring prolonged ventilation.

Introduction

Every operation carries inherent risks for postoperative complications, and the field of colorectal surgery is certainly no different. Colorectal operations account for nearly 25% of all complications in general surgery [1] and have reported complication rates exceeding 35% [2, 3]. A query of data from the 2012 to 2017 American College of Surgeons National Surgical Quality Improvement Program (ACS-NSQIP) Procedure Targeted Colectomy database shows that the most frequent postoperative complication is ileus followed by bleeding and surgical site infections (Table 8.1). Less common complications include myocardial infarctions, pulmonary embolisms, and strokes (Table 8.1). While agencies such as the Centers for Medicare and Medicaid Services (CMS) view complications such as venous thromboembolism as key performance measures, it is increasingly clear that colorectal-specific complications such as ileus and anastomotic leaks have significant impacts on patients, providers, and healthcare systems [4]. It is therefore critical for colorectal surgeons to be able to recognize, understand, and manage a diverse set of complications as they will happen.

Several classification schemes exist to grade complications. One of the most commonly used is the Clavien-Dindo Classification [5, 6]. This classification scheme, refined since 1992, stratifies complications into seven grades (I, II, IIIa, IIIb, IVa, IVb, and V) with increasing severity from grade I (which represents any deviation from the normal postoperative course without a need for major intervention) to grade V (which represents death of a patient). Other classification schemes also exist including a more recently proposed Comprehensive Complication Index [7] by Clavien and Dindo, the Accordion scale [8], and the ACS-NSQIP classification of complications [9]. Despite the heterogeneity in these classification schemes, it is clear that complications matter, as they are associated with increased risks of patient mortality [4, 10], longer lengths of stay [1], more readmissions [4, 11], higher costs [12], and worse long-term oncologic outcomes [13]. Significant responsibility therefore lies with the colorectal surgeon to be experienced not only with performing the index operation(s) but also with managing postoperative complications.

The aims of this chapter will be to provide an overview of common risk factors for postoperative complications and to

Complications listed in order of overall frequency. All numbers expressed as % (frequency)

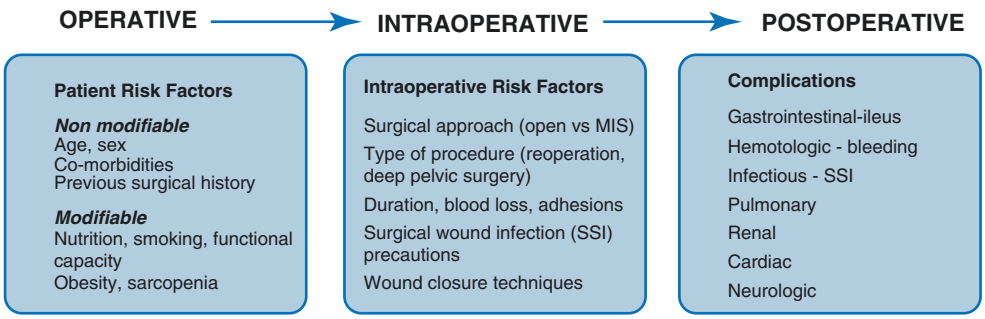

Fig. 8.1 Risk factors for postoperative complications in colorectal surgery

review the management of general complications in colorectal surgery. The discussion will be framed pragmatically in order of frequency of complications using the ACS-NSQIP. Successful acquisition and application of this knowledge will build a foundation for excellence in the care of colorectal surgery patients.

Risk Factors

Successful management of postoperative complications begins with a thorough understanding of the risk factors leading to those complications (Fig. 8.1). Some of these risk factors are non-modifiable (i.e., age and sex/gender), but others are potentially modifiable (i.e., nutrition and smoking). The latter risk factors are prime targets for single-level interventions (i.e., smoking cessation-only) versus more comprehensive interventions (i.e., prehabilitation and enhanced recovery pathways).

Non-modifiable Risk Factors

Age

Older age is a significant risk factor for postoperative complications. The reasons are multifactorial and due to decreased physiologic reserve, worse organ system function(s), cognitive impairment, and increased frailty [14]. Studies have shown that even within the geriatric population, increasing age is a strong independent predictor of mortality and postoperative complications [15, 16]. Among octogenarians [17] and nonagenarians [18], studies have suggested that common operations can be performed safely, but complication rates often exceed 25%. While age is non-modifiable, interventions can target age-associated risk factors such as poor nutrition, sarcopenia, and decreased physiologic reserve. Comprehensive recovery pathways such as Enhanced Recovery Programs (ERPs), for instance, have shown promising early results in improving surgical outcomes and reducing complications for the elderly [19].

Sex

Sex has been shown to be associated with risks of postoperative complications. Recent single-institution studies have associated the male sex with higher risks of complications for laparoscopic and open colorectal operations [15]. Within the ACS-NSQIP database, overall complications were higher for males across many major surgical procedures [20]. Similarly, males have been observed to be at higher risk for anastomotic leaks after colorectal operations [21]. While the underlying mechanism(s) are not clear, complication rates may be higher in males due to sex-based variations in risk prevalence at the patient level (i.e., smoking rates, cardiac disease, etc.) and procedure level (i.e., obesity, narrow pelvis, etc.).

Morbidities

Many patients undergoing colorectal surgery have preexisting comorbidities, and data has consistently shown that comorbidities are linked to the risk of developing a postoperative complication. Patients with American Society of Anesthesiology (ASA) scores of 3–5, for instance, are at significant risk of postoperative complications such as anastomotic leaks [22]. Similarly, patients with a high Charlson Comorbidity Index (CCI) are at increased risk for mortality and morbidities after colorectal operations [23–25]. Additional comorbidities have also been associated with postoperative complications including need for emergency surgery, body weight loss of >10%, use of steroids, congestive heart failure, renal insufficiency, and neurologic deficits [26]. More recent studies have suggested that comorbidities and comorbidity indices should not be considered in isolation. Patients often have "clusters" of comorbidities that in combination drive the risks for complications [27]. While some comorbidities may not be modifiable, a priori knowledge of them can at least provide some knowledge to better educate patients on risks and expected outcomes.

Prior Surgeries and Adhesion Formation

Prior abdominal surgical history is increasingly common, and colorectal surgeons often face reoperative scenarios. For laparoscopic operations, a history of prior abdominal surgery has been shown to be predictive of the need for open conversion, unintentional enterotomies, postoperative ileus, reoperations, and longer operative times [28]. Similarly, the presence of adhesions from prior operations appears to most influence colorectal resections with respect to adhesions-related complications [29]. While past surgical history is considered non-modifiable, experience of the colorectal surgeon is important to help mitigate complications in this circumstance.

Modifiable Risk Factors

Nutrition

Malnutrition is common and may occur in upward of 50% of surgical patients [30]. Several scoring systems such as the Nutrition Risk Screening (NRS) tool [31] and Malnutrition Universal Screening Tool (MUST) have been used effectively to screen patients for malnutrition and help predict outcomes [32]. Early studies since 2002 have demonstrated that preoperative optimization of nutrition benefits malnourished surgical patients [33]. While the optimal content of supplements are still debatable, studies suggests that oral immunonutrition, which often contains arginine and fatty acids, may be one of the key elements [34]. In a large population-based study of 3375 patients in Washington state, significant improvements in length of stay for surgical patients were observed for those on oral immunonutrition with reductions in postoperative complications [35]. Additional evidence suggests that oral supplementation at least 7–10 days prior to an elective operation (and parenteral nutrition only as needed) may improve nutritional status in a malnourished patient to ensure a better surgical outcome [36].

Smoking

Smoking is one of the most significant risk factors for postoperative complications. Multiple studies have associated smoking with complications such as surgical site infections [37], anastomotic leaks [38], and even disease recurrence in inflammatory bowel disease [39]. Smoking risk is modifiable. Randomized trials have shown that smoking abstinence/interventions at 4 weeks before surgery reduces postoperative complications such as wound infections to levels of nonsmokers [40, 41]. In another trial, initiating a preoperative smoking-cessation program 6–8 weeks before the surgical date significantly reduced postoperative complications from 31% to 5% [42]. A recent meta-analysis of 11 randomized controlled trials demonstrated a 44% pooled risk reduction of 30-day postoperative complications with smoking cessation [43]. While the most effective type of smoking-cessation intervention remains unclear, the evidence thus far indicates that preoperative smoking cessation should be a fundamental part of any complication risk-reduction strategy, especially for high-risk specialties such as colorectal surgery [44].

Preoperative Anemia

Anemia is a modifiable risk factor for postoperative complications. In a large ACS-NSQIP study of 23,348 elective open and laparoscopic colorectal operations, preoperative anemia was an independent risk factor for postoperative complica-

tions and longer length of stays [45]. More recent studies have also associated anemia with higher risk of postoperative complications [46]. Building evidence suggest that interventions with iron infusions and oral supplementation are effective and mitigate the risks of postoperative complications [47]. In a study on 95 colorectal cancer patients, correction of preoperative anemia with intravenous/oral iron restored hemoglobin levels to normal and corrected anemia patients required no postoperative transfusions (0% compared to 38% transfusion rates for uncorrected, anemic patients) [47]. Societies such as the American Society of Anesthesiologists have established guidelines on the perioperative management of anemia with interventions recommended if time permits [48]. More recently, the Enhanced Recovery After Surgery (ERAS) Society also incorporated anemia management into the most recent 2018 colorectal guidelines [36].

Sarcopenia

Sarcopenia describes the loss of muscle mass and strength that occurs with aging. It may be further accelerated with the presence of chronic diseases and is a result of multiple physiologic mechanisms including declines in growth hormones, nutritional insufficiency, decreased physical activity, and loss of alpha-motor neurons [49]. Retrospective studies in colorectal cancer have associated sarcopenia with an over 82% increased odds of postoperative complications after colorectal surgery [50, 51]. A recent meta-analysis of 29 studies in gastrointestinal cancers showed that sarcopenia was a consistent risk factor for major complications (risk ratio, 1.40) and overall complications (risk ratio, 1.35). Effective interventions to address sarcopenia have yet to be formalized but will undoubtedly work at multiple levels including improving functional capacity and nutritional status.

Obesity

Over a third of adults in the United States are currently obese, with predictions that over half of the US population will be obese by 2030 [52]. Obesity, defined as a body mass index (BMI) of greater than 30 kg/m^2, is increasingly common in the surgical population, and colorectal surgeons often manage these challenging patients. Studies have shown that obesity increases the risk of surgical complications after colorectal surgery [53, 54]. Data using the ACS-NSQIP has suggested that a dose-dependent relationship exists between BMI and complications with increasing obesity classes leading to increasing risks of complications such as surgical site infections [55]. Taken together, these data suggest that obesity is a modifiable risk factor that may be addressable using weight-loss interventions in the preoperative and elective setting [15].

Functional Exercise Capacity

The functional capacity of a patient is measurable and has been linked to surgical outcomes. Similar to athletic training, improving functional exercise capacity is possible. In one of the first studies on prehabilitation, Carli et al. demonstrated that moderate aerobic and resistance exercise significantly improved scores on walking tests [56]. While these improvements were not yet linkable to measurable reductions in postoperative complications, this study formed the basis for further studies that have suggested benefits of prehabilitation programs [44]. A large international, randomized controlled trial by van Rooijen et al. is currently underway to test the effects of a multimodal rehabilitation program on functional capacity (6-minute walk test) in surgical patients [57].

Open Surgical Approach

Open approaches in colorectal surgery have been associated with higher rates of postoperative complications [58]. In contrast, minimally invasive techniques are significantly associated with improved short-term outcomes including decreased surgical site infections, venous thromboembolism events, and pneumonias [58–60]. These associations are complex as hospital/surgical volume and clinical culture also play important roles in determining surgical outcomes [61]. Doing the best operation in the operating room, however, ensures the best start to surgical recovery, and the benefits of minimally invasive techniques are clear – this technique should therefore be utilized whenever possible and currently remains a central tenant of colorectal ERP pathways [36].

Assessing Risk Factors

Risk calculators use population-level data to quantify the risk of complications for individual patients. The POSSUM (Physiological and Operative Severity Score for the enUmeration of Mortality and morbidity) [62] and APACHE (Acute Physiology and Chronic Health Evaluation) [63] scoring systems are two original examples of validated scoring systems that use clinical information to risk stratify. A relatively newer system is the ACS-NSQIP Risk Calculator [64] which was developed to predict risk of postoperative complications, length of stay, mortality, and readmission based on patient- and procedure-level factors (Fig. 8.2). This powerful calculator continues to evolve with the steady accumulation of robust national data annually and identification of new risk factors. In fact, the ACS-NSQIP Risk Calculator was recently updated to include geriatric-specific risk factors to better predict outcomes for the growing geriatric population [65].

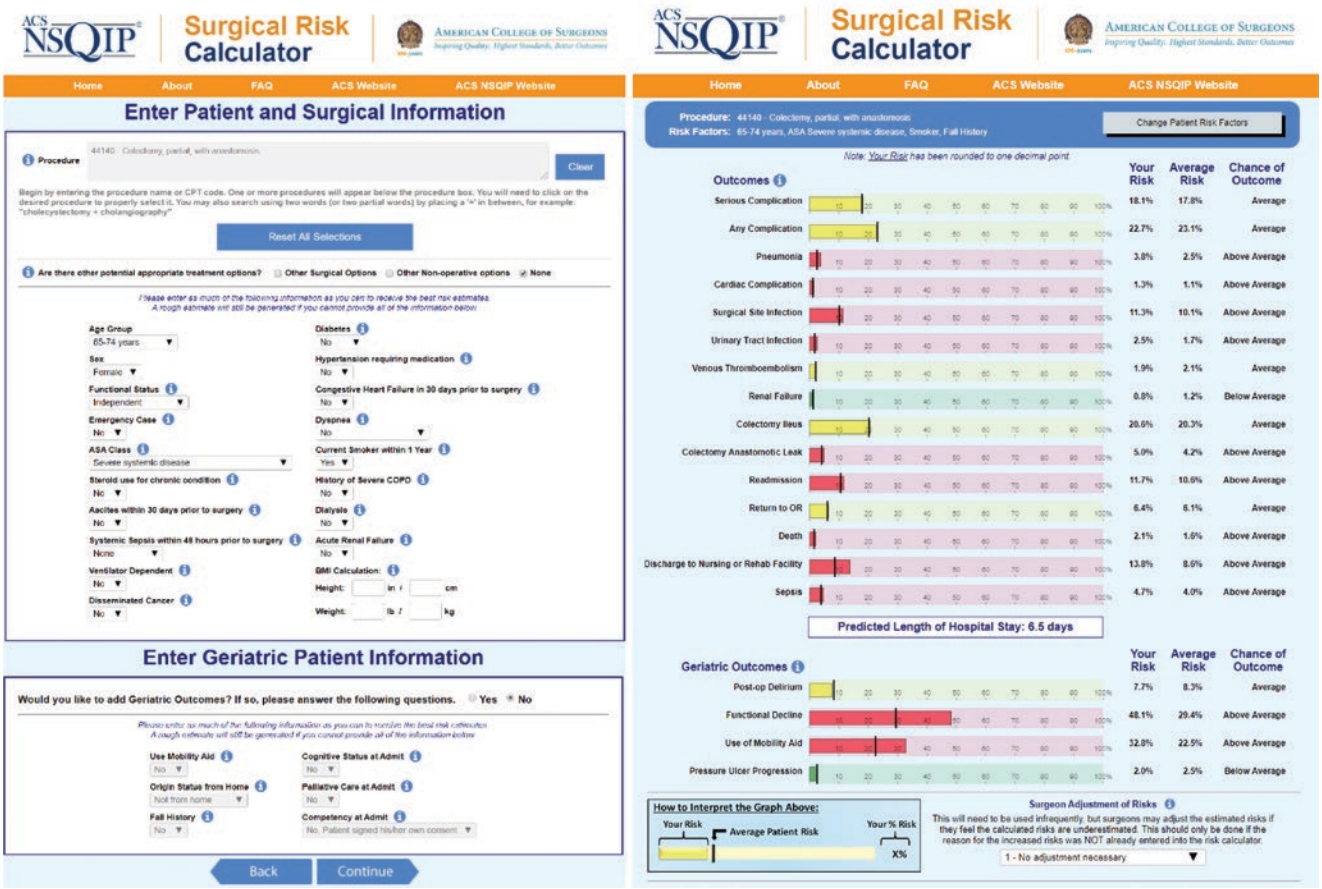

Fig. 8.2 The American College of Surgeons National Surgical Quality Improvement Program (ACS-NSQIP) Risk Calculator including new geriatric risk factors

Addressing Risk Factors

Once risk is identified, however, the question remains: What can be done? Single-item interventions to address individual risk factors such as malnutrition and smoking have previously been highlighted, but larger gains may be seen with more comprehensive and multilevel interventions. These include programs that are meant to optimize patients before major surgery such as the STRONG program [66] and comprehensive recovery programs such as Enhanced Recovery Programs which aim to mitigate the surgical stress and organ dysfunction associated with major surgery [36]. Prehabilitation is a relatively newer but synergistic program that has gained attention in addressing the risks of complications by specifically targeting risk factor categories (nutrition, smoking, obesity, and physical activity) before surgery [67]. Data is still limited, however, with the most recent study from Carli et al. (2020) showing no demonstrable improvement in reduction of complications as measured by the CCI [68]. Larger multi-institutional trials will aim to establish the effectiveness of such interventions [57].

Postoperative Complications

According to the 2012–2017 ACS-NSQIP database, the most common postoperative complications in colorectal surgery are (1) gastrointestinal complications (ileus), (2) hematologic complications (bleeding), and (3) infectious complications (surgical site infections [SSIs]) (Table 8.1). Other postoperative complications such as cardiac, renal, and pulmonary complications also occur in colorectal surgery but less frequently. This section will review the most common postoperative complications as guided by the ACS-NSQIP database. In addition, a review of other associated but important complications will be presented in an organ system approach.

Gastrointestinal Complications (#1)

Gastrointestinal complications are the most frequent complications after major abdominal operations and range from minor nausea/vomiting to ileus and obstructions. The sever-

ity of complications is determined by several risk factors including the type of operation performed, the approach (minimally invasive vs. open), and even blood loss during the case (Fig. 8.1) [69].

Ileus (Functional Bowel Obstruction)

Ileus, which is a functional obstruction of the small bowel, is the single most common complication after colorectal surgery. In the ACS-NSQIP, postoperative ileus rates occur in 12–17% of patients after colorectal surgery (Table 8.1) [4]. This complication drives significant lengths of stay and costs for healthcare systems [4]. The pathophysiology of ileus is unclear but is likely a consequence of disturbances to normal peristalsis governed by the enteric nervous system as a result of anesthetic and surgical manipulation [69]. Disturbances in the large bowel are called pseudo-obstruction or Ogilvie's syndrome [70]. Several factors are known to slow return of bowel function including medications (i.e., opioids), electrolyte abnormalities, inflammatory conditions, pain, and degree of operative manipulation. Patients present with symptoms of nausea, vomiting, bloating, burping, and hiccups in the absence of flatus or bowel movements. Abdominal distension and accompanied tympani are usually observed on physical exam. Abdominal radiographs and computed tomography (CT) scans show dilated loops of bowel but with no transition points or concerns for mechanical obstruction.

Studies have suggested that postoperative ileus can be subdivided into severe ileus and non-severe ileus [71]. In a prospective database from 40 international centers in 5 countries, the rates of severe and non-severe ileus were 9.3% and 6.1%, respectively, even under an Enhanced Recovery Program. Non-severe ileus, or a "primary" ileus, was best treated with nonoperative management including nasogastric tube decompression, bowel rest, intravenous fluids, mobilization, and avoidance of opioids. Severe ileus was very different and driven by intraabdominal complications such as abscesses. As a result, management for severe ileus centers on addressing the underlying insult.

Recommendations for treating functional obstruction such as ileus are to (i) ensure there is no mechanical component to the obstruction, (ii) start with nonoperative management with bowel rest and decompression, and (iii) address underlying causes (electrolyte abnormalities for non-severe ileus and intraabdominal pathology for severe ileus).

Postoperative Small Bowel Obstruction (Mechanical Bowel Obstruction)

Mechanical bowel obstructions in the postoperative setting for the small bowel and colon are most often caused by adhesions. For the small bowel, these obstructions are termed early postoperative small bowel obstructions (ESBO) and occur in upward of 9.5% of abdominal operations [72, 73]. ESBO clinically mimics postoperative ileus, and the differentiating the two can be difficult. Making the correct diagnosis is critical as there is an 8–9% strangulation risk with ESBO [72]. Compared to laparoscopic approaches, open cases are at increased risk for developing this complication. Diagnosis can be made through abdominal radiographs, which may show air-fluid levels in loops of small bowel, and CT scans, which may show a transition point. Strangulation is uncommon from the adhesions themselves, but increasing distension leads to bowel necrosis as mural tension leads to decreased mucosal perfusion. Treatment is usually initially nonoperative with nasogastric decompression, and success rates have been reported as high as 87% [73]. However, if the obstruction does not resolve, then the patient may require operative intervention. The time to wait remains controversial with reports showing safe waiting times from 24 hours to 7 days [74–76], but these decisions are complex and individualized. Reoperations are not without risk as there are increased risks for complications especially for those patients who had an index open operation [72].

Hematologic Complications (#2)

Colorectal operations affect the hematologic system directly and through the coagulation pathway. The 2012–2017 ACS-NSQIP data show that postoperative bleeding and transfusions are the second most common complication following colorectal surgery (Table 8.1). Additional complications such as venous thromboembolism occur less frequently but have major impacts on patients and healthcare systems.

Postoperative Bleeding and Transfusions

Bleeding requiring reoperation is rare after colorectal surgery, but bleeding requiring transfusions may occur in up to 10% of colorectal operations [77]. Risk factors for bleeding include intraoperative factors and medical coagulopathies such as hemophilia A (factor VIII deficiency), hemophilia B (factor IX deficiency), von Willebrand's disease, warfarin therapy, and platelet disorders [78]. One unique intraoperative factor that may lead to significant bleeding in colorectal surgery includes operations in the pelvis. The presacral space is lined by a presacral venous plexus that can be easily disrupted during proctectomy. Trauma to these veins may lead to massive hemorrhage [78].

All postoperative bleeding requires an assessment, resuscitation, and ultimately control. Mild bleeding with no systemic symptoms is often self-limited. Withholding anticoagulants and antiplatelet agents such as nonsteroidal anti-inflammatory drugs (NSAIDs) is first-line and effective step. Severe bleeding with systemic changes such as tachycardia and hypotension requires more aggressive interventions. While radiographic techniques such as CT angiography may be used to identify bleeding sources, delay may be fatal.

In a study of 196 reoperations for bleeding, 77% of takebacks occurred within 24 hours of the index operation with a 28% mortality rate [79]. An expeditious return to the operating room must always be considered if the patient demonstrates signs of exsanguination. Intraoperatively, the source needs to be localized and controlled, clots evacuated, and the peritoneal cavity carefully examined. It is not uncommon to find no active source of bleeding, especially after operations that require significant adhesiolysis and mobilization of retroperitoneal structures. In these situations, a reoperation is still useful as evacuation of the clot may help with achieving final hemostasis.

Presacral bleeding is a challenging situation that all colorectal surgeons must be able to manage. The algorithms are well-established and focus on initial control with packing, resuscitation, and then further action if bleeding persists. These additional actions include suture ligation, sterile thumbtacks, rectus muscle welding, and hemostatic agents [78]. The principles of damage control surgery are also relevant to massive presacral bleeding. In the situation where bleeding control cannot be established, patients should be temporized, packed, and taken back to the ICU to correct acidosis, coagulopathies, and hypothermia. A second operation is usually performed in 24–48 hours with the goal of restoring intestinal continuity, removing packing, and achieving final closure [78]. A related complication is abdominal compartment syndrome, a life-threatening condition that results from massive uncontrolled hemorrhage and/or aggressive resuscitation leading to increased abdominal pressure [80]. When pressures exceed 20 mmHg [78], the compartment must be rapidly decompressed to reestablish flow to the viscera, usually via an abdominal laparotomy. With decompression, symptoms tend to resolve. Complications are high, however, with multi-organ dysfunction and mortality rates approaching 50% [81].

Venous Thromboembolism

Venous thromboembolisms (VTEs) include deep vein thrombosis (DVT) and pulmonary embolism (PE). Colorectal surgery patients are at high risk for developing VTEs because many colorectal diseases such as cancer and inflammatory bowel disease create hypercoagulable states. Among colorectal surgical patients, VTE rates are reported from 1.1% to 2.5% [82]. While not as prevalent as complications such as ileus, VTEs are a common cause of preventable deaths. Many risk factors have been identified including obesity, steroid use, sepsis, reoperations, ASA class 3, and having another postoperative complication [82]. Based on these factors, the American College of Chest Physicians (ACCP) has published important guidelines on risk stratification to guide VTE prophylaxis [83]. These stratifications use validated scoring systems (Caprini Score and the Roger Score) to stratify patients to early ambulation, mechanical prophylaxis, or chemical prophylaxis with low-molecular-weight heparin (LMWH) or low-dose unfractionated heparin (LDUH). Diagnosis for VTEs can be made by (i) ultrasound scanning and D-dimer testing for DVTs and (ii) CT pulmonary angiography and/or D-dimer testing for PEs [84]. Ventilation perfusion scanning (V/Q scan) and V/Q SPECT are reserved for patients with contrast allergies or renal impairment. Prevention of VTEs is more effective than treatment of this complication. Once a VTE is diagnosed, treatment relies upon systemic anticoagulation with chemical agents such as LMWH, coumadin, or newer oral anticoagulants such as dabigatran, apixaban, or edoxaban. In cases where anticoagulation is contraindicated, inferior vena cava (IVC) filters need to be considered to prevent development of a fatal PE.

Infectious Complications (#3)

Infectious-related complications occur frequently after colorectal operations. These complications are usually related to the surgical site. However, infectious complications can occur well away from the surgical bed including urinary tract infections and *Clostridium difficile* infections.

Surgical Site Infection (SSI)

In the United States, an estimated 500,000 cases of surgical site infections (SSIs) are reported each year [85]. As the leading cause of nosocomial infections after surgery, SSIs add over 3.7 million excess hospital days and $10 billion in excess costs per year to the healthcare system [86]. SSIs also add significant morbidity with a 2–11 times higher risk of death for patients who experience an SSI [87]. Importantly, most SSIs are thought to be preventable [88]. Colorectal operations have one of the highest rates of SSIs with reported rates from 15% to over 30% [89].

SSIs are infections in areas where surgery was performed. Classically, SSIs are categorized to (1) superficial incisional (limited to skin/subcutaneous tissues), (2) deep incisional (involves muscle/fascia), and (3) organ space. Risk factors for SSIs include patient factors (i.e., age, nutritional status, diabetes, smoking, obesity, coexistent infection at another site, microorganism colonization, altered immune response, and duration of postoperative stay) and operative factors (i.e., preoperative antiseptic preparation, antimicrobial prophylaxis, duration of operation, operation room venting, use of foreign materials, surgical site, and surgical technique) (Fig. 8.1).

The WHO [90, 91], ACS/SIS [92], and CDC [93] guidelines are major publications that represent the consensus of multidisciplinary experts on SSI prevention strategies. The ACS/SIS, WHO, and CDC reviewed 17, 29, and 42 individual SSI reduction processes, respectively. Interestingly, only a minority of reviewed processes were recommended at the

Table 8.2 Centers for Disease Control and Prevention (CDC) recommendations on prevention of postoperative surgical site infections [93]

Evidence level	#	Specific recommendations	Level of recommendation
Category IA	8	1. Administer IV ABX before skin incision in all C-section procedures 2. In clean and clean-contaminated, do not administer additional IV ABX after incision closed, even in presence of a drain 3. Perioperative glycemic control and target <200 mg/d 4. Maintain perioperative normothermia 5. For patients with normal pulm function under GETA, administer increased FiO2 during surgery and after extubation in immediate postop period 6. Perform intraoperative skin prep with alcohol-based antiseptic agent 7. For prosthetic joint arthroplasty on immunosuppressive therapy, follow #2 8. For prosthetic joint arthroplasty, follow #2	Strong recommendation/ high-quality evidence
Category 1B	4	1. Administer ABX when indicated based on guidelines and time to incision 2. Do not apply antimicrobial agents to incision (topicals) for SSI prevention 3. Advise patients to shower or bathe (full body) with soap (antimicrobial or nonantimicrobial) or an antiseptic agent on at least the night before OR day 4. Do not withhold transfusion of necessary blood products to prevent SSI	Strong recommendation/ accepted practice
Category 2	5	1. Application of autologous platelet-rich plasma is not necessary 2. Consider use of triclosan-coated sutures for SSI prevention 3. Application of a microbial sealant after intraop skin prep is not necessary 4. Use of plastic adhesive drapes with or without antimicrobial properties is not necessary 5. Consider intraop irrigation of deep/subcut tissues with iodophor solution	Weak recommendation
No recommendation	25	1. No RCTs evaluating benefit/harms of weight-adjusted IV ABX dosing and effect 2. … [continues for 24 other parameters]	No recommendations

highest level of evidence. The CDC, for example, noted that only 12 processes had high-quality evidence to support their implementation and 25 processes had no recommendations whatsoever due to the lack of evidence (Table 8.2) [93]. The framework to approaching these guidelines, however, is to consider that there are "core" measures and "supplementary" measures. The former has the most evidence to back their use. The supplementary measures have limited evidence but are in-practice at many institutions.

When comparing the three guidelines, five core themes emerge. These include effective antibiotic prophylaxis, proper preparation of patients and surgeon skin, maintenance of normothermia, glycemic control, and FiO2 of >80% intraoperatively and postoperatively. Antibiotic prophylaxis remains the core of any SSI reduction bundle, as originally championed by SIP/SCIP, and focuses on administering the proper antibiotic within 1–2 hours before incision. Skin preparation focuses on alcohol-based antiseptics combined with agents such as chlorhexidine. Normothermia (≥36 °C) is recommended throughout the operation in addition to perioperative glycemic control, although specific glucose ranges vary across guidelines. Finally, maintaining high FiO2 (>80%) is the most consistent recommendation across all three guidelines. These five elements represent the core components of any effective SSI reduction bundle. Additional elements should be considered supplementary but left to the discretion of the institution to include with consideration of cost-effectiveness. Bowel preparation with a combination of mechanical and oral antibiotics, for example, is recommended by the American Society for Enhanced Recovery (ASER) to reduce the risk of SSIs after colorectal operations [94].

Treatments of SSIs are based on source control. For superficial infections, the treatment typically involves opening the incision, exploring the space, irrigating, and debriding the wound with subsequent regular wound care. Deep incisional and organ space infections may be amenable to percutaneous drainage under image guidance. Those that cannot be adequately drained, in the manner, necessitate a return to the operation room for exploration, washout, drainage, and debridement. Should implanted material be involved (i.e., infected synthetic mesh after a parastomal hernia repair), then it must be removed. Antibiotics alone do not usually address the underlying nidus of infection for deep incisional and organ space infections.

Anastomotic Leaks

Anastomotic leaks are perhaps the most feared complication in colorectal surgery and can occur with any intestinal reconstruction. This complication will be discussed extensively in Chap. 10 and will not be further covered here.

Wound Dehiscence

Wound dehiscence is a partial or complete disruption of any or all layers of the operative wound. Disruption with extrusion of abdominal viscera is evisceration, which requires immediate operation. Long-term effect of wound disruptions manifest as incisional hernias. Wound dehiscence is rare and occurs in 1–3% of colorectal surgeries [95]. Systemic and local factors contribute to the development of this complica-

tion. Systemic factors include any comorbid conditions that lead to poor wound healing (i.e., diabetes mellitus, uremia, impaired immune function, steroid use, poor nutritional status, cancer, obesity, and smoking). Local factors include inadequate closure, increased intra-abdominal pressure, and poor wound healing. In a Swedish population-based study of 30,050 patients in 2007–2013, wound dehiscence requiring reoperation occurred in 2.9% of patients after colorectal cancer surgery. While these complications were rare, adjusted mortality risk was significantly increased by 26% [95].

Proper wound closure is one of the most important and modifiable factors to prevent wound dehiscence. Key principles include a clean initial incision, appropriate tissue handling/suture material, and adequate spacing of the sutures. The STITCH trial was a multicenter randomized controlled trial that compared small bites (5 mm of fascia every 5 mm of advancement) to large bites (1 cm of fascia every 1 cm of advancement) with respect to the development of incisional hernia [96]. The small bite technique was more effective than the large bite technique with lower rates of incisional hernia (13% vs. 21%). Placement of retention stitches should be considered in high-tension wounds or patients with increased risk factors. In a randomized controlled trial of 300 high-risk surgical patients randomized to closure with retention sutures versus standard continuous fascia closure-only, wound dehiscence and evisceration occurred significantly less in the retention group (4% vs. 13.3% and 0.7% vs. 2.7%, respectively) [97].

Other Infectious Complications

Urinary tract infections (UTIs) are the most frequently acquired nosocomial infection. The incidence of postoperative UTI after colorectal operations approaches 4% [98]. Risk factors include preexisting contamination of the urinary tract, urinary retention, and instrumentation such as indwelling urinary catheters. In a large retrospective study of the 2005–2012 ACS-NSQIP database, patients with postoperative UTIs had significantly longer length of stays (+5 days), higher reoperation rates (11.9% vs. 5.1%), higher 30-day mortality (3.3% vs. 1.7%), and more concurrent complications such as sepsis [98]. Diagnosis of UTI is made by examination of the urine with confirmation by cultures. Prevention involves treating urinary tract contamination before surgery, prevention or prompt treatment of urinary retention, and careful instrumentation when needed. Treatment includes adequate hydration, proper drainage of the bladder, and urine-specific antibiotics.

Clostridium difficile Colitis

Clostridium difficile (*C. diff*) is one of the most common nosocomial pathogens and the cause of 10–20% of antibiotic-associated colitis and diarrhea [99]. Postoperative *C. diff* infections occur at an incidence of 0.2–8.4% after major surgeries [99]. While infrequent, the overall incidence of *C. diff* infection is increasing in the United States [100] with significant morbidity for affected patients. Risk factors include antibiotic use, PPI use, low albumin, and prior hospitalization [99]. The history, physical exam, and laboratory testing should all be used to aid in the workup and diagnosis of *C. diff* colitis. Stool testing should follow protocols to ensure the highest specificity and sensitivity while remaining practical and time-sensitive. Depending on patient presentation, radiographic and endoscopic testing can complement the workup to determine the most appropriate and effective treatment plan. Treatment options range from oral antibiotic therapy (oral vancomycin) to consideration of fecal transplantation to urgent/emergent surgery.

Pulmonary Complications (#4)

Pulmonary complications may occur after any major surgery. In colorectal surgery, pulmonary complications include postoperative respiratory failure requiring prolonged ventilation, pneumonia, and aspiration. Each of these complications drives longer hospitalizations and often leads to further serious complications.

Postoperative Respiratory Failure

Postoperative respiratory failure is defined as postoperative ventilation for >48 hours or patient reintubation. In the 2012–2017 ACS-NSQIP database, prolonged ventilation occurred in 3.3–4.3% of colorectal patients with reintubation rates around 2.3% (Table 8.1). Risk factors include poor preoperative lung function, age, concomitant comorbidities (i.e., obstructive sleep apnea, pulmonary hypertension, and cardiovascular disease), smoking, and aspiration. Preventative measures include fast-track extubation, effective pain therapy, breathing training, physiotherapy, noninvasive ventilation, use of bronchodilators, and appropriate volume resuscitation. Studies using ERPs have demonstrated positive results in reducing the occurrence of these pulmonary complications by standardizing best practices for pulmonary function [101]. In a retrospective analysis of 1298 patients under an ERP, minimally invasive approaches and >70% compliance with ERP processes prevented pulmonary complications. Patients who did have pulmonary complications had a significantly longer hospital length of stay (+15 days) [101]. Treatment of respiratory failure is primarily supportive and includes early tracheostomy (to decrease dead space), protective ventilation, lowered peak pressures (<30 mmHg), increased positive end-expiratory pressure (PEEP 10–20 mmH_2O), early patient mobilization, and bronchoscopy as needed. Critical cases may lead to use of extracorporeal membrane oxygenation (ECMO).

Pneumonia

Pneumonia is the most common pulmonary complication among patients who die after surgery. Mortality rates for postoperative pneumonia vary from 20% to 40% and include both hospital-acquired pneumonia (HAP) and ventilator-associated pneumonia (VAP) [102, 103]. In colorectal surgery, the incidence of postoperative pneumonia has been reported from 1% to 4% [104]. The etiology of postoperative pneumonia is multifactorial. Atelectasis, aspiration, and secretions are important predisposing factors. Patients may also be exposed to nosocomial infections such as *Pseudomonas aeruginosa* and *Klebsiella* in the ICUs [105]. Clinical findings suggestive of postoperative pneumonia include fever, tachypnea, increased secretions, and physical exam suggestive of pulmonary consolidation. Chest X-rays and CT scans of the chest may show patchy opacification and/or localized consolidation. Several strategies may be used to decrease the risk of postoperative pneumonia. Respiratory exercises, deep breathing, coughing, and mobilization may help prevent atelectasis, which is a precursor of pneumonia. It is important to stress that control of postoperative pain is important for these actions to occur – one of the many focuses of ERPs [36]. Subglottic secretion suctioning on ventilated patients has also been shown to reduce ventilator-associated pneumonias [106]. The benefits of minimally invasive approaches may also extend to prevention of pneumonia [107] and to the elderly [108]. Treatment is supportive and based on aggressive ventilatory support and parenteral antibiotics.

Pulmonary Aspiration

Postoperative aspiration occurs in 1–2% of surgical cases [109] with mortality rates exceeding 30% [110]. Normal protective reflexes are often compromised in the postanesthetic state, with depressed mental status and the presence of a foreign body (i.e., nasogastric or endotracheal tubes). Additional risk factors include older age, pulmonary disease, need for intraoperative blood transfusions, dementia, and malignancy [110]. Aspiration of orogastric contents leads to severe pneumonia and pulmonary compromise with resultant prolonged hospital lengths of stays, costs, and death [109]. Prevention of aspiration includes preoperative fasting, proper positioning, careful intubation, and use of histamine-2 blockers [111]. Effective aspiration prevention protocols have been further developed that focus on bedside swallowing evaluations and stepwise advancement of oral intake [112]. Treatment of aspiration involves reestablishing patency of the airway and preventing further damage to the lung. Endotracheal bronchoscopy may be required to remove solid matter. Fluid resuscitation and antibiotics should be started concomitantly with aggressive management to prevent death and development of other complications.

Renal Complications (#5)

Renal complications affect the urinary tract and include acute kidney injury and postoperative urinary retention. While often reversible, these complications increase the risk of having long-term damage such as chronic kidney injury requiring dialysis.

Acute Kidney Injury

Acute kidney injury (AKI) describes a decrease in renal function over a course of hours to days that may range from a minor decrease in glomerular filtration to complete renal failure. The ACS-NSQIP defines AKI as a change in serum creatinine >2 mg/dl or a need for acute renal replacement therapy [64]. Postoperative AKI is a common complication in surgery and may affect up to 40% of the surgical population [113] and 14% of the colorectal population [114]. Development of postoperative AKI is associated with significant risks of both short- and long-term mortality, chronic kidney disease, and hemodialysis [113]. Risk factors include hypovolemia, bleeding, nephrotoxic agents, and cardiovascular failure. Preventative measures include avoidance of hypoperfusion and careful administration of nephrotoxic drugs including contrast agents. Treatment is supportive and based on volume replacement, preventing further renal damage and alleviating any obstructive pathologies.

Postoperative Urinary Retention

The inability to void postoperatively is common after anorectal and pelvic operations. Postoperative urinary retention (POUR) rates may occur in up to 25% of colorectal patients [115]. Even under modern ERP pathways, POURs still occur. In a study of 513 ERP patients in Switzerland, POUR occurred in 14% of patients [116]. These patients had worse surgical recovery including slower mobilization rates, more pain, and more UTIs. In that study, independent risk factors for POUR include male gender and thoracic epidural analgesia [116]. The treatment of POUR requires catheterization of the bladder and subsequent removal based on voiding ability. Efforts have recently been made in preventing POUR by administrating tamsulosin in the days before and after surgery. In one study, a threefold decrease in POUR rates was observed (25–6.7%) after administration of tamsulosin 3 days before surgery and 3 days after surgery [115].

Cardiac Complications (#6)

Cardiac complications following colorectal surgery are rare but life-threatening. Patients with risk factors of cardiac disease need to undergo appropriate cardiovascular testing and intervention prior to surgical intervention. Important guidelines from the American College of Cardiology (ACC) and

American Heart Association (AHA), supported by the ACS, exist that provide evidence-based recommendations for risk stratification and optimization of patients before major surgery including colorectal surgeries [117].

Myocardial Infarction

Approximately 1.5% of all patients undergoing a colorectal operation in the United States experience a postoperative myocardial infarction (MI) with mortality rates exceeding 28.5% [118]. Nearly 16% of all surgical patients, however, may experience a myocardial injury, and even these mortality rates are high (8.9%) [119]. Risk factors for postoperative MI include history of congestive heart failure, chronic renal disease, age >70 years old, peripheral vascular disorders, cancer, valvular disease, and hypertension [118]. Risk stratification and perioperative optimization are critical for colorectal patients as avoidance of this complication is the best strategy. The most cited and comprehensive guideline for stratification and optimization is the 2014 ACC/AHA Guideline on Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery [117]. These guidelines provide stepwise approaches to preoperative cardiac assessments including (i) initial clinical risk stratification of patients to low (<1% risk of major adverse cardiac event, MACE) and elevated (>1% MACE) risk categories, (ii) functional capacity assessment by metabolic equivalent of task (MET) for elevated risk patients (<4 MET = poor, 5–10 MET = moderate/good, and ≥11 MET = excellent), (iii) pharmacological stress testing for elevated risk patients with poor (<4 MET) or unknown functional capacity, and (iv) coronary revascularization for those with abnormal stress testing [117]. Treatment for MIs and other MACEs is supportive, and immediate consultations with cardiology (and potentially cardiac surgery) should be made to best individualize care and rescue these patients.

Dysrhythmias

Dysrhythmias such as atrial fibrillation occur after colorectal surgery. In a study of 571 colorectal patients, the incidence of postoperative atrial fibrillation (POAF) was 6.6% within 30 days of surgery [120]. This complication was closely associated with development of other complications including pneumonia, abdominal fluid collections, and sepsis. Patients with POAF were at higher risk for in-hospital mortality (9.1% vs. 2.6%) and 1-year mortality (33.3% vs. 8.8%) [120]. Preventative strategies to POAF include pharmacologic therapies (e.g., continuing beta-blockers), fluid optimization, and minimizing risk of other complications [121]. Treatment for POAF necessitates the involvement of cardiologists as there are both short- and long-term management strategies using rate-control medications (beta-blockers) and cardioversion [122].

Neurological Complications (#7)

Neurological complications in colorectal surgery include those complications that are captured by ACS-NSQIP (cerebrovascular accidents such as strokes) and those that are not but are equally important to identify (sexual dysfunction, delirium, etc.). While these complications can be devastating, significant improvements have been made in preventing them and managing them.

Perioperative Cerebrovascular Accidents

Perioperative strokes occur infrequently (0.3% rate from 2012 to 2017 ACS-NSQIP database) (Table 8.1) but are associated with significant perioperative morbidity and mortality. Most are thromboembolic events and occur within the initial 72 hours postoperative period. Risk factors include the type of surgery performed, intraoperative hypotension, history of previous stroke, cardiac issues (atrial fibrillation, valvular heart disease, mechanical valves, etc.), hypertension, peripheral vascular disease, age, neoplastic disease, and smoking [123]. Cerebrovascular events usually present with an acute neurologic change (i.e., weakness, facial droop, slurred speech). Workup involves getting an initial non-contrasted CT of the head to differentiate whether the stroke is ischemic or hemorrhagic. Treatment is dependent on the type of stroke, and neurology consultations are recommended for individualized management.

Sexual Dysfunction

Colorectal operations carry a risk of postoperative sexual dysfunction, typically due to injury to the nerves during pelvic dissection [124]. The pudendal nerves are not typically damaged during proctectomy; however, the nerves which are important in coordinating erection (nervi erigentes) and ejaculation (hypogastric nerves) may be affected. The hypogastric nerves include pre- and postganglionic sympathetic fibers from vertebral levels of T10-L2 and descend in the retroperitoneal space at the level of the sacral promontory. Injury to these nerves can occur during the posterior dissection of a total mesorectal excision or during transection of the inferior mesenteric artery and can result in ejaculatory dysfunction. The nervi erigentes (or pelvic splanchnic nerves) arise from the anterior rami of S2-S4 and enter the sacral plexus along the anterolateral wall of the rectum. Erectile dysfunction may occur due to avulsion from excessive traction of the rectum during proctectomy or by direct injury of the nerves during dissection near the seminal vesicles and prostate.

The incidence of postoperative sexual dysfunction in males varies widely in the medical literature (from 5% to 90%), and a significant number of patients may suffer from preoperative dysfunction [124]. In a prospective study of 169

patients who underwent proctectomy for rectal cancer, Adam et al. [125] found that 71% of males reported erectile dysfunction after surgery (vs. 24% preoperative) and 78% reported ejaculatory dysfunction (vs. 32%) ($p < 0.001$). Stage T3 or T4 tumors and low rectal tumors were independent risk factors of worse sexual function. Similarly, Dulskas and Samalavicius reported postoperative erectile dysfunction in 63.9% of patients; however, the incidence of preoperative dysfunction was 41.7% [126]. Sexual dysfunction may be higher in patients who undergo abdominoperineal resection than those who undergo low anterior resection.

Psychological evaluation and support of the patient and his/her partner are important and can improve the response to pharmacologic therapy [127]. Among the medications available, the efficacy of sildenafil was demonstrated in a study where 32 patients who had undergone proctectomy were randomized to treatment or placebo [128]. Erectile function improved in 80% of patients treated with sildenafil compared to only 17% of patients treated with placebo.

Determining significant changes in sexual function in older women following proctectomy can be more difficult, as a high percentage of women report baseline preoperative genitourinary dysfunction [4]. Younger female patients who undergo pelvic surgery for benign disease may be at risk of fertility problems, likely due to extensive dissection leading to intra-abdominal and pelvic adhesions. Waljee et al. reported a threefold increase in the risk of infertility following total proctocolectomy in patients with ulcerative colitis (48% vs. 15%) [129]. In a more recent meta-analysis, Rajaratnam et al. showed that the risk of infertility is almost four times higher following IPAA [130]. While it would seem that a laparoscopy would reduce adhesion formation and therefore reduce the risk of infertility, a recent retrospective comparison of 161 patients did not demonstrate a difference in infertility rates between open and minimally invasive approaches [131].

Postoperative Delirium

Postoperative delirium (POD) is a form of delirium that occurs after a surgical procedure and may occur at rates as high as 87% [132]. Risk factors include reduced cognitive reserve from preexisting comorbidities (i.e., dementia and age), sensory impairment, dehydration, substance abuse, withdrawal of certain types of medications (anticholinergics, benzodiazepines, etc.), sleep-wake cycle disturbances, and environmental change (i.e., prolonged hospitalization or ICU stay) [133]. Patients with delirium are at increased risk for adverse outcomes including higher mortality, longer hospital stays, and discharge to nursing facility [134]. Preventative measures include frequent and deliberate orientation of patient to place/time, early postoperative mobilization, and consistent use of home devices while hospitalized (i.e., hearing aids and glasses). In the ICU, sedative medication should be titrated between patient comfort and oversedation. Treatment is supportive and includes supervision/reorientation, removal of inciting agents, and pharmacologic therapies.

Conclusion

Postoperative complications are an inherent part of colorectal surgery. All lead to increased risks of mortality, prolonged hospital length of stays, readmissions, and other adverse outcomes. The most common complications in colorectal surgery include ileus, bleeding, and surgical site infections. It is critical for colorectal surgeons to be aware of the many risk factors for these complications and to optimize patients preoperatively. When complications occur, surgeons need to recognize them early, respond in an expedient manner, and administer the appropriate treatment to rescue the patient and achieve the best possible outcome.

Anastomotic Construction

9

H. David Vargas and David A. Margolin

Key Concepts

- Anastomotic construction represents a fundamental and essential skill restoring intestinal continuity and preserving bowel function and continence.
- It encompasses a broad range of methods and configurations and can be performed utilizing a spectrum of operative platforms.
- While anastomosis may be a heterogeneous endeavor, consistent fundamental principles must be preserved in all its forms.
- Stapling technologies represent a challenge for surgeon knowledge and understanding their use in clinical practice given the numerous innovations and specific tissue–device interactions.
- Colonic mobilization techniques bringing bowel into proximity to the distal limb while preserving blood supply represents an essential and critical skill for anastomotic construction. Surgeons must be familiar with advanced techniques for mobilization to achieve anastomosis.

Introduction

Anastomotic construction represents one of the fundamental activities of the intestinal surgeon. Following closely behind the principal goal of resection of the pathologic condition, restoration of a functional intestinal tract invariably remains an important aspect of a patient's sense of well-being and health as well as their perception of a successful operation. Fortunately, a healed and functional anastomosis is common, and the inability to perform an anastomosis remains a relatively rare phenomenon. This current perspective belies the early history of surgery of the intestinal tract where anastomotic failure and mortality were exceedingly high (Fig. 9.1) [1]. Advances in surgical technique and scientific discovery were critical to safe anastomotic construction.

Intestinal anastomosis encompasses a broad range of surgical activity: the multitude of pathologic conditions requiring resection, the variety of anatomic segments that can be resected, the numerous permutations of suture materials, and the array of anastomotic configurations. Adding to the complexity of this topic, we must also consider the different means of access to the peritoneal cavity, including laparotomy or minimally invasive approaches such as laparoscopy or robotic surgery.

In spite of remarkable technological advances, anastomotic leak continues to plague our best efforts even 20 years into the twenty-first century. It continues to be a most feared complication. The morbidity of leak is far reaching, often involving reoperation, lengthy hospital stay, loss of function, poorer oncologic outcomes, or even operative mortality [2]. Unfortunately, anastomosis outcomes vary, in part based on surgeon performance [3, 4]. This is particularly sobering as perhaps there are few operative outcomes that affect a surgeon's personal measure of competence and self-esteem. As individual surgeons, we are acutely aware of the dire implications for our patients who suffer an anastomotic leak. Therefore, the topic of anastomotic construction represents an audacious and humbling endeavor for the authors to embark upon.

The objective is pragmatic and straight forward: to discuss general principles and technical options for anastomotic construction. Going forward, we trust and will rely upon the reader's tolerance and understanding where philosophies and techniques may differ from their own. In the end, we hope that author and reader alike will have subjected themselves and their operative technique to scrutiny and honest appraisal, and will consider the following with intellectual rigor and openness.

Physiology of Anastomotic Healing

Intestinal anastomotic healing proceeds through the well-elucidated phases described for other models of tissue injury and repair [5, 6]. The status of collagen and tensile strength is critical to anastomotic integrity (Fig. 9.2). However, differences exist as a result of the unique anatomic and physiologic properties of the intestinal tract. Anatomically, the intestinal tract has four layers with characteristics that play unique role in anastomotic healing. The exceptions to this are importantly, the esophagus and the lower aspect of the rectum, both of which notably are lacking serosal layers. Anastomoses involving these specific organs prove more challenging and are marked by higher leak rates [6].

The importance of the serosa was highlighted by Lembert [1, 7, 8]. He popularized the critical idea that apposition of the serosa and inversion of the mucosa was critical to anastomotic healing. Halsted's canine investigations revealed that the submucosal layer contained the highest concentration of collagen and possessed the greatest tensile strength. He emphasized the role of submucosal purchase during intestinal suturing, and the Halsted stitch actually omitted the mucosa. The incorporation of the submucosa provides the initial tensile strength to an anastomosis during *the lag or inflammatory phase* when collagen degradation predominates. During this inflammatory phase, the clotting cascade is activated by platelets and release of inflammatory mediators, causing a fibrin plug to occur at the mucosal defect and assisting in hemostasis. Neutrophils migrate to the wound and essentially clean up the necrotic tissues. Collagenolysis liberates amino acids, especially proline and lysine, which become available for later collagen synthesis. Therefore, the anastomosis is weakest during the first 2 days after surgery, as integrity of the anastomosis relies entirely upon the suture material approximating the submucosa until collagen synthesis occurs [5, 6].

At day 2–4, the proliferative phase begins. This phase is marked by collagen synthesis. Fibroblasts are generally responsible for this activity, but unique to healing in the intestinal tract, smooth muscle cells also contribute to collagen synthesis [6]. Smooth muscle cells from the muscularis mucosae and the muscularis propria contribute to this production. Tensile strength develops as a result, and compared to soft tissue repair, this occurs much more rapidly in the gastrointestinal tract. Similar to cutaneous healing, neither process achieves pre-injury tensile strength. It is estimated that at 1-week small bowel anastomoses achieve nearly 100% of the expected strength. Colonic anastomoses obtain about 50% of their ultimate anastomotic strength in the same time frame [5, 6]. Finally, the remodeling phase of healing is marked by collagen maturation and cross-linking, increasing the tensile strength of the anastomosis.

Epithelial repair, otherwise known as g*astrointestinal restitution*, occurs rapidly as a result of migration of crypt cells from adjacent unwounded epithelium. The integrity of the epithelial layer can be complete by day 3 if mucosal apposition occurs [5]. Critical to this process is restoration of the inner mucus layer. Crypt goblet cells secrete a viscous mucus layer that serves as an important inner protective layer of the mucus layer of the intestinal tract separating the commensal bacterial flora of the microbiome from the epithelium and healing anastomosis [9–11]. One of the major concepts recently introduced regarding anastomotic healing has been the revelation of local changes in the microbiome. The development of pathogenic intestinal bacteria results in collagenolytic activity that undermines tensile strength and anastomotic healing [10–12]. The importance of commensal bacteria and potential deleterious local effects such as these highlight the critical aspect of gastrointestinal restitution and restoration of the mucus layer barrier to the healing of intestinal anastomosis.

In summary, gastrointestinal anastomoses progress through the various phases of healing with important specific differences resulting in rapid restoration of tensile strength and restitution. Anastomotic construction techniques should minimize parameters prolonging the inflammatory phase and collagenolysis: avoidance of tension, minimize necrosis, airtight closure, approximation of the submucosa, and preservation of perfusion. These parameters give rise to the basic tenets of anastomotic construction.

Fundamental Principles for Anastomotic Construction

Anastomotic construction depends on joining two ends of bowel that are healthy and well-perfused. The physical union is airtight and without any tension. Operative technique should involve anatomic mobilization by dividing named vessels and preserving blood supply, minimally traumatic dissection, precise and secure approximation, all while maintaining aseptic technique. Importantly, these fundamental concepts must be preserved across the various operative platforms—open and minimally invasive—knowing that potential advantages and challenges exist for each approach and for specific steps. Regardless of platform, the anastomosis generally represents one of the final operative steps and, independent of the time required for the preceding steps, requires focused attention to detail and meticulous technique.

Operative Planning

Operative decision making necessitates preoperative planning. One of the keys to successful operations depends on the preparation of the surgeon and team so that each step has been imagined, contemplated, and specific details considered. In particular, the principal objective –surgical treatment of the pathologic condition and the planned appropriate extent of resection – must be clearly defined. Localization of pathology preoperatively is a critical item for anticipating segmental or extended resection. Endoscopic description of the segment can be inaccurate and tattoos are potentially helpful in intraoperative localization, but not in preoperative planning. Endoscopic clip placement with X-ray can be helpful (Fig. 9.3). The plan for mesenteric resection and division/preservation of named vessels is dependent on precise localization, and therefore should be a major part of preoperative planning.

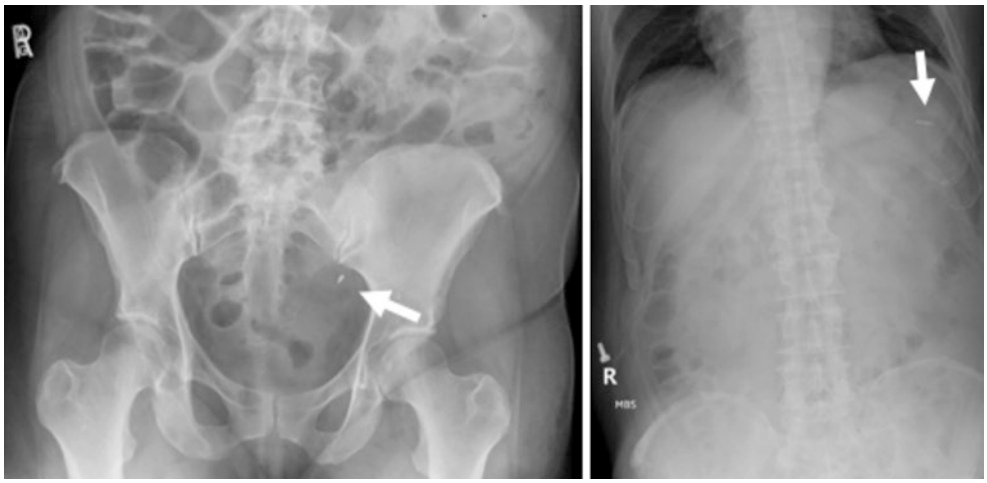

Fig. 9.3 Note white arrows indicating endoscopic clip placed at 60 cm from anal verge seen on plain X-ray in two different patients. Clip placement with radiograph can provide accurate preoperative localization for purposes of specific operative planning

After appropriate resection has been defined, one can then turn attention to the anticipated anastomosis. Several issues must be considered. Are the two bowel ends mobile or is one fixed (rectal or anal)? [13] Is there significant physical distance separating the ends? What specific techniques need consideration to enable adequate mobilization for tension-free anastomosis? How are the respective mesenteries oriented in relation to one another, and how will the anastomosis configuration be affected? Finally, what specific methods for actual bowel anastomosis will be used?

Successful healed anastomoses depend on careful preoperative planning, and a critical aspect of this preparation includes anticipation of obstacles and contingency strategies. Familiarity with multiple operative methods and the ability to adapt to variances in anatomy, pathologic findings, or operative conditions is critical. One must possess versatility or "surgical agility."

Mobilization

While remaining cognizant of the steps of anastomotic construction, the operative team must conduct the planned resection for the specific pathologic condition. Resection extent should not be influenced or potentially compromised by the anticipated anastomosis and potential concerns of bowel length and reach. One should not succumb to the allure of what is technically expedient. The savvy surgeon acknowledges that only after appropriate resection should one be concerned with the task of anastomosis, confident that he or she possesses the skill to mobilize the residual bowel and achieve a tension-free anastomosis.

Proximity refers to bringing the two segments in space for tension-free anastomosis. Tension threatens the initial anastomotic integrity, which for several days is entirely dependent upon the tensile strength of sutures or staples [6]. Tension also leads to ischemia that diminishes conditions for healing [14]. One of the fundamental aspects of anastomotic construction therefore is a tension-free anastomosis.

Small Bowel Mobilization

Small bowel resections represent the simplest bowel resection and typically do not require any significant mobilization given the intraperitoneal nature of the bowel and attached mesentery. The two limbs of bowel for anastomosis can be brought into proximity easily for a tension-free anastomosis.

Small bowel mobilization can be important in certain situations. One should be aware of the particular challenge of an extracorporeal anastomosis during right colectomy. Exteriorization of the proximal transverse colon will be affected by omental adhesions and gastrocolic adhesions. The entire hepatic flexure should be mobilized, by dividing the gastrocolic ligament and dissection off the sweep of the duodenum. Other features that affect the ability to perform this anastomosis in proper fashion include: the size of the omentum especially in the obese patient, a large specimen, shortened mesentery, and increased abdominal wall thickness. Each of these factors must be taken into account when considering specimen extraction site and size of incision.

Small bowel mobilization techniques, however, are critical when performing ileoanal anastomosis [15–17]. The root of the mesentery must be dissected to the pancreas and proximal aspect of the superior mesenteric artery. Relaxing incisions, or "step ladder incisions," can be made anterior and posterior in the mesentery or windows within the mesentery (Fig. 9.4) [18]. Finally, transillumination of the mesentery can identify arcades providing points of safe mesenteric vessel transection, again enabling further lengthening of the mesentery for additional reach of the ileal reservoir for anal anastomosis [19]. A recent cadaveric and angiographic study using fresh human cadavers examined various mobilization techniques and mesenteric division strategies for gaining length for ileal pouch anastomotic construction. This study validated the effectiveness of step ladder incisions technique [20].

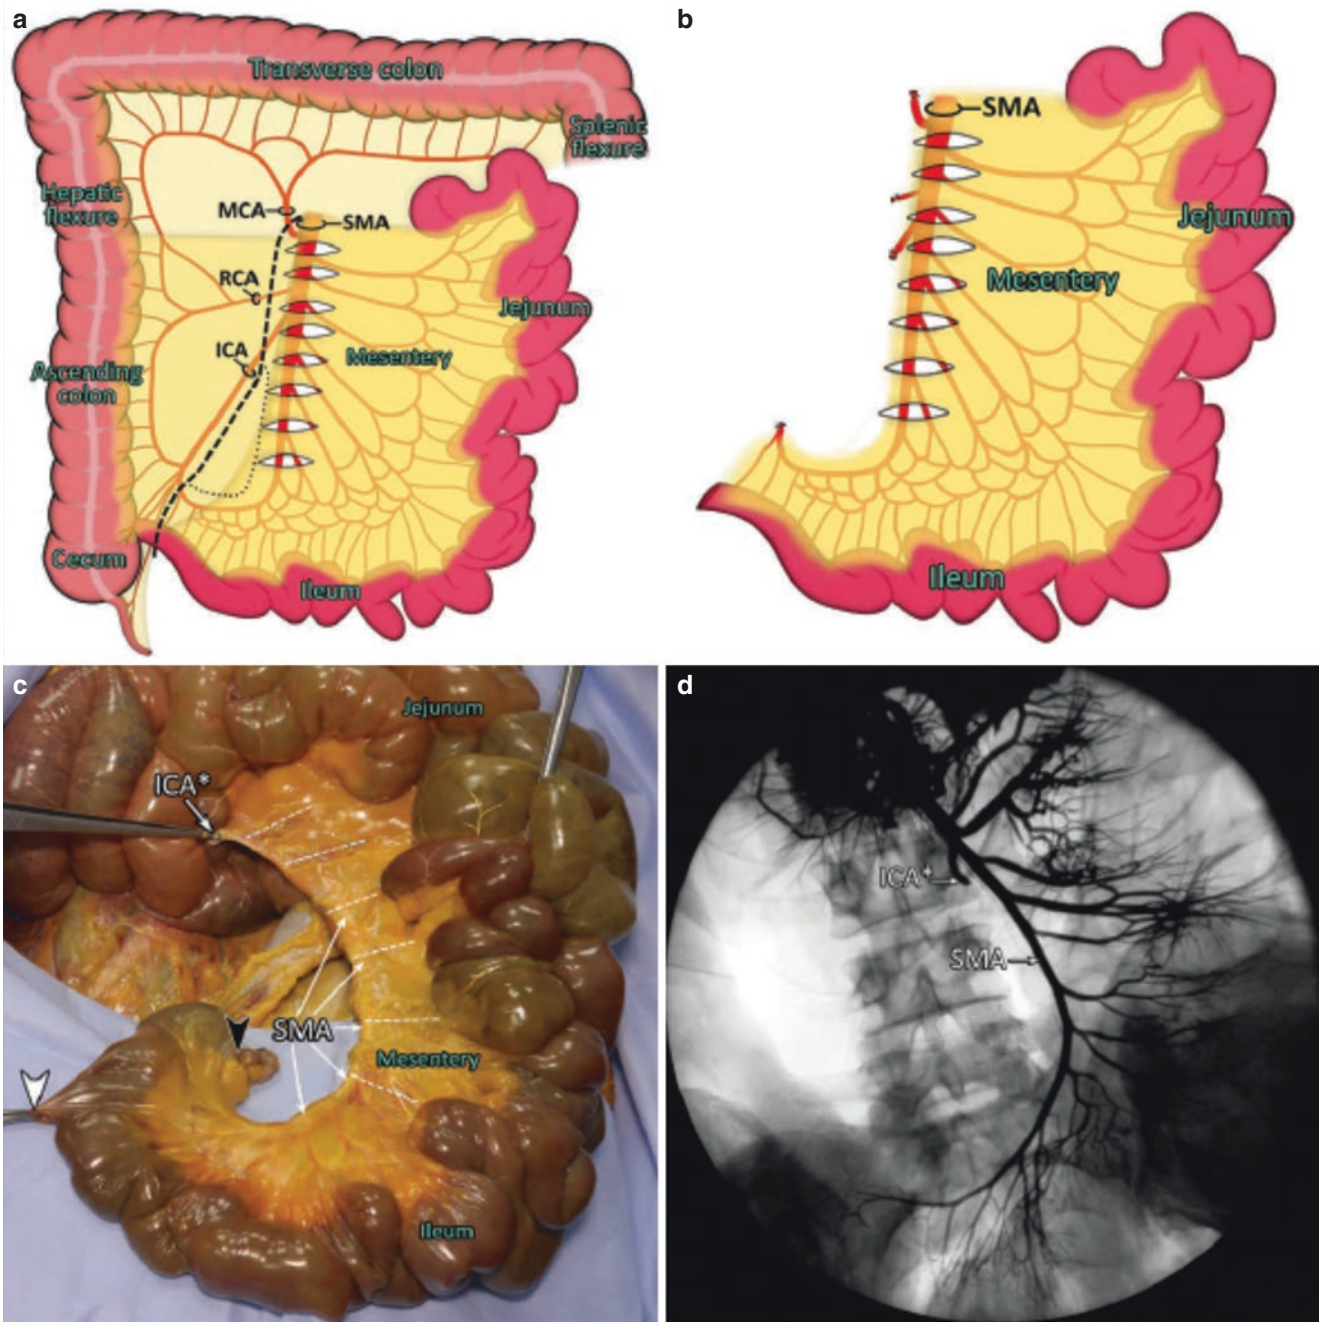

Fig. 9.4 Mesenteric lengthening 1. (**a**) incision of mesocolon and ligation levels of colic vessels during proctocolectomy are included by dashed line. Stepladder incisions are shown on the mesentery. (**b**) Appearance of the small intestine mesentery after proctocolectomy, and mesenteric lengthening is demonstrated. (**c**) Relaxing transverse incisions made on the small intestine mesentery are shown on the cadaver by dashed lines. The SMA and its ileal/jejunal branches in the mesentery were visualized by injecting diluted barium sulfate (white arrowhead, apex of the pouch; black arrowhead, transection point of the terminal ileum). (**d**) Angiographic image of the SMA and branches after mesenteric lengthening is shown. *Ligated vessels; ICA, ileocolic artery; MCA, middle colic artery; RCA, right colic artery; SMA, superior mesenteric artery. Colonic Mobilization

Mobilization is a central issue for resections involving the left side of the colon and rectum. This is because one end of the anastomosis is essentially anatomically fixed [13]. A critical skill for the intestinal surgeon must be mastery of proximal mobilization of the residual left and more proximal colon following left-sided or rectal resection. Essentially, anastomotic construction requires full anatomic dissection and mobilization of the left colon. Whether or not splenic flexure mobilization is necessary for left-sided colonic resec-

tion or low anterior resection is often debated. What should not be debated, however, is the necessity of mastering this maneuver so that when called upon one can perform precise execution with proficiency.

Splenic Flexure Mobilization

This requires sophisticated knowledge of and operative technique for dissection of the anatomic tissue planes and division of embryologic adhesions (Fig. 9.5). The major steps include dissection of the left colon and transverse colon mesenteries completely off the retroperitoneum back to the midline aorta. Attachments to the kidney, stomach, spleen, and inferior border of the pancreas are divided, mobilizing the mesentery back to the inferior mesenteric vein.

High ligation of the inferior mesenteric artery provides upwards of 10 cm of additional length when compared to low ligation [21]. Division of the inferior mesenteric vein at the base of the pancreas produces substantial length [21]. This is an essential step to obtain adequate mobilization and mesenteric length for low pelvic anastomosis (Fig. 9.6).

Maximal mobilization can be further gained by mobilization of attachments to the pancreas beyond the inferior mesenteric vein, as the axis can be further shifted well to the right of the ligament of Treitz to where the middle colic artery arises (Figs. 9.7 and 9.8a, b). Complete dissection of the omentum off of the transverse colon—essentially separating the gastrocolic ligament—enhances release.

Finally, there often exists a hinge-like embryologic conformation of the mesentery of the splenic flexure that must be divided or released to straighten the mesentery (Fig. 9.9). This "unhinges" the angled conformation of the bowel at the splenic flexure (Figs. 9.10, 9.11, and 9.12) and creates a straightened mesentery and splenic flexure that can then descend (Figs. 9.13 and 9.14a, b) in a straight line from the middle colic vessels. This enables the descending colon conduit to reach well below the symphysis pubis to achieve a tension-free anal anastomosis.

Again, while some may choose to debate its necessity in all cases of low anterior resection [22], it would be folly to question the value of possessing the skill to perform full mobilization of the splenic flexure and familiarity with specific details for straightening the left colon [23]. While it is generally accepted that anastomotic leak following low anterior resection appears to correlate with decreasing anastomotic height—that is, the lower the anastomosis the higher the leak rate—master surgeons are able to defy such trends. Remarkably low rates of leak with left-sided anastomoses can be achieved consistently irrespective of anastomotic level [24], and the senior author of this series suggests that the key to low pelvic anastomosis is complete splenic flexure mobilization (personal communication).

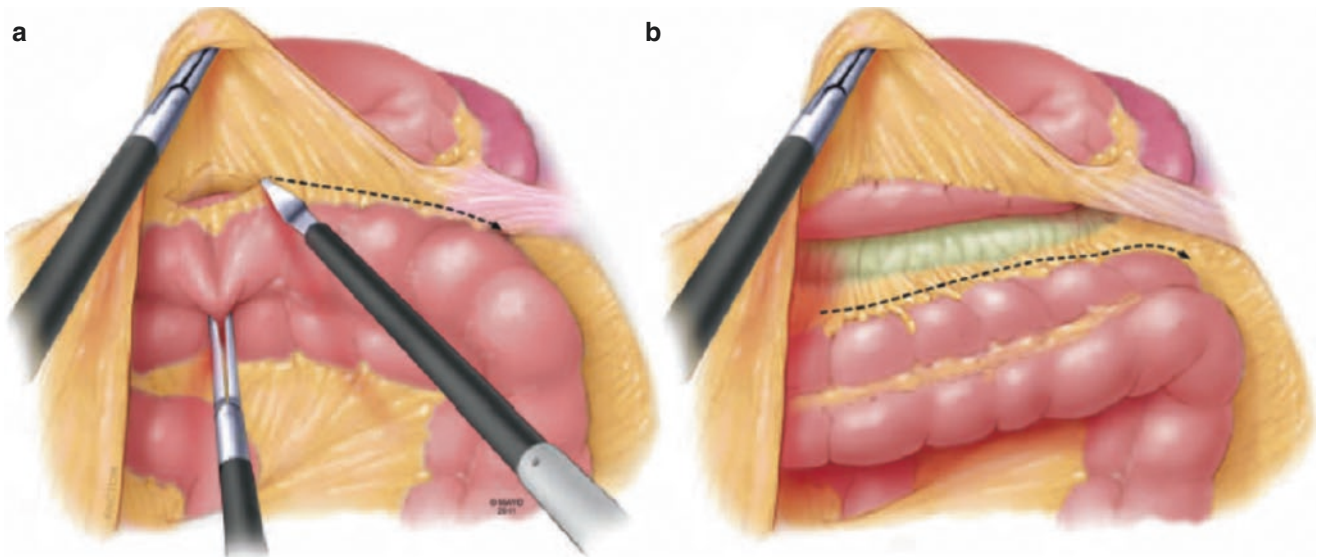

Fig. 9.5 Mobilization of splenic flexure, medial to lateral approach. The greater omentum is reflected superiorly and a transverse incision is made along the gastrocolic ligament releasing the transverse colon and entering the lesser sac. Care must be taken to avoid dissection posterior to the pancreas, where troublesome bleeding may occur. As dissection continues laterally, the renocolic and splenocolic ligaments are divided, as well as any other retroperitoneal attachments of the flexure. The spleen often remains out of view with this approach. (Reused with permission Merchea et al. [93]. Copyright © 2012 John Wiley and Sons)

Special Mobilization Techniques

In some instances involving extended resections of the left and transverse colon, or in cases of reoperation where prior left-sided resections have previously taken place, advanced mobilization techniques are available to bring bowel ends into proximity for anastomotic construction. Repeat low anterior resection often requires consideration for extraordinary mobilization to achieve anastomotic construction [25].

Retroileal Anastomosis or Ileal Mesenteric Window

First described by Toupet, the transverse colon can go underneath the small bowel through a surgically created "window" in the small bowel mesentery between the superior mesenteric artery and the ileocolic artery (Fig. 9.15) [26]. The maneuver requires complete splenic flexure mobilization to the root of the middle colic artery, dissecting the transverse colon mesentery at its root allowing the mesentery to pivot at the most proximal extent. This occasionally requires the cecum to be mobilized off the retroperitoneum as well as the root of the small bowel mesentery to facilitate the mesenteric window creation. Transillumination of the mesentery can be performed to identify the major vessels of the small bowel mesentery [27–29]. There is a bare area between the superior mesenteric artery and the ileocolic artery. A 4–5 cm long defect should easily accommodate the transverse colon and attached mesentery (Fig. 9.15). The mesentery should be straight and parallel to the longitudinal axis of the colon with a preserved marginal artery. The "cut edge" or divided edge of the mesentery of the transverse colon points left as the bowel descends to the right of the aorta through the mesenteric window toward the pelvis (Fig. 9.15a–d). This maneuver has also been performed using the laparoscopic platforms [30–32].

Right Colon De-Rotation (Deloyer's Procedure)

Infrequently, following extended resection, the right colon may be chosen as the conduit for anastomosis to the rectum or anal canal. The conduit blood supply is based upon the ileocolic artery and necessitates dissection to the origin of the ileocolic artery. This provides mobility of the mesentery to rotate without acute kinking of the vessel [33]. The de-rotation can also be described as an inversion of the cecum and terminal ileum [34]. The cecum and attached terminal ileum are rotated along the axis of the ileocolic artery in the sagittal plane, with the cecum moving superiorly and the ascending colon caudally (Figs. 9.16 and 9.17) The dorsal surface of the mesentery and ascending colon become ventral in position following de-rotation (Figs. 9.18, 9.19, and 9.20). Mobility of the mesentery and length of the ileocolic artery can enable reach of the conduit to the low pelvis and even the anal canal for ultra-low anastomosis. Functionally, preservation of colonic reservoir, water-absorptive surface area, and maintenance of the ileocecal valve improves post-operative function [34]. In a series of 48 patients, 67% of patients reported fewer than three bowel movements per day [35]. The maneuver has also been described laparoscopically [36]. In terms of safety, anastomotic leak rates in this series indicate predictable safe anastomotic healing. Appendectomy should be performed given the new location of the cecum in the mid-right side of the abdomen.

Perfusion

One of the central principles of anastomotic construction remains preservation of blood supply and tissue perfusion following mobilization. Again, like tension, this fundamental concept seems empirical. Mastery of mesenteric anatomy, precise identification of named vessels, and meticulous dissection technique enable mobilization resulting in well-perfused bowel ends for anastomotic construction. Clinical assessment of bowel for anastomosis is therefore a critical skill. Color, motility, and visible bleeding from the mucosa represent basic means for assessment of the bowel perfusion and viability.

One approach in the case of left colectomy or low anterior resection, for example, is to purposefully dissect and skeletonize the marginal artery at the distal descending colon. The vessel is transected in order to observe brisk pulsatile arterial bleeding prior to precisely performing proximal resection (Fig. 9.21). This clinical assessment of adequate blood supply provides reliable information for anastomotic construction [24]. If such bleeding is not present, one proceeds proximally on the mesentery until brisk arterial inflow is

present; this would identify the appropriate point of proximal bowel division. The value of clinical assessment cannot be overstated, and experience would indicate that it is reliable for anastomotic construction [24].

Indocyanine green fluorescence angiography is an intraoperative technique that is increasingly used to assess viability of the intestinal bowel during anastomotic construction (Fig. 9.22) [37–39]. ICG absorbs near-infrared (NIR) light at 800 nm and emits fluorescence. As ICG binds extensively to plasma proteins and is confined to the intravascular com-

partment, tissue microperfusion is indicated by the presence of fluorescence [40]. This technique has been employed during both open and minimally invasive surgery operations. Although the test is a subjective assessment and not yet routinely quantitative, additional information can be obtained to assess perfusion. The PILLAR II trial was a prospective multicenter clinical trial evaluating the utility of ICG fluorescence. Decisions regarding proximal resection were altered in 8% of cases [41]. Additional studies are necessary to determine if anastomotic leak can be reduced based on its use [42]. ICG may prove to be a useful adjunct to clinical assessment and provide means for confirming more precise resection of nonviable bowel, thereby confirming surgical decision making critical to anastomotic construction.

Anastomosis Configuration

The configuration of anastomosis refers to the form in which the bowel ends relate to one another. End-to-end anastomosis, end-to-side, side-to-end, and side-to-side anastomoses are the general anastomotic configurations described. Choice of configuration is often a matter of pragmatism. Certain configurations are technically practical, physically sensible, and aesthetically more pleasing. The configuration should restore continuity in a manner that does not create tension on the mesentery or on the physical union of the bowel ends. It is important to consider that anastomoses are constructed with the patient supine. In the upright position, the mesentery and attached bowel will be affected by gravity, thereby impacting anastomotic construction and possibly tension.

Small bowel anastomosis can be performed end-to-end or side-to-side. The side-to-side anastomosis can be in the configuration of the traditional antiperistaltic functional end-to-end or it can be made in isoperistaltic fashion.

Following right colectomy, size discrepancy of the bowel must be addressed if an end-to-end anastomosis is chosen. This can be accommodated by performing a Cheatle slit along the antimesenteric aspect of the smaller bowel to then match the size of the larger bowel for end-to-end anastomosis (Fig. 9.23). Another way to compensate for size discrepancy is to perform a side-to-side anastomosis. An example of this is anastomosis between the ileum and the transverse colon following right colectomy. Classically, the two ends of bowel are aligned in antiperistaltic fashion (Fig. 9.24a–d) with anastomosis performed at the antimesenteric aspect of the bowel. Side-to-side can also be performed in isoperistaltic configuration (Fig. 9.25), and this method has been gaining popularity with minimally invasive surgical techniques.

Finally, size discrepancy can be addressed by an end-to-side or side-to-end configuration (Fig. 9.26). The advantage to an end ileum to side of transverse colon is that this can be performed utilizing circular stapler without any intersecting staple lines (Figs. 9.27, 9.28, and 9.29).

A relatively recent novel anastomotic configuration is the Kono-S anastomosis configuration. This technique was described as a specific method for anastomosis in the treatment of Crohn's disease. It is a variation of a side-to-side configuration that involves the antimesenteric side of both portions of bowel. The bowel is divided proximally and distally resecting the involved Crohn's disease. The mesentery of the bowel to be resected is divided directly adjacent to the mesenteric edge of the bowel, thereby preserving blood supply and enteric nerves [43]. The bowel is transected with staplers placed transversely across the intestine wall perpendicular to the mesentery. The ends of the divided bowel are sutured together acting as a "column," excluding the anastomosis from the mesentery. The antimesenteric aspect of each portion of bowel is opened longitudinally and the anastomosis is performed transversely in Heineke-Mikulicz fashion (Figs. 9.30 and 9.31). Cohort studies demonstrate acceptable safety when compared to traditional side-to-side anastomosis and this technique has been associated with a lower incidence of recurrent disease [44, 45].

In the case of extended right colectomy with anastomosis to the distal third of the transverse colon, mobilization of the splenic flexure reduces the distance the ileum must traverse in spite of the mobility of the intraperitoneal ileum. In this case, isoperistaltic side-to-side appears to be advantageous. When subtotal colectomy is performed, one can mobilize the sigmoid colon and transpose it to the right lower quadrant and hypogastrium. Then, ileal to sigmoid colon anastomosis side-to side-configuration can be performed with the ileum resting in the native or in vivo position (Figs. 9.32 and 9.33).

Colocolonic anastomosis is rare. Splenic flexure tumors can present technical challenge in terms of extent of resection and

the residual bowel present for anastomosis [46, 47]. While the optimal resection may be debatable, splenic flexure resection has been described leaving mid-transverse colon and sigmoid colon for anastomosis. In this instance, side-to-side anastomosis can be performed, but the mesenteric mobility and the more rigid nature of bowel wall do not lend itself well to side-to-side anastomosis. The authors prefer an end-to-end anastomosis as it appears to lay neatly (Fig. 9.34). This can be performed with circular or linear staplers or can be hand-sewn.

Pelvic anastomoses are considered the most challenging technically and can be influenced by unique considerations that may dictate anastomotic configuration. A pelvic end-to-end anastomosis may be necessary as a result of bowel length or surgeon preference. While pelvic reservoirs may be the preference of the surgeon, a narrow pelvic inlet can limit the size of the conduit or proximal bowel that can traverse the pelvic floor for anastomosis. This is most commonly found in the male pelvis or obese individuals. Conversely, that being said, a wide pelvis may easily accommodate either a colonic J-pouch or a side-to-end anal anastomosis should a pelvic reservoir be desired.

Anterior resection or sigmoid colectomy with anastomosis to the upper rectum generally is performed in an end-to-end fashion (Fig. 9.35). Occasionally, size mismatch can make side of colon to end of rectum technically appealing. The same is true for ileorectal anastomosis where one can choose side-to-end versus end-to-end reconstruction.

Low Pelvic Anastomosis

Low pelvic anastomosis can occasionally be limited by reach or size of pelvic inlet. However, functional challenges can result from straight coloanal anastomosis prompting use of reservoir reconstruction. Low anterior resection syndrome can be a debilitating functional consequence of low colorectal or coloanal anastomosis, affecting quality of life of patients following treatment for mid to low rectal cancer.

Pelvic reservoirs such as the colonic pouch (Fig. 9.36) or the side-to-end anastomosis with 5 cm efferent colonic end (Fig. 9.37) appear to provide functional benefit in regard to stool frequency and urgency [48–51, 52]. Some argue that by 2 years after surgery, the function of a straight anastomosis ultimately will approximate that of a colonic J-pouch [53, 54]. Other series indicate that colonic pouch continues to provide functional advantage even at 5 years [6, 48, 55]. Even if a straight anastomosis achieves equivalency at 24 months, a patient suffering from LAR syndrome for 24 months can be so discouraged that they elect to return to a stoma. Poor function is second only to anastomotic leak as a cause for conversion from an existing low pelvic anastomosis to permanent colostomy [56, 57]. In any case, a colonic reservoir like a J-pouch does not by itself obviate the possibility of LAR syndrome and upwards of 30% of patients may still experience increased frequency and urgency.

Some have concerns about the increased complexity of reconstruction with a colonic pouch and the additional staple line. A recent ACS-NSQIP study revealed that colonic J-pouch compared to straight anastomosis was associated with fewer reoperations, organ space infection, and increased ICU usage [58]. In general, in regard to anastomotic leak colonic J-pouch anal anastomosis compares favorably to straight anastomosis in spite of the perception of a more complex anastomosis [50, 59, 60]. The anastomosis is side-

to-end with more reliable perfusion of the proximal aspect of colon conduit compared to the end of colon. The mass of the mesentery resulting from the side-to-side pouch construction fills the dead space of the presacral area of the pelvis, further reducing areas for fluid accumulation, which theoretically assists in reducing pelvic sepsis.

All of these features are shared by the side of colon to end of anorectum reconstruction (STE; "Baker-type anastomosis"). A technical aspect is that the efferent limb distal to the STE anastomosis should be 5–6 cm long. Compared to a colonic J-pouch, the bowel function appears equivalent [61, 62] and is superior to a straight anastomosis [60]. In terms of morbidity, there is no difference when compared to a colonic J-pouch. STE, however, may be faster to perform than a colonic pouch [61, 62]. The additional time to construct a neorectal reservoir should be balanced against the potential long-term benefits.

Methods for Anastomotic Construction

Multiple methods of anastomotic construction exist but can be broadly divided into hand sewn or stapled. In some respect, this is naïve as more often than not both major methods are combined to greater or lesser degrees. A two-layered hand-sewn intestinal anastomosis may first be preceded by bowel transection with linear cutting staplers. Similarly, a robotic isoperistaltic side-to-side small bowel to colon anastomosis following right colectomy often involves hand-suturing the common defect closed. While technique and method often can seem to be polarized, the reality is that anastomotic construction techniques require understanding and mastery of both major categories.

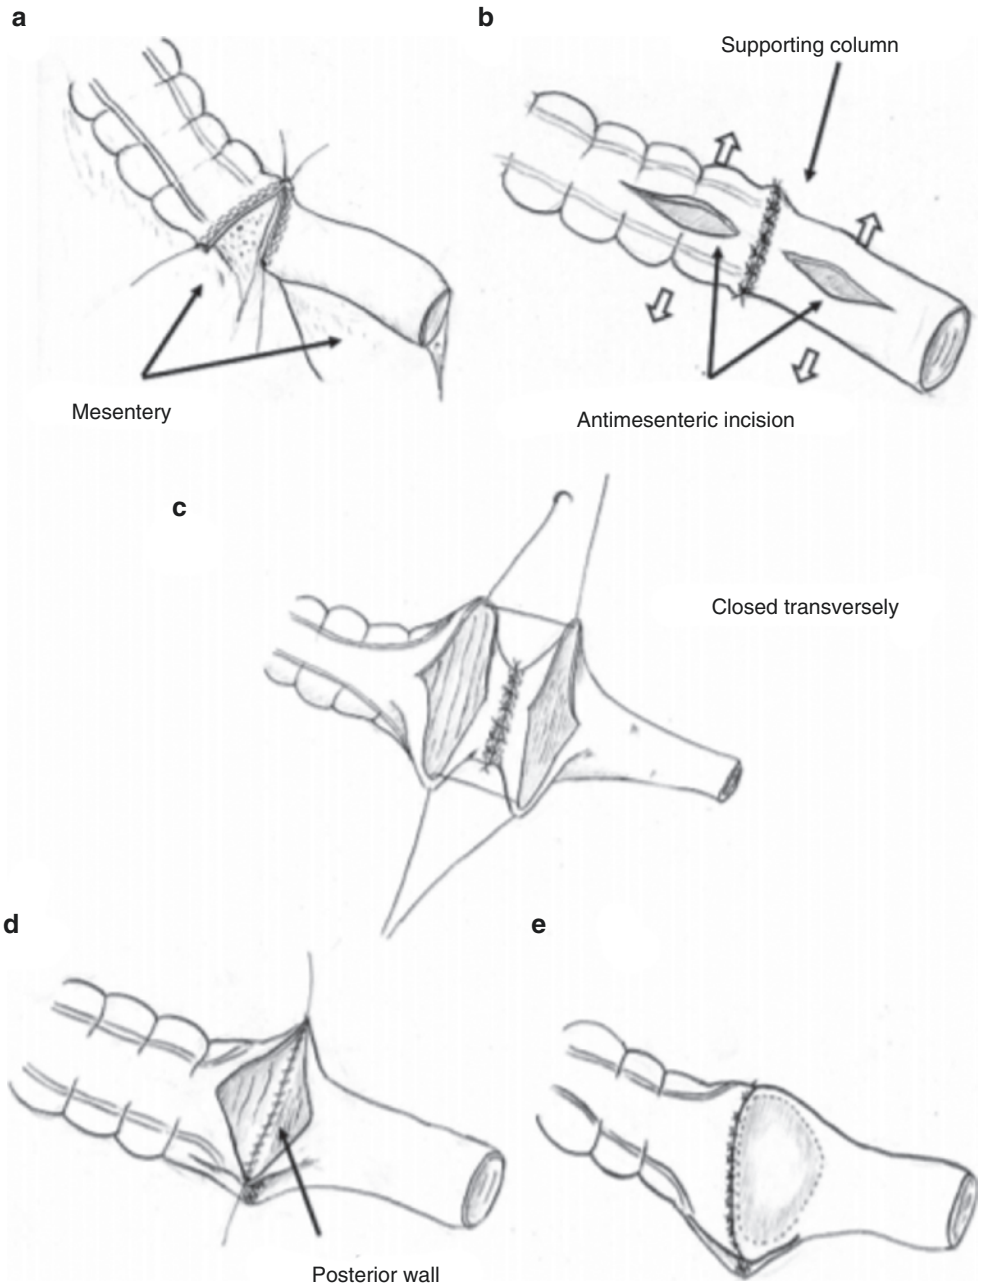

Fig. 9.30 Kono-S anastomosis for Crohn's disease. (**a**) The bowel was divided with a linear stapler perpendicular to the mesentery. Each stapled line was connected and reinforced (supporting column). (**b**) Antimesenteric longitudinal incisions (7–8 cm) were performed on each stump, starting within 0.5–1 cm away from the staple line. (**c**) Antimesenteric orifice was closed transversely. (**d**) Single layer running suture was used as posterior wall. (**e**) Anterior wall was closed in two layers with running and interrupted sutures. (Reused with permission [15]. Sutured Anastomosis

Hand-sutured anastomoses historically represent the earliest form of intestinal anastomotic construction [1, 7, 8]. It continues to be a mainstay of surgical practice. The ability to consistently perform the precise technique requires tremendous technical discipline, concentration, and manual dexterity, given the fact that tissues are neither uniform nor static. Certainly, proficiency and skill range from workmanlike to that of an artisan depending on surgeon traits: innate dexterity, meticulous attention to detail, and intense concentration. To do it well requires practice and experience. The technique has evolved over time and can be applied for any potential type of anastomosis involving small or large bowel, rectum or anus, and performed using any configuration. Thus, the hand-sewn method for anastomotic construction must be considered a fundamental and dependable technique, and intestinal surgeons must be unwavering in their commitment to mastering this technique.

Specific aspects of sutured anastomosis have been examined and investigated including: suture material, inverted versus everted technique, continuous versus interrupted, single- versus two-layered, and importance of tissue pur-

chase and travel [63, 64]. Both animal and clinical investigations have played a role in clarifying optimal practice [64]. Slieker et al. performed a systematic review exploring the scientific evidence for anastomosis and must be credited for the comprehensive effort to clarify the basis for hand-sutured anastomotic construction [66]. The spectrum of variables was examined: suture material, inverting or everting, layers incorporated and size of tissue purchase, distance traveled, and tension of tying. In addition, the number of layers of anastomosis—single- versus two-layered—is often discussed and debated. At times, the seemingly innumerable variables of hand-sutured anastomosis understandably perplex and intimidate the novice surgeon.

In regard to suture material, several features should be considered. Compared to braided suture, monofilament causes less local trauma as it passes through tissues and is less prone for adherence of bacteria [8, 63, 64]. However, monofilament suture has its detractors. Some argue that it is more expensive. It can be challenging to handle due to "memory" or its tendency to return to its original shape. Finally, in contrast to braided suture, knot tying with monofilament is less forgiving given the tendency for a knot to slip.

Slowly absorbable suture (either polyglycolic acid or polydioxanone sulfate) as opposed to rapidly absorbable suture such as chromic catgut provides adequate tensile strength for an adequate period of time and persists well into the remodeling phase of healing [63, 64]. Permanent suture is not necessary as slowly absorbable suture's durability persists until maximal tensile healing has occurred. Finally, some sutures such as linen or silk cause more local tissue inflammation [63, 64] that can affect phases of healing [5, 6].

Inverting anastomosis was popularized by Lembert and involves the apposition of serosa to serosa that results in the mucosal layer being inverted [7]. Everting anastomoses compared to inverting create larger stomata but are criticized for greater local inflammation and resulting adhesions [65]. Interestingly, bowel transected by a stapler is closed without inversion. Studies generally showed equivalency in leak; therefore, the everted sutured anastomosis generally has been abandoned [9].

In terms of tissue purchase, in addition to Lembert's emphasis on the serosa, Halsted highlighted the importance of the submucosal layer in intestinal suturing [9]. He showed that this layer offered the greatest collagen content and the highest degree of inherent tensile strength compared to the other layers. Suture material provides the tensile strength for an anastomosis during the lag or inflammatory phase when collagenolysis prevails. On the other hand, mucosa does not provide any intrinsic strength. Optimal size of recommended purchase varies and may not be well-founded. A range from 3 to 4 mm has been offered and one should take into consideration the caliber of the bowel lumen and thickness of tissues [1, 9]. There remain multiple types of suture techniques involving the type of bite. A

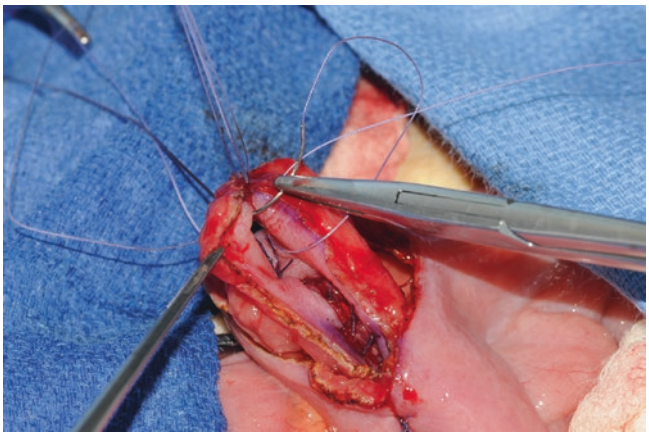

Fig. 9.38 Simple interrupted suture—3 mm bite serosa, submucosa with small purchase of mucosa (back wall of Kono-S anastomosis). (Photo courtesy of HDV)

simple suture encompassing all layers is most commonly practiced with strong emphasis on serosal and submucosal purchase that inverts the mucosa (Fig. 9.38).

The degree of tension placed on sutures during tying should account for tissue swelling and edema that will occur in the early phase of healing. Too much tension leads to ischemia, necrosis, and potential loss of tensile strength. Halsted instructed that one should avoid tying so tightly that tissues appeared "anemic" or strangled. Tying should feel secure with no visible gaping or separation, but with an approximation that will accommodate the ensuing edema.

Sutured anastomosis can be performed using interrupted or continuous suturing technique. Continuous suturing is faster. No difference in outcome can be identified comparing the two techniques [66].

Czerny modified Lembert's technique by adding an inner layer approximating the mucosa (Fig. 9.39). This continues to be a very popular approach to hand-sutured anastomosis. The posterior first rows are interrupted Lembert sutures. The bowel is opened and the inner layer is approximated in continuous fashion full thickness bites posteriorly. The anterior portion of this closure is often performed with the Connell stitch. Finally, the second layer anteriorly is completed using interrupted Lembert sutures. However, the two-layered method takes longer than single layer [67]. In addition, critics point out that two layers result in aperture stenosis relative to one layer, and studies have revealed greater degrees of ischemia and necrosis [66]. Finally, two-layer anastomoses require greater operative time and are therefore felt to be inferior to single-layered in most instances [67]. A Cochrane Database Review revealed that single-layer was equivalent to two-layer technique in terms of anastomotic leak, perioperative complications, mortality, and hospital stay [68]. A recent small, randomized prospective study confirmed these findings [69]. A randomized prospective multicenter trial in Germany unfortunately suffered from slow recruitment and failed to accrue the intended cohort. Thus, the group could not produce conclusive evidence to resolve the debate, but its publication certainly points to the profession's continued interest in establishing a best practice [70].

Hand-sewn anastomosis continues to be an important method and an essential skill for anastomotic construction. In many ways, this technique is the most versatile of method, as it can be performed for a variety of anatomic segments and creates the spectrum of configuration types. Although there are differing opinions regarding suture material and other variables, the reality is that hand-suturing technique must be relied upon in the most challenging situations or anastomosis types. When stapler instruments fail, hand-sewn anastomosis techniques should be the fail-safe technique as a contingency. Following mucosectomy or intersphincteric resection for low rectal cancer, hand-

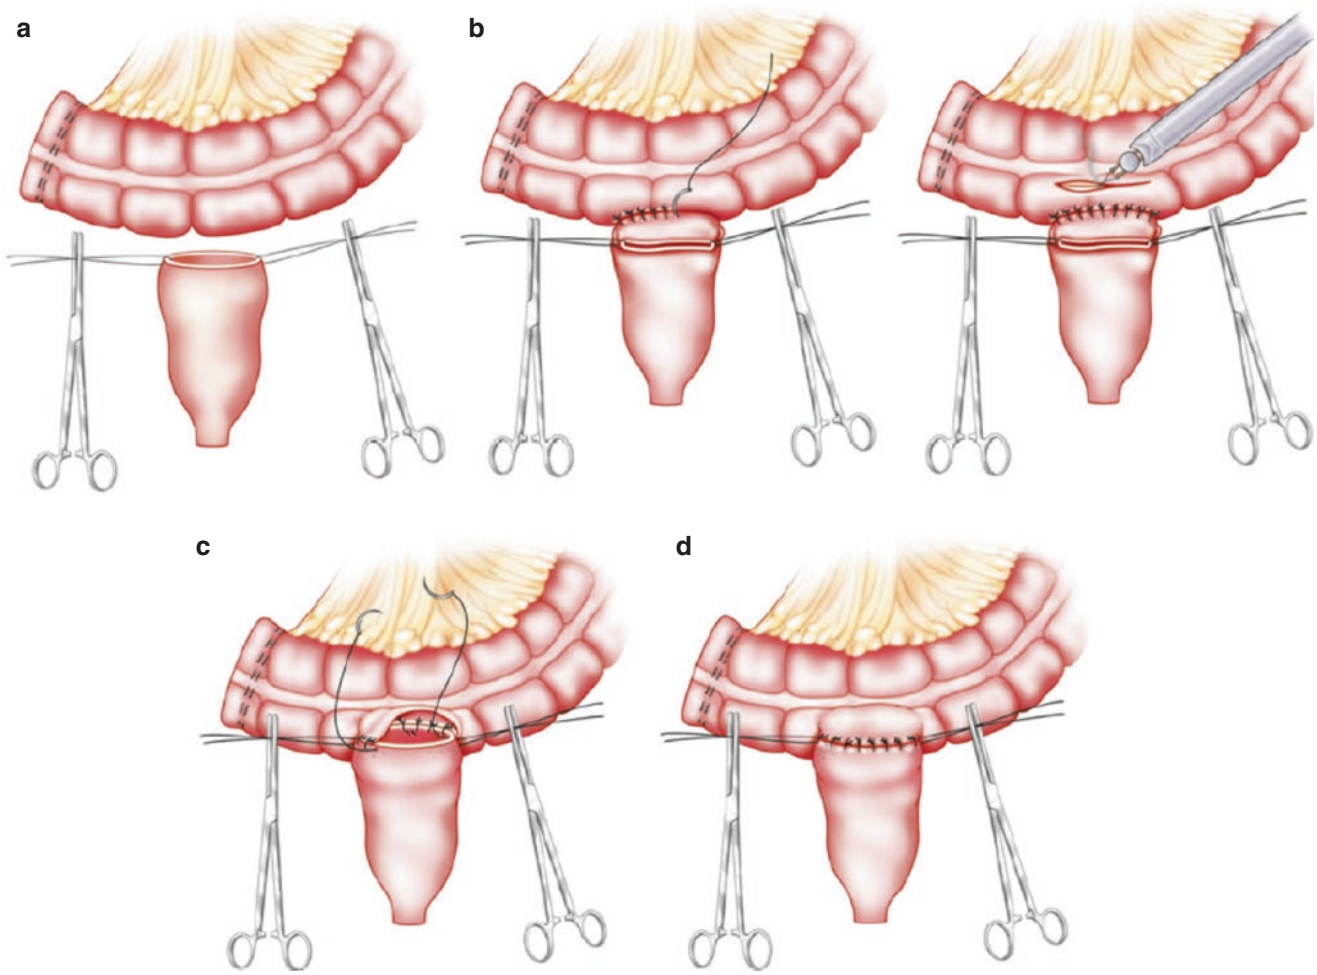

Fig. 9.39 Hand-sewn colorectal anastomosis. (**a**) The distal end of the colon is closed, and stay sutures are placed on the rectum. (**b**) A posterior layer of sutures are placed (left) and a colotomy is made (right) to match the size of the opening on the rectal stump. (Reused with permission from Hunt and Silviera [95]. Copyright © 2016 Springer Nature)

sewn anal anastomosis is generally the relied upon method to achieve the most technically challenging of colorectal anastomoses—the anastomosis within the anal canal (Fig. 9.40). While there continues to be a spectrum of practice regarding suture material and specific technique, hand-sewn anastomosis remains a critically important skill that requires constant practice and focused dedication to attain mastery.

Stapled Anastomosis

Surgical staplers are now a mainstay of modern surgical practice and a major enterprise for medical industry, with sales projected to be four billion dollars in the United States by 2022 [71]. While hand-sutured anastomosis represented the first technique for anastomotic construction, it was initially fraught with high morbidity and mortality [1]. Multiple scientific and technical advances occurred that enabled evolution of safe hand-sewn anastomoses. Surgeons recognized the challenges in precision and reproducibility of the hand-sutured technique [7]. Mechanical methods for anastomotic construction were pursued to address this issue. Introduced in 1917 by Hultl, the original tissue stapler design proved heavy and unwieldy. However, this first iteration established fundamental design concepts including the importance of tissue compression, creation of B-shaped staples, and the presence of two overlapping rows of staples that secure an airtight seal while possessing gaps that ensure perfusion (Fig. 9.41). Remarkably, modern day staplers continue to depend on these essential concepts, and staple shape remains a measure of accurate stapler performance [72]. Surgical staplers revolutionized anastomotic construction, and Hultl's modest design represented a major paradigm shift in operative technique.

Modern stapling technology comes in three distinct types: linear or transverse noncutting, linear cutting, and circular

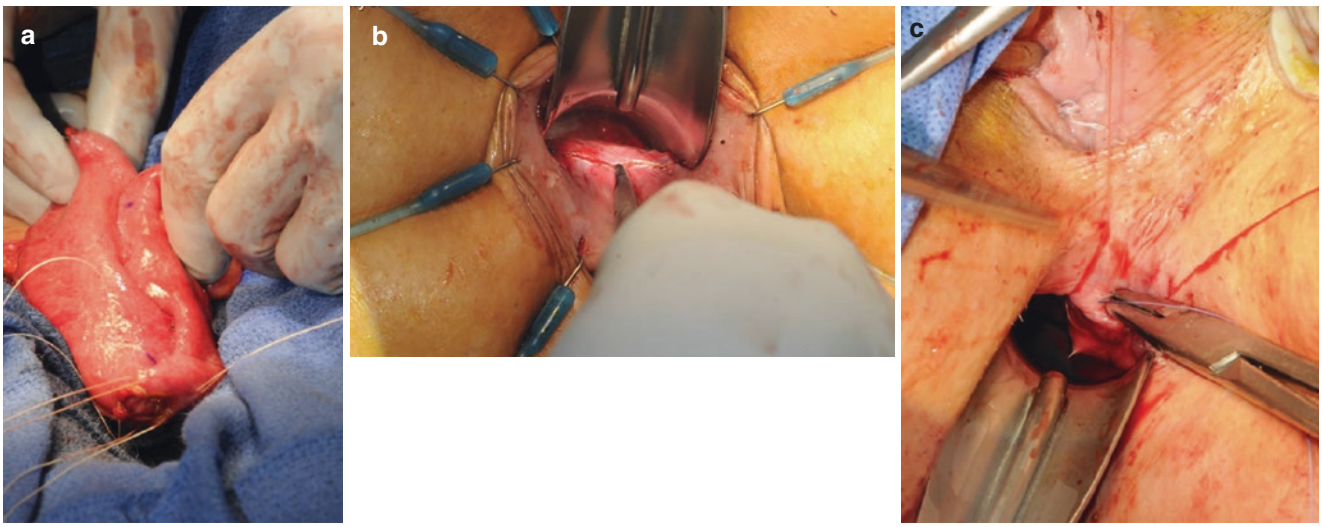

Fig. 9.40 Ileal J-pouch anal anastomosis after mucosal proctectomy. (**a**): Ileal J pouch; (**b**): Mucosal proctectomy for familial polyposis; (**c**): Hand-sewn anal anastomosis. (Photos courtesy of HDV)

cutting models. Various manufacturers and unique characteristics may differentiate staplers. Each stapler type has been used for anastomotic construction. The linear noncutting and transverse staplers are primarily used for bowel resection or closure of a defect or lumen. Linear cutting staplers and circular staplers are the types usually employed for anastomosis. Just as staplers often require some element of suturing, anastomotic construction often requires using a combination of different stapler types. Understanding specific design characteristics therefore must be appreciated. Stapled anastomosis can be undertaken for both open and minimally invasive platforms, though important technical variations are required to perform anastomotic construction.

The titanium staple is permanent and incites the lowest levels of tissue reaction and inflammation compared to other suture material [64, 73]. When shaped properly, staples provide greater levels of tensile strength than suturing.

Types of Tissue Staplers

Linear noncutting staplers (Fig. 9.42) place two overlapping staggered rows of staples to produce airtight compression with an array that allows perfusion. Following stapling, the tissue must then be divided manually. A variation of the transverse stapler is the Contour® (Ethicon), a curve-shaped stapler head designed for pelvic transection of the rectum, which provides three staple lines with knife cutting to leave one row on the specimen side of the resected rectum. This closes the specimen to prevent contamination.

Cutting staplers, either linear or circular, also provide the same staggered overlapping staple lines and then are cut between rows of staples with an internal knife leaving staples on both sides of the cut. These staplers are utilized for the actual construction of intestinal anastomosis. Linear cutting staplers vary in length, staple height, and number of rows of staples created. Generally, linear cutting staplers enable creation of side-to-side bowel anastomosis. Staplers have been modified specifically for laparoscopic and now robotic surgery by placing the end effector at the tip of a thin shaft that traverses access ports into the peritoneal cavity. In addition, linear cutting staplers provide an increased number of rows (from four to six), leaving three rows on either side of the cut. Circular staplers differ in diameter. Based on stapler manufacturer,

the device can be chosen based on staple height or the device can be closed to a point that corresponds to the desired staple height. One can perform anastomoses in a variety of configurations though its greatest contribution to anastomotic construction has been performing end-to-end low pelvic anastomoses.

Compression and Tissue Stapling

Compression between the stapler head and anvil causes tissue thinning as water is forced out of intracellular and extracellular spaces. Initial resistance of tissue to load compression ultimately results in stress relaxation of tissues [72]. Proper staple formation occurs as a result of adequate compression

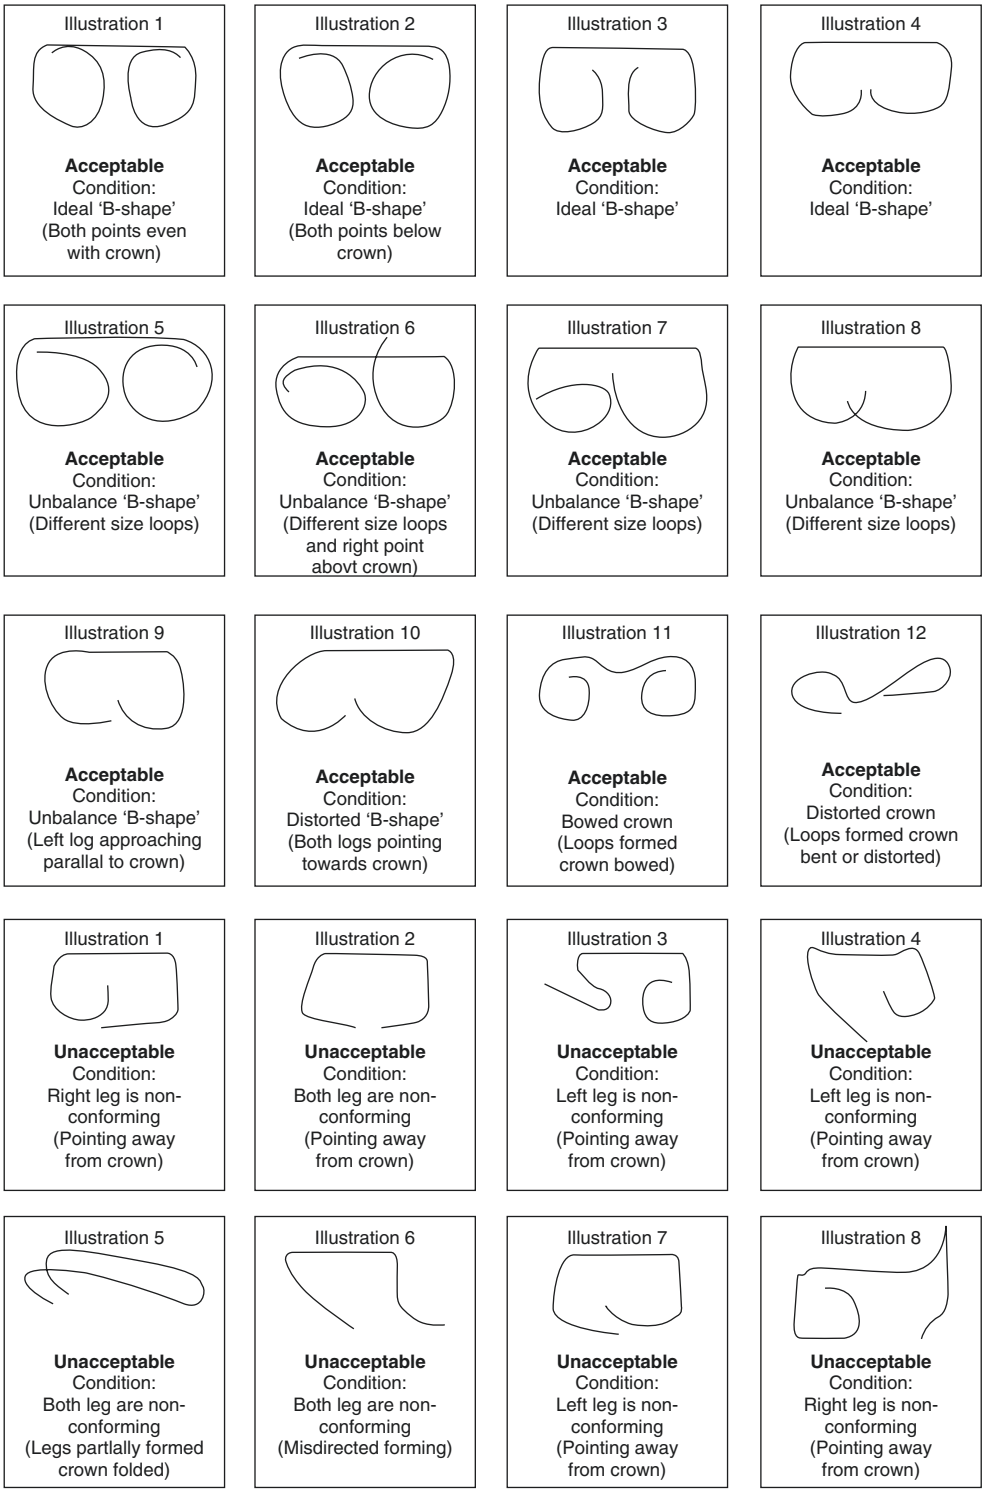

Fig. 9.42 Acceptable and unacceptable staple forms produced after firing of staples into tissue to create an anastomosis. **Note:** Presence of unacceptable forms can compromise integrity and strength of the staple line resulting in an increased rate of leaks and bleeding. (Reprinted from *Am J Surg*. Akiyoshi et al. [96]. Copyright © 2011 Elsevier)

and tissue thinning. Excessive compression can result in tissue tearing and loss of tissue purchase by staples [73] (Baker photo of staple line dehiscence). Approximation of the anastomosis is maintained by proper staple formation and tensile strength of the metal. Compression develops by different mechanisms. Linear and circular staplers provide load to tissues by parallel closure of the stapler head to the anvil. Minimally invasive linear cutting staplers use a cantilever mechanism. The latter may explain differences in compression created near the apex of the stapler as opposed to the distal tip, and accordingly, staple formation can be affected [74].

One of the initial decisions by surgeons regarding linear stapler use is the staple height specific for the organ and anticipated thickness. Staple height can be varied with taller staples with thicker diameters used for increasing thickness of tissue (Fig. 9.43). General recommendations regarding staple height are suggested for various intestinal segments. Inappropriately short staple height relative to tissue thickness can result in tearing, with evidence of this ranging from visible serosal laceration to complete staple line failure [72, 74, 75].

Nakayama et al. examined linear cutting staplers and the role of pre-compression on staple formation in a porcine model utilizing gastric tissue. Several important observations are worthy of mention from this seminal work. First, pre-compression improved staple formation, and there was a correlation between longer duration of compression and more consistent staple form. Second, there was obvious mismatch of staple height where the blue cartridge was used on the thickest bowel (pylorus). Poor staple form occurred irrespective of pre-compression, and thus gross mismatch could not be overcome by varying actual stapler execution. While it can be difficult to precisely know tissue thickness and to what degree pathologic conditions may alter typical wall thickness, slight inaccuracies of staple choice may be addressed by purposefully prolonged tissue precompression prior to staple firing. Third, the tip of the stapler formed staples less consistent than the base. Thus, the area furthest from the action point where precompression develops may experience some decremental level of load on the tissue. Again, increasing precompression time was found to also improve staple formation at the tip. Finally, inspection of the staple line formation comparing the two sides—proximal and distal side ("specimen-side" and "patient-side")—revealed that the staple formation was reliable between the two sides. This suggests that in the clinical setting, following staple firing and complete transection, reviewing the specimen side of the staple line of transection one can infer the status of the staple line left in vivo [74].

Rectal transection in open surgery can typically be accomplished with a single firing of a 30-45 mm transverse staple. Multiple applications of the linear cutting stapler are frequently necessary for rectal transection in laparoscopic or robotic surgery. This appears to be a risk factor for anastomotic leak. Poorly formed staples at the tip of the linear staple line represent a potential hazard. This "migratory" staple can result in stapler malfunction and jamming [72]. Prior to subsequent stapler firings, the in vivo and specimen side staple lines are inspected. If present, the "migratory" staple should be removed.

Another feature unique to laparoscopic linear cutting staplers is the interval firing stroke mechanism. Unlike linear cutters designed for open use, multiple strokes complete the staple line for each cartridge. Compression can be influenced by the speed of stroke firing [75]. In addition to a period of precompression time, interstroke waiting also may impact reliable staple formation [76]. Motorized powerized firing mechanisms perform this aspect of stapling on newer versions of linear staplers. Davinci Sureform linear cutting stapler® (Intuitive) can alter the stroke firing sequence as a result of its tissue thickness sensor, and mid-stroke the mechanism can pause allowing more compression to occur prior to completion. The Signia Stapling System® (Medtronic) similarly assesses compression characteristics of the tissue and alters stroke firing. Future studies will be required to see if these features will improve rates of staple formation, especially at the distal end of staple lines in particular. What is clear is that manufacturers are appropriately focusing efforts on these challenging issues of tissue thickness, compression, and firing stroke mechanism to improve staple formation.

Circular staplers revolutionized stapling to the mid-to-low rectum following low anterior resection, but can be

Color	Rows	Tissue type	Open staple height	Closed staple height
Grey	6	Mesentery	2.0 mm	0.75 mm
White	6	Vascular	2.5 mm	1.0 mm
Blue	6	Standard	3.5 mm	1.5 mm
Gold	6	Standard/thick	3.8 mm	1.8 mm
Green	6	Thick	4.1 mm	2.0 mm

Fig. 9.43 Dimensions of commonly available staple cartridges that are used to accommodate different tissue thicknesses for appropriate tissue management. (Reused with permission from [83]. Copyright © 2014 Dove Press)

employed for end-to-side or side-to-end anastomoses for both pelvic and abdominal anastomosis construction. Interestingly, the circular stapler creates compression differently than the linear cutter in that it staples and cuts upon one single firing. Anastomotic donuts of excised tissue produce the final lumen of the bowel approximation. The mucosa is inverted and two or three rows (depending on manufacturer) of staggered staples are inserted.

Nakayama investigated double stapling and found that the circular stapler produced reliable B- shaped staples irrespective of precompression time or degree of closure of instrument [76]. The authors comment that this most likely is due to the parallel closure mechanism by which compression occurs. Inspection of anastomotic donuts for the presence of all layers as well as intact rings is recommended to assess staple line integrity. Air leak testing is a necessary adjunct for pelvic anastomosis [77]. Videoendoscopy allows for visual inspection as well as air leak testing.

In summary, strategies for safe use of staplers (depending on brand and model) includes assessing tissue thickness and estimating appropriate cartridge load and staple height. Consider waiting longer than the recommended 15 seconds and perhaps as long as 1 minute prior to firing the stapler. Similarly, pausing in between strokes may allow for additional compression and more reliable staple formation. If sequential stapler fires are required to completely transect the entirety of the bowel, look carefully at the staples at the tip for a possible aberrantly formed, loose "crotch" staple that should be removed prior to stapling. After transection, inspection of the specimen side of the staple line can be assessing for staple line integrity, staple formation, and evidence of serosal tearing to alert to possible threatened anastomotic construction. An additional investigation following rectal transection and prior to double stapling is to perform endoscopy with air leak testing [77–79]. While it remains to be seen if the suggestions will translate into better outcomes, consideration for safe practice seems reasonable.

While favored for their consistent and reproducible construction, stapled anastomoses may leak. This holds true even in the case of ileocolic anastomosis, considered to be one of the lower risk anastomoses. In recent large European comparative studies, stapled anastomotic construction has been identified as a factor for leak [80–82]. Errors have been identified during technical performance and these potentially affect patient outcomes [72, 83, 84]. It is important to point out that stapler end effector takes place housed within an instrument, which in the case of laparoscopic or robotic platforms, is separate and at a distance from the surgeon. This is inherently a danger point in anastomotic construction. Automation and physical separation reduce the ability of surgeons to be involved in the actual staple insertion, and the technology impacts our ability to inspect the granular details of an anastomosis. This lack of access to the staple line may diminish surgeon vigilance. Therefore, stapled anastomotic construction requires detailed understanding of the instrument–tissue interaction, and similar to hand-sutured technique, execution of a stapled anastomosis requires focused attention to detail [83].

Compression Ring Anastomosis

This technique is not commonly performed in North America and is currently not performed by either author. However, we remain aware of its use in other centers around the world. Interestingly, some form of compression anastomosis method has been available since the early history of surgical anastomosis construction. First introduced in the nineteenth century by Denans and later refined and popularized by the Murphy Button, this mechanical instrumentation to achieve anastomosis has undergone multiple evolutions and innovations. The idea rests on a sutureless rejoining of the two ends of bowel with a ring left in vivo that acts to physically compress the circumference of the layers of one end of the bowel wall to the other. Ischemia and necrosis occur slowly over time during which the physiology of healing results in regaining intrinsic tensile strength and bowel integrity. The initial integrity of the anastomosis is based upon the purchase of the tissue by the device's circumferential purchase and the compression exerted. The device that can be either metallic or biodegradable eventually passes transanally.

There is no foreign body retained within the wall itself, and the theoretic benefit is less inflammation due to a reduction in the lag or inflammatory phase of healing. Experimental studies in a porcine model demonstrate initial bursting pressures exceeding stapled anastomoses [85]. Histopathology studies have revealed diminished numbers of inflammatory cells as well as less scar formation compared to stapled anastomosis [86]. Interestingly, fewer adhesions were also noted to the anastomosis [86]. The ring, which can be comprised of absorbable or permanent materials, will then be passed per anus with the resumption of fecal flow.

A recent meta-analysis examined compression compared to conventional (hand-sewn and stapled) colorectal anastomosis. Ten RCT's included nearly 2000 patients in the analysis. There were no significant differences in anastomotic leak, stricture formation, or mortality. There was a shorter time to return of bowel function in the compression group but there was no difference in terms of length of hospital stay. No significant difference was seen in post-operative morbidity except for a higher rate of bowel obstruction in the compression group, OR – 1.87. The authors concluded that there was no significant advantage of compression anastomosis over conventional [87].

In summary, compression ring method continues to be a technology available for anastomotic construction and may offer potential benefits from a healing model perspective.

The Conundrum of Best Practice and Continuing Challenge

Clarifying the best practice for anastomotic construction represents one of the most compelling areas of interest. Staplers, though more costly than suture materials, generally offset this difference by being faster. Most identify anastomotic leak as the critical parameter given the tremendous morbidity and increased mortality. In addition, leaks represent a tremendous financial burden due to increased consumption of health-care resources as well as the loss of productivity for those suffering from leak.

Comparison studies looking at hand-sewn versus stapled anastomoses generally do not show any clear-cut difference. A Cochrane Database Review has examined this topic most recently in 2012. The review included nine randomized controlled trials (1233 patients, 622 with stapled, and 611 with the hand-sewn technique) comparing the safety and effectiveness of stapled versus hand-sewn colorectal anastomosis surgery. Meta-analysis was performed. Outcome measures were mortality, anastomotic dehiscence, narrowing (stricture), hemorrhage, need for reoperation, wound infection, anastomosis duration (time taken to perform the anastomosis), and hospital stay. No significant statistical differences were found except that stricture was more frequent with stapling ($P < 0.05$), and the time taken to perform the anastomosis was longer with hand-sewn techniques [88].

Interestingly, looking specifically at ileocolic anastomosis, a prior Cochrane Database Review suggested superiority of the stapled technique over hand-sewn. This systematic review found seven randomized controlled trials with a total of 1125 participants (441 stapled, 684 hand-sewn) comparing these two methods. The leak rate for stapled anastomosis was 2.5%, significantly lower than hand-sewn, 6%. For the sub-group of 825 patients with cancer in four studies, stapled had fewer leaks compared with hand-sewn, being 1.3% and 6.7% respectively. Of note, in 264 noncancer (including patients with Crohn's disease) patients in three studies, there were no differences for the reported outcomes. Overall, there was no significant difference in the other outcomes of stricture, anastomotic bleeding, time of anastomosis, reoperation, mortality, intra-abdominal abscess, wound infection, and length of stay [89].

However, since this review several reports continue to examine this topic of technical differences. The HASTA trial examined ileostomy closure, comparing hand-sewn to stapled anastomosis [90]. This multicenter prospective randomized controlled trial compared 337 randomized patients undergoing closure of loop ileostomy after low anterior resection for rectal cancer in 27 centers. The primary endpoint was the rate of bowel obstruction within 30 days after ileostomy closure. Rate of anastomotic leakage was not different (stapler: 3.0%, hand suture: 1.8%, $P = 0.48$). The overall rate of postoperative ileus after ileostomy closure was 13.4%. Seventeen of 165 (10.3%) patients in the stapler group and 27 of 163 (16.6%) in the hand suture group developed bowel obstruction within 30 days postoperatively [odds ratio (OR) = 1.72; 95% confidence interval (CI): 0.89–3.31 = 0.10]. Operative times were shorter in stapled group.

Several large European studies assessed outcomes of right colectomy including anastomotic leak. Data from the German Society for General and Visceral Surgery registry from 2010 to 2017 were analyzed [91]. A total of 4062 patients who had undergone open right hemicolectomy for colonic cancer were analyzed. All patients had an ileocolic anastomosis, 2742 hand-sewn and 1320 stapled. Baseline characteristics were similar. No significant differences were identified in anastomotic leakage—stapled 3.9% versus hand-sewn 3.0%. No difference was seen in postoperative ileus, reoperation rate, surgical-site infection, LOS, or death. The stapled group had a significantly shorter duration.

A Danish nationwide database examined 1414 patients undergoing right hemicolectomy for adenocarcinoma with primary anastomosis between October 2014 and December 2015 [82]. There were 391 (28%) in the stapled group and 1023 (72%) in the hand-sewn group. Forty-five patients (3.2%) developed anastomotic leak; 21 of 391 (5.4%) and 24 of 1023 (2.4%) in the stapled and hand-sewn groups, respectively ($P = 0.004$). This difference was confirmed in multivariable analysis (adjusted OR: 2.91; 95% CI, 1.53–5.53; $P < 0.001$) and after propensity score matching (OR: 2.41; 95% CI, 1.24–4.67; $P = 0.009$). Thirty-day mortality was 15.6% (7/45) and 2.1% (29/1369) in patients with and without anastomotic leak ($P < 0.001$).

Finally, a multicenter international European cooperative study recently published findings examining right colectomy [92]. This study reports the morbidity and mortality rates for right-sided colon cancer and identifies predictors for unfavorable short-term outcome after right hemicolectomy. This included all patients undergoing elective or emergency right hemicolectomy or ileocecal resection over a 2-month period in early 2015. Predictors for anastomotic leak and 30-day postoperative morbidity and mortality were assessed using multivariable mixed-effect logistic regression models after variables selection with the Lasso method. Of the 2515 included patients, an anastomosis was performed in 97.2% ($n = 2444$): hand-sewn in 38.5% ($n = 940$) and stapled in 61.5% ($n = 1504$) cases. The overall anastomotic leak rate was 7.4% (180/2444), 30-day morbidity was 38.0% ($n = 956$), and mortality was 2.6% ($n = 66$). Patients with anastomotic leak had a significantly increased mortality rate (10.6% vs. 1.6% no-leak patients; $P > 0.001$). At multivariable analysis, the following variables were associated with

anastomotic leak: longer duration of surgery (OR = 1.007 per min; $P = 0.0037$), open approach (OR = 1.9; $P = 0.0037$), and stapled anastomosis (OR = 1.5; $P = 0.041$).

Ileocolic anastomosis is generally considered a straightforward operation with relatively simple anastomotic construction options. These reports highlight the continued issue of anastomotic leak and the absence of differences in outcomes based on technique. Tension and the need for mobilization are far less an issue compared to left-sided resection. Despite our perception of technologic improvement in stapling devices and their broad use, anastomotic construction and unanticipated outcomes continue even with our best efforts. Hand-sewn anastomosis continues to provide arguable equivalent results when compared to stapling techniques. Anastomotic construction continues to be a compelling and challenging topic for study in an effort to improve our understanding of best practice in surgical technique. The hope is that we can reduce the role of the surgeon's performance as a factor in undesired outcomes. The heterogeneity of this endeavor requires a vast array of operative techniques and methods. The reality is that some operations, including the most challenging ones we undertake, require a hand-sewn technique. Surgeons must possess and master a broad skillset that enables judicious adaptation and execution of the various techniques appropriate for each unique operation. Most importantly, we do so firmly intent and focused on adhering to the fundamental principles defining safe anastomotic construction: precise, tension-free, and secure approximation of well-perfused, healthy bowel.

Anastomotic Complications

10

Charles M. Friel and Cindy J. Kin

Key Concepts

- Mechanical bowel prep and oral antibiotics prior to colon resection are associated with a lower risk of anastomotic leak.
- A significant proportion of anastomotic leaks present after the immediate postoperative period, especially if there is a history of pelvic radiation.
- Most early anastomotic bleeds are self-limited; late bleeds may be a sign of anastomotic leak.
- Anastomotic stricture after cancer resection should undergo endoscopic biopsy and imaging to rule out recurrent cancer.
- Benign anastomotic strictures may be amenable to endoscopic management, but some will require surgical revision or completion proctectomy with permanent colostomy if the strictured anastomosis is in the pelvis.
- Anastomotic complications often lead to significant detriments to quality of life with regard to pain, defecatory function, sexual function, and urinary function. Discussion of these issues with patients is critical for surgical decision-making.

Anastomotic Leak

The unfortunate reality faced by every surgeon who performs bowel resections is the occurrence of anastomotic leaks. The incidence of anastomotic leak after bowel anastomosis ranges from 2% to 21% and is associated with significant risk of short- and long-term morbidity [1–5]. This complication can be a devastating event that sets off a cascade of other unfortunate events, resulting in significant detriments to quality of life, increased pain, prolonged disability, and sometimes death. Anastomotic leaks are associated with significantly higher healthcare resource utilization and cost, as patients with this complication are more likely to require additional diagnostic tests, procedures or reoperations, hospital days, outpatient care, and readmissions [6, 7]. Perhaps the most frustrating aspect of anastomotic leaks in colorectal surgery is the fact that leaks and their severe consequences still occur despite the adoption of evidence-based perioperative guidelines, efforts to optimize patient risk factors, and adherence to surgical principles. Although important progress has been made toward reducing the risk of anastomotic leak, there is still much work to be done to increase our understanding of the pathophysiology of anastomotic leak, and effective strategies for prevention.

Risk Factors

The site of anastomosis is strongly related to the risk of anastomotic leak. The risk of leak is lower for small bowel and ileocolic anastomoses, and higher for ileorectal and distal colorectal anastomoses [8, 9]. Patient-related risk factors for anastomotic leak are diabetes mellitus, hyperglycemia and high HbA1c, male sex, higher body mass index, tobacco use, inflammatory bowel disease, chronic immunosuppressive medications, radiation enteritis, malnutrition, hypoalbuminemia, and active infection [10–16]. Among patients undergoing rectal cancer resection for cancer, additional risk factors for anastomotic leak include more distal anastomoses, neoadjuvant pelvic radiation therapy, and advanced tumor stage [17–20].

Intraoperative risk factors include the inability to achieve a tension-free anastomosis and poor blood supply to the ends of bowel used for anastomosis, blood loss and blood transfusions, prolonged operating time, and intraoperative contamination [10–16]. Using multiple stapler firings across the rectum, which is commonly done in laparoscopic and robotic approaches, may also be associated with a higher risk for

anastomotic leak [21–23]. The operating surgeon is another potential risk factor, although little is known about which surgeon characteristics would increase the risk for a surgical complication [24, 25]. Closed-suction drainage is commonly used in low pelvic anastomoses, but whether its routine use reduces the risk of anastomotic leak is still under debate [26–31]. Even when an anastomotic leak occurs, it is rare that the drain placed during the initial operation would effectively control the pelvic sepsis by draining pus or stool. However, as multiple studies have not shown that drains increase the risk for a leak, placing them at the time of surgery may still be helpful in the event of an abscess or leak, as the interventional radiologists may reposition a surgically placed drain into a better location. These drains may also be useful in controlling pelvic hematomas, thus preventing them from causing inflammation and pressure on the anastomosis.

The role of proximal fecal diversion in reducing the risk of anastomotic leak is also unclear. It has been cited as a risk factor for leak, as a protective factor, and as a neutral factor [17, 32, 33]. It certainly decreases the risk of septic complications of a leak, and it may even prevent an anastomotic leak from manifesting any clinical signs [34–36]. Therefore, the risk for reoperation is lower, as is the risk of mortality [19, 37, 38].

There has been considerable debate over whether mechanical bowel preparation and/or oral antibiotics prior to colorectal resection reduces the risk of anastomotic leak, because the studies had revealed a diverse range of outcomes [39–41]. Multiple analyses using the American College of Surgeons National Surgery Quality Improvement Program database over the last several years are consistent with the conclusion that both mechanical bowel preparation and oral antibiotics together are associated with a lower risk of anastomotic leak [42–50].

An emerging body of research suggests that another risk factor for anastomotic leak resides in the gut microbiome [51]. This offers a biologic explanation for why mechanical bowel preparation with oral antibiotics is helpful for reducing anastomotic leak. This is a particularly compelling area of research as it may explain the leaks that occur in patients with no other risk factors, which are often the most frustrating and confusing events for surgeons. Enterococcus faecalis has been demonstrated to degrade collagen and activate tissue matrix metalloproteinase 9 (MMP9) in host intestinal tissue, thus potentially contributing to the pathogenesis of anastomotic leakage. Particular strains of E. faecalis have greater ability to degrade collagen and activate MMP9, and these strains are more likely to be found in leaking anastomoses in rat models [52]. Pseudomonas aeruginosa colonizing intestinal tissues can mutate to increase collagenase activity and destroy tissue more effectively [53]. Standard oral or intravenous antibiotics do not eliminate these organisms. Recent studies have examined the ability of other compounds or diet modifications to reduce the virulence of these organisms and prevent anastomotic leak in animal models [54–56]. This field of investigation continues to rapidly evolve and findings in the near future may dramatically alter our understanding of why anastomotic leaks occur and how to prevent and treat them.

Diagnosis

The diagnosis of anastomotic leak is not always obvious. Aside from extravasation of retrograde contrast enema on computed tomography (CT) scan, which has the highest sensitivity and specificity for anastomotic leak, there is very little consensus on what clinical findings are confirmatory for an anastomotic leak [57–59]. In the immediate postoperative period, clinical signs that raise concern for an anastomotic leak include fever, leukocytosis, increased pain, suspicious drainage from the wound or surgical drain, and prolonged ileus. If the CT is performed within the first 4 days of the operation, findings may be nonspecific as it often takes until the fifth day for infected fluid to develop rim enhancement. While a postoperative CT may demonstrate an obvious leak with free air, extraluminal extravasation of oral or rectal contrast, or a defect in the anastomosis with adjacent free fluid or an abscess, it more frequently demonstrates rim-enhancing fluid collections or specks of free air that are equivocal for a leak.

Leaks are commonly assumed to occur within the first week of the operation during the index hospitalization, but, in reality, up to half of leaks may present after the patient has been discharged, with a significant proportion detected over a month after surgery [8, 60]. Among patients undergoing low anterior resection for rectal cancer, a third of anastomotic leaks become clinically evident over a month after the operation [61]. In the immediate postoperative period, leaks may present with nonspecific symptoms such as ileus or low-grade fever, or with frank peritonitis and sepsis (Fig. 10.1). Late leaks tend to present insidiously with pelvic pain and failure to thrive.

Elevated serum C-reactive protein (CRP) and procalcitonin are biomarkers that serve as early indicators of anastomotic leak after colorectal surgery. These biomarkers are used in some enhanced recovery clinical pathways, as length of hospitalization has shortened significantly and thus may result in patients with leaks that are not yet clinically apparent being discharged. Serum CRP levels less than 172 mg/L on postoperative day 3, 124 mg/L on postoperative day 4, and 144 mg/L on postoperative day 5 all correspond to a negative predictive value of 97% for anastomotic leak [62]. CRP levels are expected to be higher in patients undergoing open colorectal surgery compared to patients undergoing laparoscopic surgery. In patients undergoing open surgery,

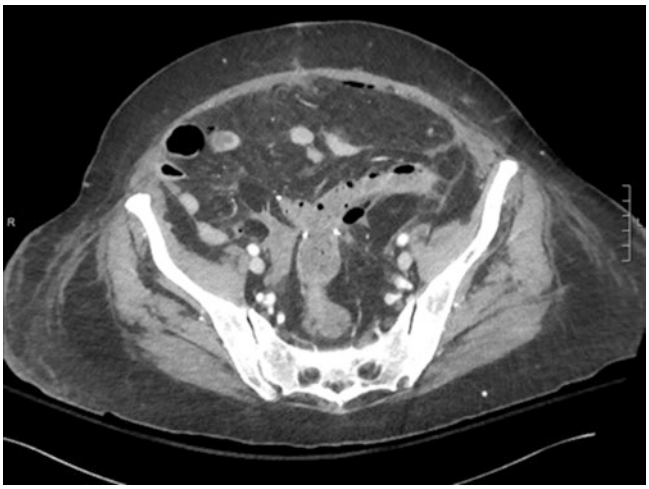

Fig. 10.1 Colorectal anastomotic leak: CT image of a patient who developed anastomotic leak on postoperative day 5 after undergoing sigmoid colectomy for diverticulitis complicated by colovaginal fistula. She required operative intervention for washout and takedown of the anastomosis and creation of an end colostomy

CRP levels over 209 mg/L on postoperative day 3 and 123.5 mg/L on postoperative day 4 are most predictive of leak. In patients undergoing laparoscopic surgery, a CRP level over 146.7 mg/L on postoperative day 2 was most predictive of leak [63]. Serum procalcitonin is also a biomarker studied for its association with anastomotic leak, and can be used in conjunction with CRP. The negative predictive value is 96.9% for a procalcitonin less than 2.7 ng/mL on postoperative day 3, and 98.3% for a procalcitonin less than 2.3 ng/mL on postoperative day 5 [64, 65]. If these biomarkers surpass the cutoff values and the patient appears clinically well, the decision to discharge the patient should be weighed against the higher risk for readmission [66]. A serum CRP value less than 145 mg/L on postoperative day 3 has a 93% negative predictive value for readmission within 30 days of surgery [67].

Management of Anastomotic Leak

In the event of an anastomotic leak, the strategy for managing it depends on several factors: the patient's clinical condition, the timing of the leak, the location of the anastomosis and leak, and whether the leak is contained. On one end of the spectrum, the patient with sepsis with fecal peritonitis has a clear indication for emergent return to the operating room for exploration and washout with source control. The operative decision of whether to take down the anastomosis, or place drains and divert proximally depends on the degree of operative exposure and the location of the anastomosis. If the surgeon cannot safely gain access to the anastomosis due to obliterative adhesions, then the best option is to lay drains in the area of the leak and bring up a proximal stoma to divert the fecal stream. If the surgeon can safely expose the anastomosis, then management largely depends on the location of the anastomosis and the size of the defect. For small bowel and ileocolic anastomoses, resection and re-anastomosis can be performed if the bowel ends are viable and mobile. If the status of the patient or the bowel is marginal, then formation of an end ostomy and mucus fistula, or a divided end-loop stoma is the safest option. For colorectal anastomoses with a significant defect, then the safest option is to take down the anastomosis and bring up an end colostomy. Measures to prevent a dehiscence of the top of the rectal stump, which can lead to chronic pelvic abscesses, include oversewing the rectal stump staple line and placing a rectal tube for decompression. Drains should also be placed over the rectal stump given the high likelihood of a dehiscence. While it may be possible to use a minimally invasive approach to reoperate on patients who have recently undergone a minimally invasive operation, it is quite likely that a laparotomy will be required to perform an adequate washout and gain source control. The surgeon must maintain objectivity in what can be a trying time for all parties, and remain steadfast in doing the safest operation for the patient.

On the other end of the spectrum, the patient with a contained leak and a small abscess <3 cm may successfully undergo non-operative management with broad-spectrum antibiotics. Larger abscesses may require percutaneous drainage in addition to broad-spectrum antibiotics. Fecal diversion may or may not be necessary, depending on the severity of the leak. For colorectal or coloanal anastomotic leaks, drain placement may be performed transrectally through the anastomotic defect and into the extraluminal abscess cavity, and depending on the distance of the leak from the anus, can be performed either by the surgeon or by our colleagues in interventional radiology. Non-operative treatment of leaks may be successful in allowing maintenance of the primary anastomosis in half of patients with anastomotic leaks [68]. If the patient remains stable and the leak is well controlled, then closure of the anastomotic defect and collapse of the associated abscess cavity may occur without the need for a major anastomotic revision. If the leak is not well controlled with drainage and fecal diversion then the patient may need to undergo resection of the anastomosis. If possible, it is ideal to wait at least 3 months to reoperate to allow for resolution of inflammatory adhesions that would make reoperation more treacherous. Waiting even longer will often result in healing of the anastomosis without the need for operative intervention [69]. For colorectal anastomoses that fail to resolve with drainage, resection of the anastomosis with redo colorectal or coloanal anastomosis may be possible. However, completion protectomy with permanent end colostomy may be necessary or preferable to maximize quality of life.

If the anastomosis is distal enough, in select cases a leak may be repaired transanally using an endorectal advancement flap, dermal advancement flap, or primary suture repair [70, 71]. Some groups have described the use of transanal endoscopic platforms such as Transanal Minimally Invasive Surgery (TAMIS) or Transanal Endoscopic MicroSurgery (TEMS) to directly repair anastomotic leaks [72, 73]. Depending on the degree of pelvic or intra-peritoneal contamination, transanal repair may be combined with laparoscopic washout. Creation of a diverting loop ileostomy should also be strongly considered if one of these techniques is used. These transanal techniques are often not feasible given how fibrotic the tissues tend to be around the site of a leak, so completion proctectomy or proctectomy with coloanal anastomosis may be the only options.

Chronic presacral sinus tracts result from anastomotic leaks in the pelvis that do not heal and are a source of ongoing inflammation (Fig. 10.2). Patients may suffer from symptoms including pelvic pain, fevers, rectal discharge, and tenesmus. These tracts typically occur if there is a leak from the posterior aspect of a colorectal anastomosis. Among patients undergoing low anterior resection for rectal cancer after neoadjuvant chemoradiation therapy, presacral sinus tracts may occur in 9.5% and thus represent a significant clinical dilemma [61]. There are several strategies for treatment of these tracts. One option is fecal diversion in combination with a septotomy, in which the bowel wall between the lumen and the sinus tract is divided, effectively unroofing the sinus tract and including the underlying cavity as part of the lumen. This can be done via a direct transanal approach if the anastomosis is distal enough [74]. The transanal endoscopic techniques can be used to access and divide the septum overlying more proximal sinus tracts. This procedure may need to be performed several times over several weeks to months to get the tract to heal in fully [75]. Fibrin glue injection into these sinus tracts has been described and can be done directly via a transanal approach if the opening is distal enough, or endoscopically if it is more proximal [76, 77]. Depending on their level of experience, interventional radiologists may be able to place a transrectal drain through the anastomotic defect into a presacral sinus tract or abscess, and when the tract is small enough, they can inject fibrin glue as they remove the drain to obliterate the space and prevent reaccumulation of an abscess (Fig. 10.3**).** These techniques are often not successful in eliminating the sinus tract and it may be necessary to proceed to resection of the anastomosis, debridement of the cavity, and either re-anastomosis or completion proctectomy [78].

Newer endoscopic techniques for addressing anastomotic leaks have emerged and early reports have demonstrated

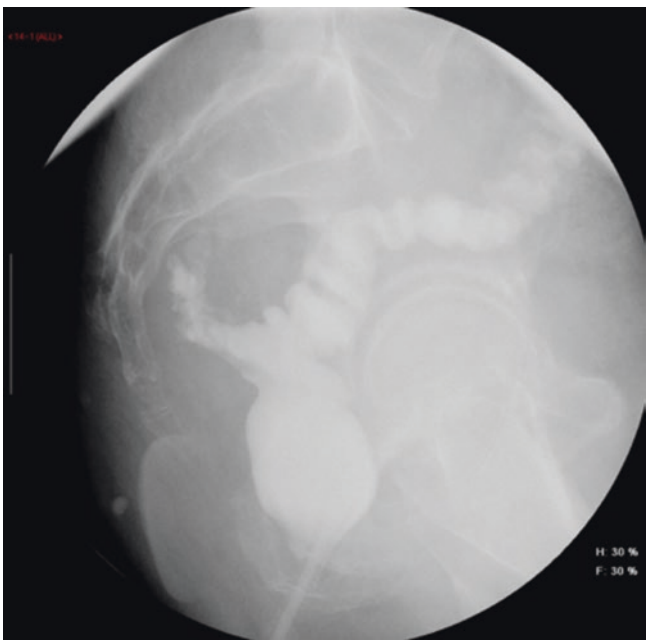

Fig. 10.2 Colorectal anastomotic leak: Fluoroscopic image of a patient who developed a leak 9 days after low anterior resection

Fig. 10.3 Presacral sinus tract: CT image of a patient who developed a chronic presacral sinus abscess after a colorectal anastomotic leak. A transanal drain was placed through the anastomotic defect and into the presacral abscess. When the cavity had become essentially a sinus tract, fibrin glue was injected into the tract as the drain was removed to fill the tract and prevent reaccumulation

promising results. These include endoscopic vacuum sponge placement, intraluminal covered stents, and over-the-scope clips. Endoscopic vacuum-assisted closure of presacral abscess cavities caused by chronic anastomotic leaks has been shown to be effective in healing the majority of patients [79, 80]. The endoluminal vacuum sponge system is generally managed on an outpatient basis and changed every 2–3 days. It is unclear whether it results in faster healing as it takes weeks to months for complete resolution. It may prevent the formation of a presacral sinus tract and is generally well-tolerated and safe [81–84]. Fecal diversion is commonly part of the strategy, but not in all cases that have been effectively treated. Timely diagnosis and treatment increases the likelihood of success, as patients who start primary endoluminal vacuum therapy within 15 days of diagnosis have a higher chance of success compared to those who undergo salvage therapy with this technique more than 15 days after diagnosis of the leak [85, 86]. Endoscopic placement of covered intraluminal stents has been used to treat colorectal anastomotic leaks with some success in small series [87, 88]. Endoscopic closure of colorectal anastomotic leak using an over-the-scope clip has also been described [89]. Data on the success of this strategy are sparse so the likelihood of successful healing is not known [90, 91]. It should be used only in select cases that would be most amenable to this, and in cases in which the intra-abdominal sepsis has been well controlled. As more surgeons and gastroenterologists report on their experience with these advanced endoscopic techniques, we will gain a better understanding of the indications and limitations of these strategies.

Outcomes After Anastomotic Leak

The risk of perioperative mortality increases in the presence of an anastomotic leak, and ranges from 3% to 14% [9, 11, 92]. For patients with rectal cancer, anastomotic leaks are associated with decreased overall 5-year survival (44–53% versus 64%) and cancer-specific 5-year survival (42% vs 67%) [20, 93, 94]. In some series, patients with anastomotic leaks after colorectal cancer resections were found to have increased local and systemic recurrence rates while in others, there was no difference between those who had anastomotic leaks and those who did not [94–100]. The worse oncologic outcomes have traditionally been attributed to the delay in adjuvant chemotherapy due to the septic complications of a leak. However, there are other potential mechanisms for increased recurrence in patients who suffer a postoperative infection. Postoperative infection has an effect on the cytokines present in the peritoneal fluid and peripheral blood of patients in such an inflammatory state which may increase the ability of residual tumor cells to migrate and invade, and thus potentially allow them to contribute to recurrences [101, 102]. Anastomotic leak and intra-abdominal abscess is also associated with upregulation of genes that encode for cytokines that promote tumorigenesis and angiogenesis, further contributing to this understanding of the pathophysiology of increased recurrence after postoperative infection [103].

The risk of a permanent ostomy after an anastomotic leak depends on the location of the anastomosis – the more distal the leaking anastomosis is, the higher the risk of a permanent ostomy. Functional outcomes and quality of life are also worse after anastomotic leak, particularly one that occurs in a pelvic anastomosis [104, 105]. Colorectal anastomotic leaks are associated with more bowel dysfunction including more frequent bowel movements, poorer continence, and increased pad use [106]. It is likely that the pelvic fibrosis from the chronic inflammation induced by a leak reduces the compliance of the rectum, thus contributing to these symptoms. The potential impact of anastomotic leakage on defecatory dysfunction is underestimated, as many patients who would have had such symptoms opt for an end colostomy [107]. Sexual and urinary functions are also adversely affected and symptoms often go unreported [108]. It is important, therefore, for surgeons to be cognizant of these potential sequelae and be proactive about asking patients about their symptoms rather than passively wait for patients to bring them up. Referral to specialists in urology and gynecology may be helpful for symptomatic management.

Anastomotic Fistula

Anastomotic fistula can be due to either anastomotic leak or a technical error. Symptoms that present in the immediate postoperative period are generally attributable to an intraoperative technical complication. These most commonly occur in pelvis, if the anterior rectal wall has not been adequately mobilized from the posterior vaginal wall, allowing the posterior vaginal wall to be incorporated into the circular stapler fire and creating a stapled fistula between the bowel and the vagina. It is also possible for the ureters or urethra to be inadvertently incorporated into an anastomosis if the rectal stump has not been properly mobilized from the surrounding structures. These fistulas will certainly require reoperation with fecal diversion and reconstruction of normal anatomy. In these situations, it is highly likely that a permanent colostomy will be the result, because usually the rectal stump is rather short and the pelvic dissection was difficult during the initial operation. A coloanal anastomosis is likely to be required if restoration of intestinal continuity is to be attempted.

The more likely etiology of anastomotic fistula is an anastomotic leak that fails to heal. These can occur from a leak from any location along the GI tract. Intra-abdominal leaks from the small bowel or colon may result in an enterocutaneous fistula. High-output fistulas and persistent low-output fistulas require

Fig. 10.4 Fistula from ileocolic anastomosis: CT image of a patient who underwent right colectomy complicated by a leak, which subsequently developed into a persistent low-output fistula tract through the abdominal wall. Treatment consisted of resection of the anastomosis and creation of a new ileocolic anastomosis

Fig. 10.5 Pelvic abscess and colovaginal fistula: CT image of a patient who underwent sigmoid colectomy for diverticulitis complicated by anastomotic leak. The leak caused pelvic abscesses that necessitated through the vaginal cuff, thus resulting in a colovaginal fistula

reoperation with resection of the leaking anastomosis and construction of a new anastomosis (Fig. 10.4). Judicious timing of reoperation is critical for avoidance of a hostile surgical field that will lead to more injuries and fistulas.

Colorectal anastomotic leaks in the pelvis may also fistulize to the skin of the anterior abdominal wall, or inferiorly to the skin of the buttock. These fistulas can result from a persistent tract of a transgluteal drain initially placed for abscess drainage. Pelvic leaks can also result in fistulas to the vagina, usually if the patient has had a prior hysterectomy, and rarely via the fallopian tube. Reoperation is generally necessary to address these complications, although some may heal with fecal diversion. Patients who undergo sigmoid resection for diverticulitis that was complicated by a colovaginal or colovesical fistula are at risk for recurrence of those fistulas if a colorectal anastomotic leak occurs, since either the vagina or the bladder has a fresh suture line that will be a vulnerable site through which an abscess will necessitate (Fig. 10.5). Placement of an omental flap in the pelvis to form a physical barrier between a fresh bowel anastomosis and other suture lines in the pelvis may decrease the risk of a recurrent fistula.

A rare and potentially very morbid sequela of anastomotic leak is a fistula to the epidural space causing an epidural abscess. This can occur as a complication of a chronic colorectal anastomotic leak and may present initially with nonspecific symptoms such as weight loss, low-grade fever, and malaise. Source control and systemic antibiotics should be the first steps in management. This may involve washout of the pelvic sepsis and fecal diversion or takedown of the anastomosis. Epidural decompression and debridement may also be necessary [109, 110].

Blind Loop Syndrome

Blind loop syndrome (or blind pouch syndrome) is an occasional complication of side-to-side antiperistaltic anastomoses. The blind sac of an antiperistaltic side-to-side bowel anastomosis may dilate over time. In most patients this does not cause any symptoms, but in some, it can be the cause of complications such as small intestinal bacterial overgrowth (SIBO), pseudo-obstruction, volvulus, ulcers, bleeding, and even perforations. These complications usually occur years after the operation. With dilation leading to SIBO or pseudo-obstruction, it is often the case that patients have months to years of vague abdominal symptoms such as bloating, nausea, weight loss, poor appetite, and abdominal discomfort [111, 112]. These symptoms are inconsistently related to dietary intake or eating habits. They may undergo multiple diagnostic studies that are largely unrevealing, as the dilation of the anastomosis is considered to be within normal limits, and the anastomosis is widely patent (Fig. 10.6a, b). Anastomotic ulcers rarely occur and may cause gastrointestinal bleeding or perforation (Fig. 10.7) [113, 114]. Capsule endoscopy or double balloon enteroscopy may be helpful in making the diagnosis. The treatment for any of these complications is resection of the anastomosis with an end-to-end anastomosis. The potential for these rare complications with side-to-side anastomoses should not dissuade surgeons from using this anastomotic technique routinely. However, this syndrome should be considered if patients with a prior side-to-side anastomosis present with these symptoms, and if surgical resection is indicated, an end-to-end anastomosis should be performed to prevent recurrence of the problem.

Anastomotic Bleeding

While adequate blood supply is critical to the healing of a colonic anastomosis [115], careful hemostasis must be obtained to limit the possibility of postoperative anastomotic bleeding. The true incidence of anastomotic bleeding is difficult to know and depends on the definition of a "bleed." Undoubtedly all anastomotic suture/staple lines bleed to some extent, which may be clinically apparent when patients pass a small amount of dark blood shortly after a colonic resection. However, in patients with normal coagulation and platelet function, clotting rapidly occurs and the blood loss is minimal. Because most of these bleeding episodes are self-limited and of little clinical significance, the majority of bleeds go unreported.

Anastomotic bleeding has been reported in up to 5% of patients having a colorectal anastomosis [116–119]. In a recent study of 314 patients having colorectal surgery, the overall incidence of anastomotic bleeding, defined as a decrease in hemoglobin of 2.0 mg/dL in the setting of hematochezia, was 2.3% [118]. The timing of these bleeds ranged from 1 to 10 days postoperatively with a mean of 6 days. Of the 7 patients who had an intraluminal bleed only 4 required a blood transfusion and of these only one needed an additional intervention. Malik et al. reported on a series of 777 patients having a colorectal resection. In this series, while the total number of anastomotic bleeds was not reported, only 0.8% experienced bleeding that required an intervention. In this series the majority of the major bleeding episodes occurred within the first 24 hours with delayed bleeds being unusual [117]. In a similar series from Martinez-Serrano et al., only 0.5% of the 1389 colon resections had a significant anastomotic bleed requiring blood transfusions. These authors used endoscopy to confirm the diagnosis, but without performing any intervention. Only one patient required an anastomotic revision. Similar to the previous study, the bleeds most commonly occurred within the first 24 hours of surgery [120]. These series suggest that most bleeds will stop on their own with supportive care. Transfusion may be necessary but endoscopic or surgical intervention is rarely needed. Furthermore, while there are some delayed bleeds [121], most significant bleeding is detected within the first 24–48 hours from surgery [122]. When there is delayed bleeding anastomotic breakdown should also be considered and endoscopy or imaging should be performed to evaluate anastomotic integrity (Fig. 10.8a, b) [123].

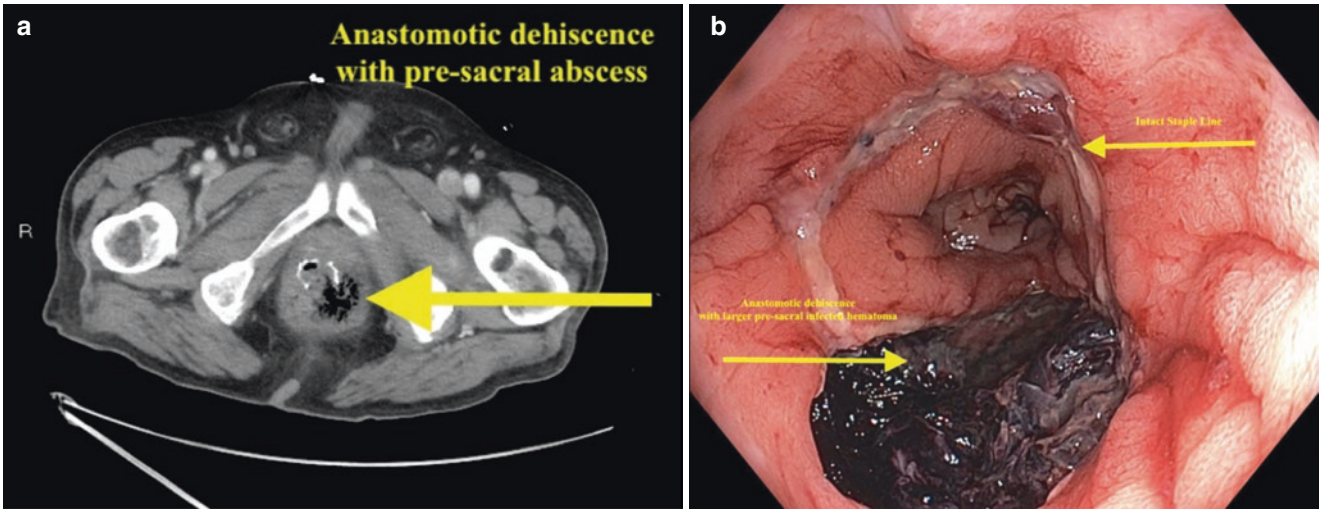

Fig. 10.8 (**a**) CT scan of patient presenting with an anastomotic bleed on POD 9 showing a pelvic abscess and anastomotic dehiscence. (**b**) Endoscopic exam confirming anastomotic dehiscence with pelvic hematoma

The clinical presentation for most anastomotic bleeds is similar to other etiologies of lower gastrointestinal bleeding. Depending on the level of the anastomosis bleeding can be either bright red blood (left-sided anastomosis) or darker clots (right-sided anastomosis) without abdominal pain. The quantity ranges significantly from a small amount to massive bleeding [117, 118]. Patient's vital signs can also range from completely normal to hemodynamic shock. Because of this variability in presentation all bleeding must be respected and mandates, at a minimum, close observation. If bleeding is persistent then monitoring serial hematocrits and coagulation parameters is important for making decisions about clinical management.

The management of an anastomotic bleed is also similar to other patients with a lower gastrointestinal bleed. The major difference between a postoperative gastrointestinal bleed and a spontaneous one is the initial workup. The etiology in the postoperative setting is rarely a diagnostic dilemma and therefore diagnostic studies, such as tagged red blood cell scans and CT angiography, are generally unnecessary. Patients are understandably anxious when passing blood, so reassurance from all healthcare providers is critical. This may mandate moving the patient to a monitored setting with close nursing observation and monitoring. All patients should have adequate intravenous access and blood products available. If there are hemodynamic changes, initial resuscitation with isotonic fluids is appropriate. Any coagulopathy should be corrected and all medications that interfere with coagulation, including nonsteroidal anti-inflammatory drugs, should be held. The need for blood transfusions will depend on the patient's hemodynamics and the clinical judgment necessary to decide if the bleeding has stopped or is ongoing. However, in the setting of large blood loss, transfusions are commonly necessary, and the practitioner need not wait for a low hematocrit to initiate a blood transfusion.

If the bleeding persists then endoscopic interventions are preferred [117, 121, 123]. Other options include angiography [124] and surgery, but both are less preferable compared to the less invasive option of endoscopy [122]. The decision to intervene depends on many factors, including the ease of endoscopic access. Left-sided anastomoses are more accessible endoscopically, so the threshold to intervene for left-sided operations is lower. Nevertheless, a right-sided anastomosis can be safely reached with an experienced endoscopist. Air insufflation should be minimized to avoid putting too much stress on the anastomosis, but anastomotic disruption is rare [123–125]. Bowel preparation is often unnecessary, especially for a left-sided anastomosis, but a rapid purge can be done if there is too much intraluminal blood to do an effective examination. If a clear bleeding site is identified, endoscopic clipping has been shown to be both safe and effective at stopping the bleeding (Fig. 10.9a, b) [117, 123]. Injection of the bleeding site with epinephrine [123] can also be done, especially when the bleeding is not focal, but this strategy may induce ischemia of the rest of the anastomosis. Electrocautery has also been successfully used but also runs the risk of anastomotic fistula [126]. Despite these potential complications endoscopic interventions appear to be safe with a low chance of secondary morbidity [123].

In the rare case when the bleeding neither stops with supportive case nor can be controlled endoscopically, the options for intervention are limited to angiography and surgery. While angiography, either with a vasopressin infusion [127] or embolization, has been successfully used to treat an anastomotic bleed, it does run the very real risk of compromising the blood supply to the anastomosis which can result in subsequent anastomotic breakdown. Therefore, angiography should be used selectively [117]. Surgery may be the better option if the anastomosis is readily accessible and there is

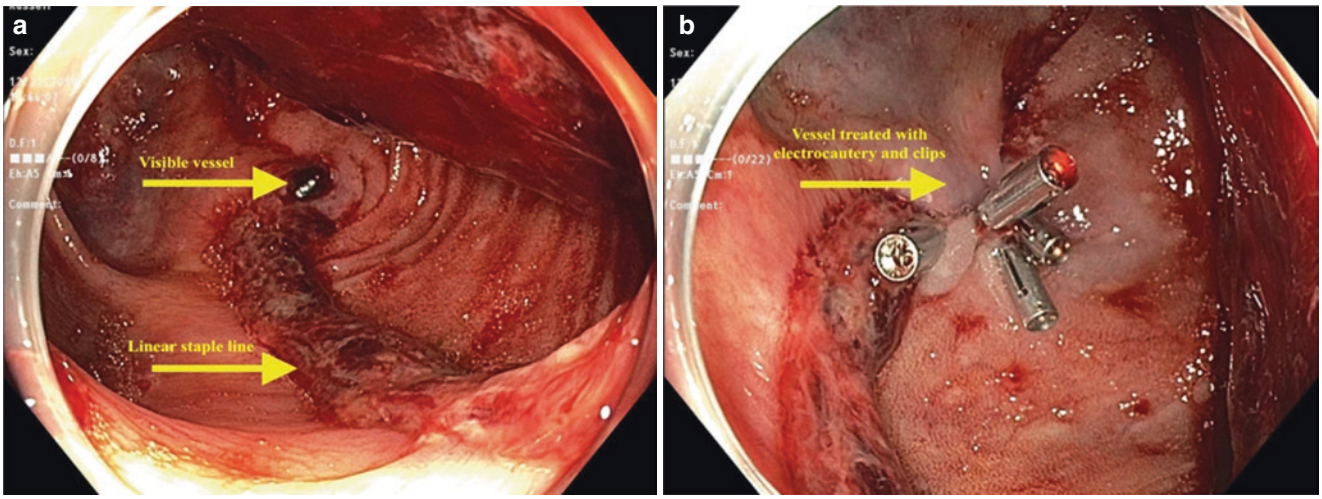

Fig. 10.9 (**a**) Endoscopic evaluation of a functional end-to-end ileocolic anastomosis 48 hours after anastomotic bleed showing staple line and visible vessel. (**b**) Anastomosis after successful use of electrocautery followed by placement of endoscopic clips to stop bleeding

appropriate colonic length for a revision. Anastomotic revision has been shown to stop bleeding in most cases and can be done safely in situations in which the bleeding cannot be otherwise controlled [117].

While there are options to treat anastomotic bleeding, prevention is always preferable to treatment. Proper healing of an anastomosis is dependent upon good blood supply, so seeing pulsatile blood flow when constructing an anastomosis should be comforting. Nevertheless, active examination and controlling this bleeding is important. Unfortunately, all anastomotic techniques are susceptible to bleeding. The Cochrane collaborative noted a slight, but statistically insignificant, difference between a handsewn and stapled anastomosis (3.1% vs. 5.4%) [116, 128] and therefore did not favor one technique over another. Regardless of the technique a well-constructed anastomosis should avoid incorporating the associated mesentery, so the antimesenteric border (Fig. 10.10) should be used for a functional end-to-end anastomosis and the mesentery cleared for an end-to-end anastomosis [118]. However, even when the mesentery is clearly free, bleeding from the staple/suture line is often noted. Therefore, for a functional end-to-end anastomosis direct visualization of the inside of the anastomosis should be done prior to closing the transverse opening. If pulsatile bleeding is present, treatment with cautery should be avoided. Instead, a well-placed figure of eight suture can control the bleeding and then be used to evert the anastomosis, so the entire staple line can be examined (Fig. 10.11). For left-sided anastomoses, endoscopic examination allows one to check for intraluminal bleeding while testing the integrity of the anastomosis [119, 129, 130]. If bleeding is noted, either a clip can be applied or a stitch can be directly placed from the outside of the bowel lumen, using the colonoscope to guide stitch placement [119, 130].

Fig. 10.10 Proper construction of functional end-to-end ileocolic anastomosis using the antimesenteric borders for staple line

In summary, while the true incidence of anastomotic bleeding is not known, clinically significant bleeding is uncommon. Most will stop with supportive care, which may include blood transfusions. For bleeding that persists, endoscopic management is the preferred intervention. Anastomotic

revision is reserved for the rare situation when endoscopic interventions have failed [117].

Anastomotic Stricture

As with anastomotic bleeding the true incidence of anastomotic stricture is not well established, which reflects variability in the definition of a stricture throughout the literature and in clinical practice. It has been estimated to be as high as 30% but this includes clinically insignificant strictures. The most common definition of a stricture is a narrowing of an anastomosis that does not allow passage of either a 12-mm colonoscope or a rigid proctoscope [131–133]. Using this definition, the incidence is likely less than 10% [128, 134, 135]. Many of these patients will develop obstructive symptoms, which can include constipation, cramping, and a decreased caliber of stool [135]. In extreme cases patients may experience overflow diarrhea and incontinence as solid stool cannot pass the stricture. The diagnosis is usually made several months following the initial resection but usually within 12 months if not associated with recurrent disease [134–136]. In addition to impacting patient function, a stricture that cannot be traversed limits the ability to completely evaluate the stricture and to monitor the proximal colon. This is particularly important for patients whose surgery was due to malignant disease since the stricture may represent recurrence and, even if benign, the patient requires ongoing surveillance of the entire colon. What is clear is that the lower the anastomosis the higher the stricture rate, with ileal pouch anal anastomoses and coloanal anastomoses [134, 137] having the highest stricture rates compared with more proximal anastomoses, such as ileocolic anastomoses.

The etiology of an anastomotic stricture is likely multifactorial. A stricture forms when the lumen is compromised by ongoing fibrosis. This can be the result of ischemia, infection, anastomotic leak, radiation and/or recurrent disease [131, 133]. Proximal diversion has also been shown to be a risk factor for a low pelvic anastomosis since no stool is passing through to dilate the anastomosis regularly [135]. In a Cochrane review left-sided end-to-end stapled anastomoses had a higher stricture rate than handsewn anastomoses (8% vs 2%) [128]. However, this may be confounded by the fact that staplers are more often used for low anastomoses, which have a higher risk for ischemia and leak, which can result in stricture. The authors of the review stated that this finding does

not necessarily favor a handsewn approach [138]. For ileocolic resections the Cochrane analysis concluded that the stricture rate of handsewn vs. stapled anastomoses were similarly low [139].

Understanding the exact anatomy of a stricture is important prior to planning an intervention [140]. This can be done endoscopically if the stricture can be traversed with a smaller endoscope or with fluoroscopic imaging if not (Fig. 10.12). It is also important to understand the anastomotic construction since an inexperienced endoscopist may not recognize that with an end-to-side or side-to-side reconstruction the anastomosis may be at 90 degrees to the lumen and misinterpret the "dog ear" as a pinpoint stricture (Fig. 10.13). Once again, when the anatomy is unclear a fluoroscopic examination can be enlightening.

Treatment of an anastomotic stricture depends on the anatomy and the etiology. In the setting of prior malignancy, recurrent disease must be ruled out with biopsies. While many malignant strictures will be clinically evident by the presence of an ulceration and/or a mass, the stricture itself may preclude and adequate evaluation. CEA monitoring and PET CT scans may be helpful under these circumstances. If the suspicion for malignancy remains high even after initial biopsies are negative, repeat biopsies may be necessary [131].

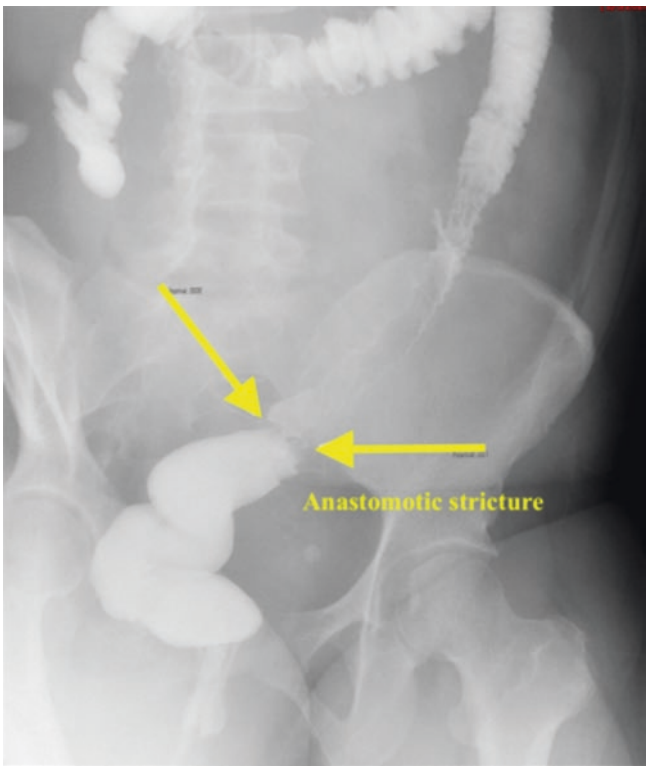

Fig. 10.12 Fluoroscopic image of a stapled end-to-end anastomosis showing a short, tight stricture

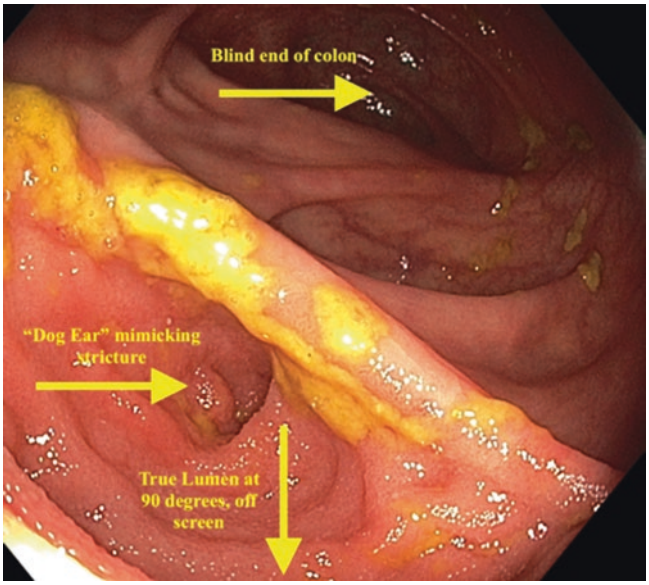

Fig. 10.13 Endoscopic image of functional end-to-end anastomosis demonstrating how the small bowel "dog ear" is easily misinterpreted as an anastomotic stricture

For strictures near the anal canal, such as after a low pelvic anastomosis or an ileal pouch anal anastomosis, dilation can often be accomplished with a digital exam. This is particularly true for patients that have a protective ileostomy who demonstrate a short stricture on a water-soluble contrast enema. For patients with a handsewn coloanal anastomosis, a digital exam prior to reversal is important since a fluoroscopic study may not appreciate the stricture if the tip of the catheter for contrast infusion is placed proximal to the strictured area. Since dilation with a digital exam can be uncomfortable, it is often done under anesthesia (Fig. 10.14). If successful, patients may require intermittent dilation to keep the anastomosis open. Patients can learn to self-dilate with Hegar dilators (Fig. 10.15) if there is a tendency for the stricture to recur. For patients with strictures that are more proximal, mechanical dilation using a bougie has also been successful.

Endoscopic balloon dilation has emerged as the preferred first line treatment for an anastomotic stricture with a success rate ranging from 67% to 100% [141, 142]. Unfortunately, most studies are small and retrospective, and lack details on the specific nature of the anastomotic strictures. Most strictures referred for dilation are probably short (<2 cm), which seems to be the population that is best treated for dilation [133, 141]. Therefore, defining the characteristics of stricture is important prior to intervention. In a series of 94 patients using endoscopic balloon dilatation, Suchan et al. reported an overall success rate of 67%. They noted that the success rate for patients having had an initial benign diagnosis was 88% with few complications. In contrast, in patients having had an initial malignant diagnosis, the success rate was only

59% with many patients experiencing recurrent strictures that needed surgical interventions [131]. In a more recent report, Biraima et al. reported on the long-term success of 76 patients with an anastomotic stricture. They reported a recurrence rate at 1 year, 3 years, and 5 years of 11%, 22%, and 25%, respectively. In 50% of the patients, success was obtained with either one or two dilations. Even in the 25% who eventually recurred most were successfully managed with repeat dilation and only two ultimately required a surgical intervention. Therefore, the secondary success rate was high at 97%, although in the 25% who initially failed, multiple dilations were often necessary. The serious complication rate was low with most being minor bleeding and one perforation, none of whom required a surgical intervention [134]. Of note, the authors did include a significant number of patients with mild stenosis (10–20 mm). When looking at risk factors for recurrence of a stricture following balloon dilation, the authors found that strictures with a luminal diameter < 10 mm, those from a handsewn anastomosis, and those requiring more than two dilations were more likely to recur over time (Fig. 10.16a–c) [134].

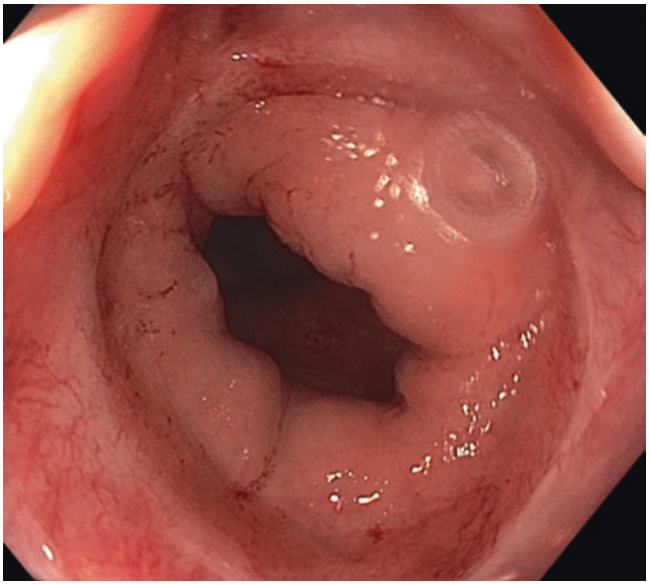

Fig. 10.14 Endoscopic image of handsewn coloanal anastomosis amenable to digital dilation

Fig. 10.15 Hegar dilators

For patients with a significant stricture, endoscopic electrocautery incision (EECI) [143–145], either using cautery or a laser, can initially open up the stricture either as definitive therapy or in conjunction with other therapies, including balloon dilation or steroid injection [146]. Several radial incisions are placed through the fibrotic mucosa along the most resistant portion of the stricture in order to relieve the tension on the stricture (Fig. 10.17) [143–145]. In the previously mentioned series from Suchan et al., 37 of the 68 patients with an initial malignant diagnosis had an incision placed through the stricture using a variety of energy devices. Most were then able to undergo balloon dilation [131]. Endoscopy, TEMS, [147], and TAMIS [148] have all been used to access the stricture and to perform the superficial incisions along the stricture or, in some cases, to fully resect the fibrotic tissue [149]. Using these techniques, success rates of 90–100% have been reported, albeit in small studies with variable long-term follow-up data. [142, 143]. Nevertheless, for short fibrotic strictures that recur following balloon dilation this is a viable alternative to anastomotic revision.

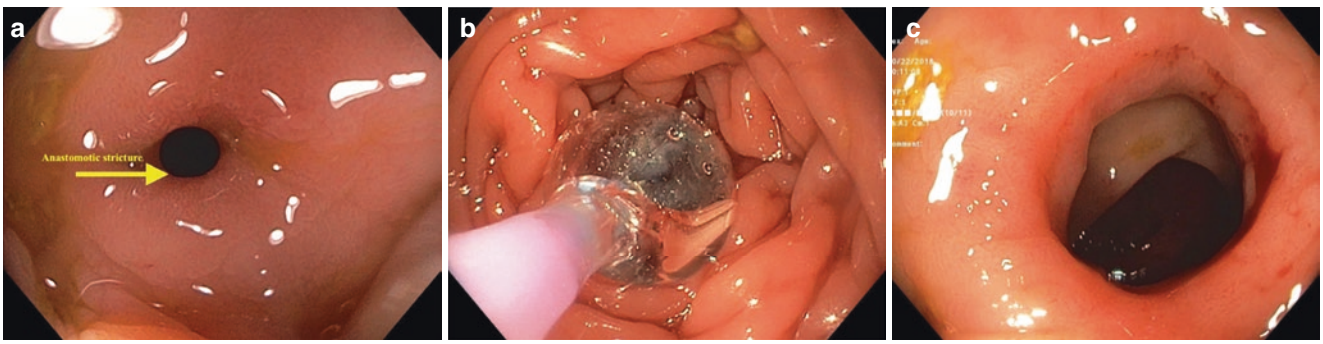

Fig. 10.16 (**a**) Endoscopic view of tight end-to-end stapled anastomosis. (**b**) Balloon dilation. (**c**) Final view after serial dilations showing a wide-open lumen

Self-expanding metal stents (SEMS) have also been used as an adjunct to treat a stricture. In theory, the radial force of the stent will allow persistent pressure on stricture which may reduce recurrence rates [150]. Unfortunately, in this setting the stents frequently migrate and therefore have not been consistently successful. In addition, there have been reports using a circular stapler via a transanal approach to resect the stricture (Fig. 10.18) [151]. However, this technique is only amenable to more mild strictures that would allow the passing of an anvil above the stricture and therefore has not been widely adopted [137]. Finally, both linear staplers [152] and electrocautery [150] have also been used to transanally perform a strictureplasty by resecting a portion of the stricture wall to open the anastomosis. Most data are limited to case reports and small series, so firm conclusions about long-term success are limited.

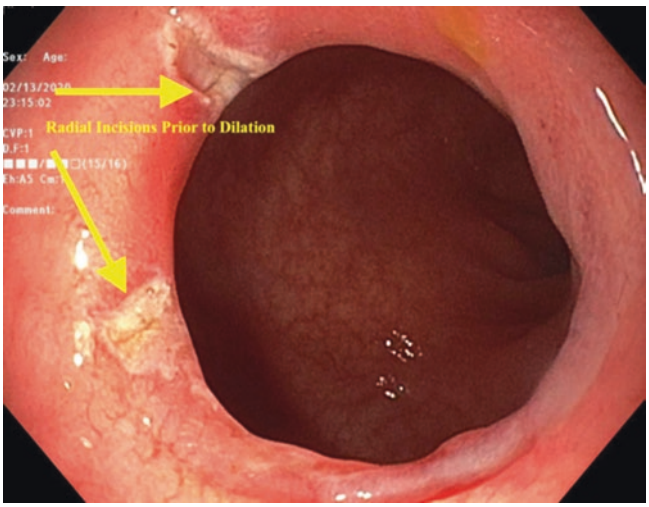

Fig. 10.17 Initial radial incision along the stricture to facilitate a safe and successful balloon dilation

Unfortunately, some anastomotic strictures are not amenable to these noninvasive procedures. Long (> 2 cm), irregular, and angulated strictures either fail interventions or are not anatomically appropriate for these procedures [133]. In these cases, a surgical revision may be the only option [136–142]. Resection and re-anastomosis are very challenging and should not be undertaken without careful consideration. Ureteral stents can help identify the left ureter which is often adherent to the colon and the associated mesentery. The area around the anastomosis will be severely fibrotic and perforation at the anastomosis is common during the resection. The key to a successful anastomosis is to get below the area of fibrosis to soft, pliable colon or rectum [133]. If this is not possible, then a handsewn coloanal anastomosis can be done [136]. Given the complexity of this operation, proximal diversion is reasonable to maximize the chances of long-term success.

Studies looking at re-do pelvic surgery following a failed colorectal anastomosis include a heterogenous group of patients with stenoses, anastomotic fistulas, and even recurrent cancer. Therefore, these studies are not limited to patients with a stricture. Nevertheless, the fibrosis associated with all these processes is significant, so these studies still provide necessary insight into the complexities of these procedures. Despite the challenges presented

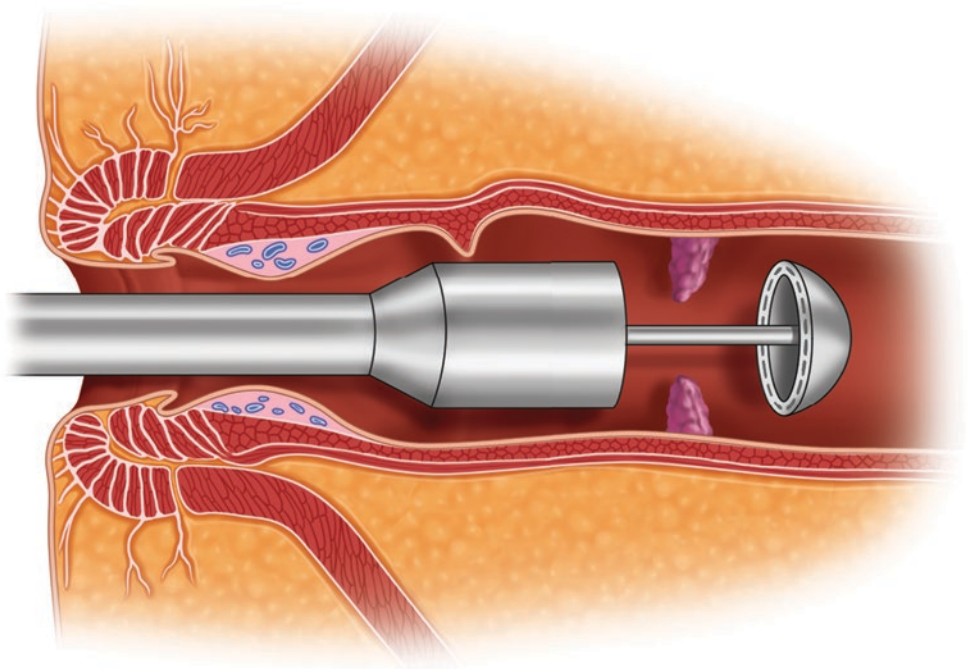

Fig. 10.18 Illustration demonstrating a transanal resection of an anastomotic stricture using an EEA stapler

with these patients, successful revisions have been noted in 57–100% [136] of selected series with a pooled success rate of 79%. When the stricture is located above 11 cm from the anal verge, a new stapled colorectal anastomosis is often feasible. However, if the stricture is less than 11 cm from the verge a handsewn coloanal anastomosis is almost universally constructed [133]. Since pelvic fibrosis is often significant a straight coloanal is most commonly performed, but if there is room in the pelvis a colonic J-pouch remains an option [153]. Both immediate and delayed (Turnbull-Cutait) procedures have been described. Depending on the amount of fibrosis, the entire anastomosis can be resected or alternatively a mucosectomy can be done leaving a rectal muscular tube similar to a Soave procedure [133, 153]. Given the high-risk nature of these anastomoses, proximal diversion is generally the rule [136]. While this success rate is promising, it is important to note that these reports are of highly selected patients and performed by very experienced surgeons in tertiary care facilities. The mean age was relatively young at 58 years, suggesting that older patients may not do well with this approach. Furthermore, while intestinal continuity was achieved in nearly 80%, 17% did have incontinence and nearly 60% had some degree of low anterior resection syndrome [136]. It is critical, therefore, to have frank discussions with patients about functional expectations and to not solely focus on defining success as being "stoma free." Nevertheless, in the fit and highly motivated patient, re-do surgery is certainly a viable option.

Remembering that preserving a high quality of life is of prime importance, it is essential to make the patient aware of all the available options, including a permanent stoma. If a stricture is either not amenable to or fails the previously described non-surgical approaches, or if the patient is not a good surgical risk due to comorbidities or anatomic constraints, a well-functioning colostomy may be the most definitive option that will maintain a high quality of life.

In summary, clinically significant anastomotic strictures will occur in up to 10% of patients following a colorectal resection. Most of these will be left-sided and within the rectum. Fortunately, many strictures are simple and can often be treated with dilation either using a balloon or manually. While often successful, repeat procedures are not uncommon. For those that fail simple dilation, a step-up approach to include incision of the stricture followed by dilation or a transanal strictureplasty may be an option [137]. Revision of the anastomosis is a daunting undertaking, but in the properly selected patients it can be successful. For those patients who are not successfully treated by any of these means, a properly constructed colostomy can restore a high quality of life and should be considered a viable option under these difficult conditions.

Part II

Anorectal Disease

Hemorrhoids

11

Jennifer S. Davids and Timothy J. Ridolfi

Key Concepts

- Hemorrhoids represent a sizeable source of patient morbidity, with a broad array of associated symptoms.
- Knowledge of anorectal and hemorrhoid anatomy is critical to selecting the appropriate treatment.
- Minimizing straining, improving hydration, and increasing fiber intake are the first step for patients with symptomatic hemorrhoids.
- Most office procedures are best suited for symptomatic grade I–III internal hemorrhoids or thrombosed external hemorrhoids.
- One's armamentarium should include a variety of techniques for symptomatic hemorrhoids to optimize outcomes and provide individualized therapy.
- Complications of hemorrhoid surgery include urinary retention, bleeding, infection, stenosis, incontinence, and recurrence.
- Special considerations include pregnant patients, as well as those with Crohn's disease, immunocompromise, or portal hypertension.

Epidemiology

Although hemorrhoids have been described since Biblical times, they continue to mystify most providers and patients [1]. Accordingly, they are one of the most common health conditions searched on the Internet [2, 3]. Hemorrhoidal disease is estimated to affect approximately 4% of the US population [4]. The true incidence of symptomatic hemorrhoids is likely underestimated due to limitations in establishing a clear diagnosis and under-reporting of symptoms to health care providers. Hemorrhoidal disease accounts for over three million outpatient office visits per year, at an estimated cost of over 770 million dollars [5]. Hemorrhoid symptoms affect men and women with equal frequency, with the highest incidence between age 45 and 65 [6]. Symptomatic hemorrhoids are more common in individuals from higher socioeconomic backgrounds and in whites [7].

Anatomy

As anatomic structures, hemorrhoids are part of normal human anatomy. Hemorrhoids are arteriovenous structures that lie in the submucosal layer within the anal canal. Their three primary locations (left lateral, right anterior, right posterior) receive arterial inflow from the terminal branches of the superior hemorrhoidal and middle hemorrhoidal arteries (Fig. 11.1). Venous outflow is from the superior, middle, and inferior hemorrhoidal veins, which drain into the internal pudendal vein and then the inferior vena cava.

Hemorrhoids are classified as either internal or external based on their anatomic relationship to the dentate line. Internal hemorrhoids are proximal to the dentate line, and external hemorrhoids are distal (Fig. 11.2). The term "mixed" hemorrhoids applies to a hemorrhoid complex containing both an internal and external component. Internal hemorrhoids have overlying columnar mucosa, whereas external hemorrhoids have overlying modified squamous epithelium (anoderm).

Internal hemorrhoids are graded based on the degree of prominence and prolapse [8]. The grading system is useful clinically for characterizing the hemorrhoids and selecting appropriate treatments (Fig. 11.2). *Grade I* hemorrhoids are visibly engorged but do not prolapse below the dentate line. *Grade II* hemorrhoids prolapse below the dentate on Valsalva or defecation but spontaneously reduce. *Grade III* hemorrhoids prolapse but require manual reduction. *Grade IV* are prolapsed and not reducible.

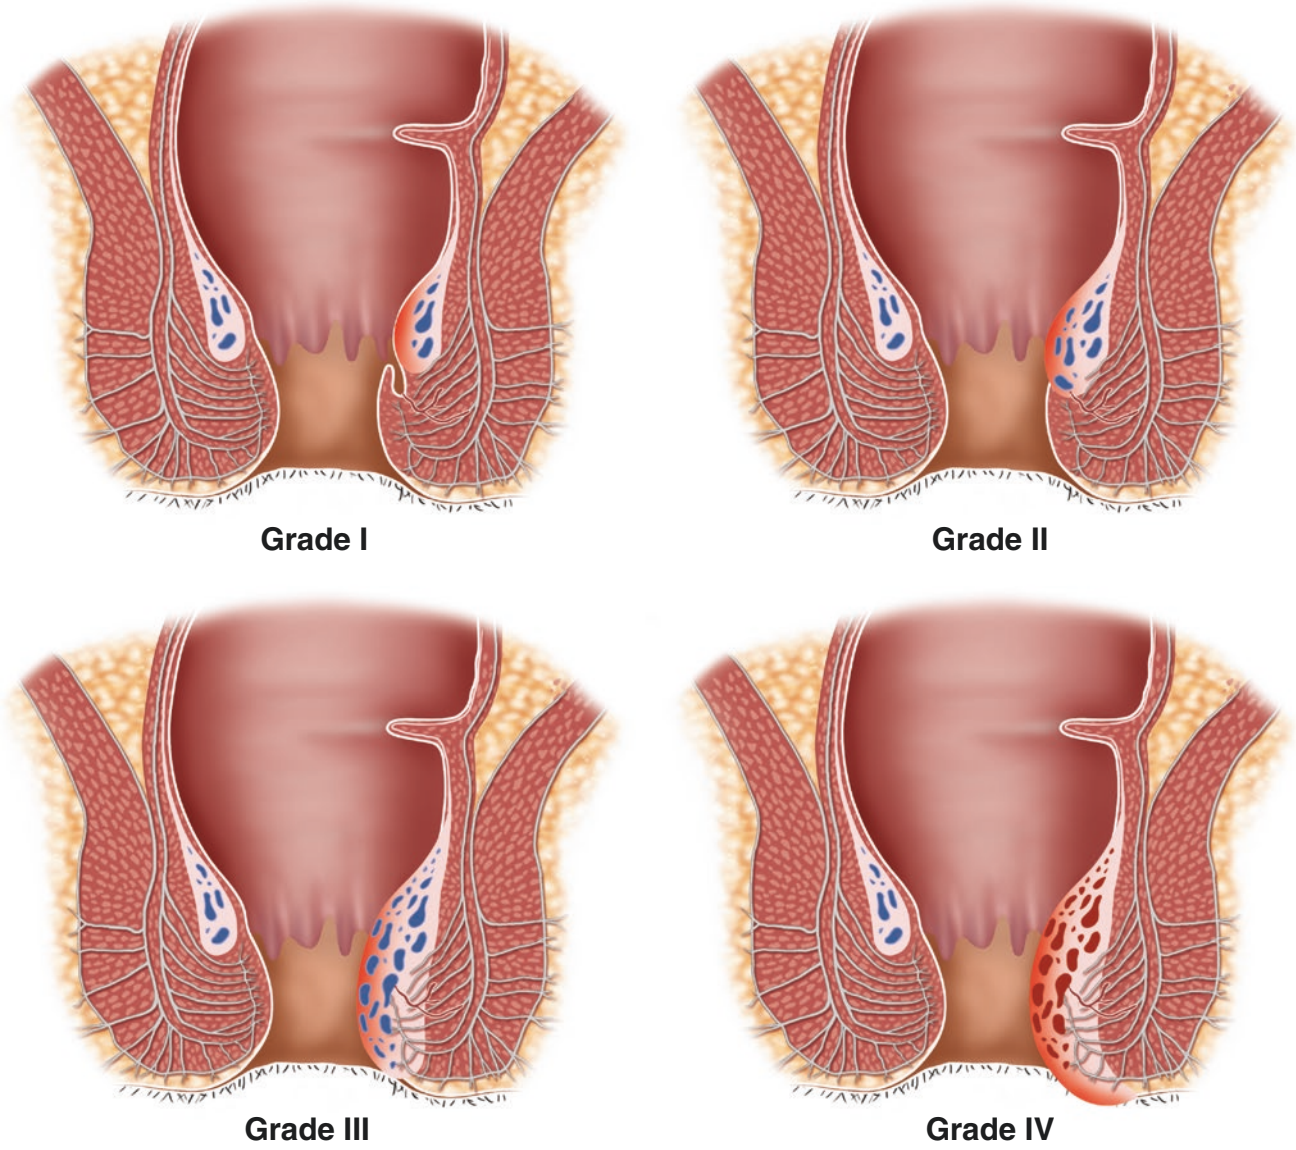

Fig. 11.2 Hemorrhoid classification and grading system

Other clinically important descriptions of hemorrhoids include "strangulated" hemorrhoids, which are grade IV that have become edematous to the point of compromised blood supply, leading to necrosis or gangrene in extreme cases (Fig. 11.3). Thrombosed hemorrhoids are typically external and contain a clot under pressure, causing them to have a rounded, bluish appearance (Fig. 11.4). The distinction between anal "skin tags" and external hemorrhoids is somewhat obscure but is often of great concern to patients. Although anal skin tags are somewhat synonymous with external hemorrhoids, they are typically considered those that are less engorged and bluish in color and are characterized by redundant anoderm. Often a skin tag will develop after a thrombosed hemorrhoid has fully resolved and the clot has absorbed.

Fig. 11.3 Strangulated, gangrenous hemorrhoids. (Courtesy of Carrie Y. Peterson, MD)

Understanding hemorrhoid innervation and sensation is essential to establish the correct diagnosis and select the appropriate treatment strategy [9]. Internal hemorrhoids have visceral innervation, and thus are sensitive to pressure but not pain or temperature. External hemorrhoids have somatic innervation and are exquisitely sensitive to pain and temperature. Importantly, hemorrhoids contribute to up to 20% of baseline continence, acting as a passive buttress to block seepage of stool, and they also engorge on Valsalva and thus potentiate their effect; this may have important implications on patients' bowel function after hemorrhoid procedures, particularly individuals who have marginal continence [10].

Pathogenesis

Multiple theories exist to explain the development of hemorrhoidal disease in some individuals. Only about 40% of those with enlarged hemorrhoids are symptomatic [11]. Straining

Fig. 11.4 Thrombosed external hemorrhoid

is felt to be a major contributor—most commonly straining with defecation as is typically encountered with constipation, due to either hard stools or pelvic outlet dysfunction. Patients who frequently Valsalva may also be at risk, with common examples being weightlifters or patients with COPD or chronic cough. Compared to a more natural "squatting" position, the typical Western commode requires its users to strain in an unnatural fashion to defecate and may be a contributor to hemorrhoid pathology. Conditions with impaired venous return, including the later stages of pregnancy or pelvic outlet dysfunction, are associated with hemorrhoid engorgement and eventual tissue swelling and laxity. Very little is understood regarding genetic factors contributing to hemorrhoidal disease, although a genome-wide association study (GWAS) found particular mutations associated with the condition [12]. On a tissue level, matrix metalloproteinases, vascular endothelial growth factor (VEGF), and nitric oxide synthase have all been shown to be associated with hemorrhoidal disease [13]. In addition to vessel engorgement, neovascularization may also play an important role [14].

Clinical Presentation

Frequently, anorectal symptoms are incorrectly attributed to hemorrhoids, by both patients and physicians unfamiliar with the associated symptoms and exam findings. A thorough history and physical exam are essential in correctly identifying hemorrhoidal disease and excluding the many other benign and malignant conditions that must be considered.

The most common symptoms associated with internal hemorrhoids are bleeding, pain, and tissue protrusion [15]. Painless bleeding with bowel movements accompanied by intermittent protrusion of tissue from the anal canal are the classic symptoms of enlarged internal hemorrhoids. The bleeding is usually bright red and is commonly described as on the toilet tissue, dripping, or even squirting into the toilet water. The degree of prolapse is also variable and may be intermittent or persistent and spontaneously reduce, require digital manipulation or may not be reducible. Other common symptoms of internal hemorrhoids include rectal pressure, mucus discharge, and soiling of undergarments with stool seepage. Although it can appear significant to patients, bleeding from hemorrhoids is rarely the cause of anemia, although possible with chronic substantial blood loss. Pain is not typically associated with internal hemorrhoids unless they are prolapsed and strangulated, which is not a subtle finding. In fact, the presence of pain should prompt the clinician to question the diagnosis in favor of other perianal processes, such as thrombosed external hemorrhoid, anal fissure, or abscess.

Common symptoms associated with external hemorrhoids include itching, irritation, perianal moisture, and difficulty with hygiene. External hemorrhoids do not cause pain unless thrombosis is present. In this instance, a firm nodule that has a blue or purple tinge is visible and palpable at the anal orifice (Fig. 11.4). These may be nontender or exquisitely painful, and the contained clot can erode through the overlying stretched skin. Spontaneous resolution of thrombosed external hemorrhoids often leaves a skin tag. These may reduce in size over time, but typically do not regress completely, and may be associated with symptoms such as itching and difficulty cleansing the region.

History

The diagnosis of hemorrhoidal disease is almost always a clinical one and should start with a medical history, with great care taken to identify associated symptoms and risk factors. Focus should be on the extent, severity, and duration of symptoms such as bleeding and extent of prolapse, issues of perineal hygiene, and presence or absence of pain. A careful review of fiber intake and bowel habits, including frequency, consistency, and ease of evacuation, should also be performed, as constipation predisposes patients to hemorrhoidal disease. Additionally, acute changes in bowel habits associated with bleeding may signify a more ominous cause, such as inflammatory bowel disease or neoplasm. All patients should be asked about other factors that are related to development of hemorrhoidal disease such as chronic heavy lifting or chronic cough from asthma or chronic obstructive pulmonary disease, or unusual toileting behavior such as withholding or limited access to bathroom facilities. Specific note should be made of anticoagulant use, fecal incontinence symptoms, previous anorectal surgery, obstetric history, and history of radiation to the pelvis, because these may affect management decisions.

Physical examination can be done in the prone or lateral decubitus position. Findings should be noted in anterior–posterior and right–left terms and documented as such. The examination begins with inspection of the gluteal cleft and then, with gentle retraction of the buttocks, inspection of the perianal area and perineum. The skin is inspected for findings such as external hemorrhoids, skin tags, condyloma, skin breakdown, fistulous openings, fissures, erythema, scars, masses, and any gape of the anus at rest. Digital rectal examination should evaluate for other anal pathology and sphincter integrity. Anoscopy should be performed to assess the anatomy [16]. Internal hemorrhoids, located above the dentate line, should be assigned a grade, which will help guide therapy. In addition, an evaluation of the patient while straining on the commode will assist in the diagnosis of hemorrhoid prolapse, as well as exclude full-thickness rectal

prolapse. Laboratory or radiographic studies are not typically required for diagnostic purposes.

Although hemorrhoids are the most common reason for hematochezia, other disease processes, such as colorectal cancer or polyps, inflammatory bowel disease, other colidities, diverticular disease, and angiodysplasia, can also precipitate bleeding [17]. While the majority of patients with hematochezia will not have colorectal cancer, rectal bleeding attributed to hemorrhoids represents the most common missed opportunity to establish a cancer diagnosis [18]. Any patient with age greater than 45, or with a change in bowel habits, anemia, weight loss, or those with a family history of colorectal cancer or suggestive of hereditary nonpolyposis colorectal cancer or Lynch syndrome, should be further examined with colonoscopy [19].

Treatment

Patients generally seek treatment for hemorrhoids once they experience symptoms. Unless patients are presenting in an acute fashion with heavy bleeding, thrombosis, or strangulation, simple non-procedural strategies are the first-line approach. An initial trial of conservative management is typically employed for a period of 6–8 weeks, at which point in-office reassessment is warranted, to determine response to treatment and decide whether further interventions are needed.

Medical Management

Stool Habits

Patients should be encouraged to maintain stooling habits that promote a healthy anal canal by minimizing pressure and strain on the hemorrhoids. Specifically, patients should be educated to avoid sitting on the toilet for prolonged periods of time (discourage reading on the toilet!). The act of defecation should not take more than just a few minutes; if an attempt is unproductive, the patient should get up and try again later when the urge returns. A foot stool will promote a more natural "squatting" position and may help those who endorse straining, or those with a component of pelvic outlet dysfunction constipation [20].

Stool Texture

Critical to alleviating hemorrhoid symptoms is improving the texture of the stool, with the goal of having soft, yet formed stools with adequate bulk [21]. Fiber acts as a "sponge" and prevents stool from becoming overly hard or loose depending on dietary variation or occasional indiscretions. This can be accomplished by supplementing the diet with soluble fiber, with a goal of 25–50 grams daily. Commercially available fiber supplements include psyllium, methylcellulose, and calcium polycarbophil. Even a strict vegetarian or self-declared "healthy eater" is unlikely to achieve this goal with diet alone and thus should be encouraged to add a supplement. Hard stool causes straining and puts pressure on the hemorrhoids, whereas loose stool can be highly irritating, and frequent defecation can cause symptoms to escalate. Fiber works best when water intake is increased to at least 64 ounces, with more being needed for warmer climates or significant physical activity. For some patients, prebiotics and probiotics are an adjunct to maintain colon health and stool texture [22]. Those with severe chronic constipation may require stool softeners or laxatives to correct their stool texture, and those with chronic loose stools despite fiber supplementation may require antidiarrheals; however, these medications should not be first line in most circumstances.

Hygiene

In addition, soaking in the bath tub, or in a sitz bath, is soothing to the hemorrhoids, allows for relaxation of the pelvic floor, can facilitate reduction of tissue prolapse, and decrease edema. Soaks can be performed at 15-minute intervals in warm water for symptomatic relief, without the need for salts or emollients, which may cause irritation.

Topical Therapies

Generally, patients present for in-office evaluation for hemorrhoids because over-the-counter remedies have already failed. There are no quality data to support the use of commercially available topical therapies (creams, wipes) and suppositories; however, if the patient reports a perceived benefit, it is generally acceptable to continue their use, given the overall low side-effect profile of these preparations. Most common topical products contain topical anesthetics such as lidocaine, steroids such as hydrocortisone, and/or pramoxine, which is an anti-inflammatory. Daily use of topicals beyond 7 days may lead to dermatitis and exacerbate symptoms [23, 24]. Formulations containing steroids also should not be used for more than 7 days as they can lead to thinning of the delicate anoderm. Warm or cold packs can also provide symptomatic relief.

Oral Therapies

Non-steroidal anti-inflammatories may help relieve general discomfort and reduce inflammation. Phlebotonics represent a class of oral plant-derived flavonoids and synthetic drugs that were originally intended for chronic venous disease and are currently used for hemorrhoidal disease predominantly in Europe and Asia, as they are not approved by the Federal Drug Administration for use in the United States. Phlebotonics have been shown to decrease hemorrhoid symptoms through multiple effects, including reducing

inflammation and increasing vascular tone [25]. Multiple studies and meta-analyses have demonstrated modest benefits in reducing symptoms of pruritis and bleeding, and also may be used in the post-operative setting [26, 27].

Office-Based Procedures

With appropriate patient selection, office-based procedures for hemorrhoids can be fast, economical, effective, and low risk. The key to achieving consistently good outcomes is careful patient selection and proper understanding of the technical aspects of each procedure. Outcomes are optimized when patients also utilize the conservative strategies mentioned above. It is important to take a thorough history, paying particular note to use of anticoagulants and bleeding disorders.

Internal Hemorrhoids

Multiple techniques exist for safe in-office treatment of symptomatic internal hemorrhoids, including rubber band ligation, infrared photocoagulation/bipolar diathermy, and sclerotherapy. Patients with grade I–II and some grade III hemorrhoids with symptoms of bleeding are ideal candidates for office procedures. Those with large prolapsing grade III hemorrhoids primarily with associated symptoms of tissue prolapse may need a surgical approach, or an attempt at conservative measures to downgrade them before attempting an office procedure. The techniques described below can all be done in either left lateral decubitus or prone position, based on surgeon preference, and involve instrumentation through an anoscope. Patients who cannot tolerate anoscopy in the office are therefore not suitable candidates for these procedures.

Rubber band ligation involves placement of a rubber band on the redundant mucosa of the hemorrhoid column above the dentate line (Fig. 11.5a). The strangulated hemorrhoid tissue captured within the band necroses after 5–7 days, leaving a small ulcer that eventually will scar in. This technique has been a mainstay of office hemorrhoid procedures since the early 1960s [28]. There are several varieties of hemorrhoid banding devices that exist, including the McGown suction ligator, which applies suction (instead of a separate grasper) to bring the tissue into the device, with a trigger to deploy the band (Fig. 11.5b). While it does require purchase of a suction machine, it enables the surgeon to perform the procedure without a hand from an assistant. The device is used through the anoscope to secure the band onto the mucosa of the selected hemorrhoid. While more than one column may be banded safely in a single office visit, studies demonstrate a higher rate of symptoms including pain and urinary retention.

With proper technique, the patients may feel mild rectal pressure during the procedure (which may last up to 1–2 days), but should not experience pain, which is most likely from band placement too distal within the anal canal. While patients on anticoagulation (other than 80 mg aspirin) are conventionally recommended to hold anticoagulation prior to rubber band ligation [29], a recent retrospective case-control study of 82 patients demonstrated no difference in bleeding risk for patients on clopidogrel compared to the control group, 3.75% versus 2.78%, $p = 0.74$ [30]. Risk of bleeding peaks at post-procedure day 5–7, when the tissue necroses and the band falls off, and in rare instances requires operative management. Risk of pelvic sepsis, characterized by fever, urinary retention, swelling, and pain, is rare but can be rapidly progressing and fatal if not immediately recognized.

Energy ablation techniques include infrared photocoagulation and bipolar diathermy. *Infrared photocoagulation (IPC)* causes coagulation and results in vascular sclerosis and fixation of the tissue (Fig. 11.6). Best used for grade I–II hemorrhoids, it uses a tungsten-halogen lamp as an energy source, converting the light to heat with a polymer probe tip. Similar to bipolar diathermy, the probe tip is applied 3–4 times to the apex of the internal hemorrhoid to deliver 0.5–2 second pulses of heat at a 2.5–3 mm depth of penetration. One advantage of this technique is that it can be used on multiple hemorrhoid columns at one time. *Bipolar diathermy* is another similar office technique for grade I–III hemorrhoids that involves the use of 20 watts of pulsed electrocautery at a depth of 2.2 mm focused at the apex of the hemorrhoid, causing tissue coagulation. If applied too distally, these techniques can cause pain and can potentially lead to ulceration or fissure formation.

In terms of outcomes, a prospective randomized trial of 122 patients comparing bipolar diathermy to IPC demonstrated similar outcomes [31]. A small prospective randomized crossover study of 94 patients comparing IPC to rubber band ligation demonstrated less analgesic use and bleeding in the IPC group in the first 24 hours following the procedures, although notably the complication rates in the RBL group were higher than typical [32].

Sclerotherapy is the oldest technique for grade I–III hemorrhoids, having been first described in 1869 [33]. The procedure involves the injection of 1–1.5 mL of a sclerosing agent into the submucosal layer of the base of the engorged hemorrhoid, using a 21-gauge spinal needle (Fig. 11.7). The sclerosant causes fibrosis and fixation of the hemorrhoid. Critical to the technical success of this procedure is avoiding injecting either too superficially, resulting in damage to the mucosa, or too deep, which can cause pain, infection, and abscess. The most common sclerosing agents are hypertonic saline and 5% phenol in oil. One of the advantages of sclero-

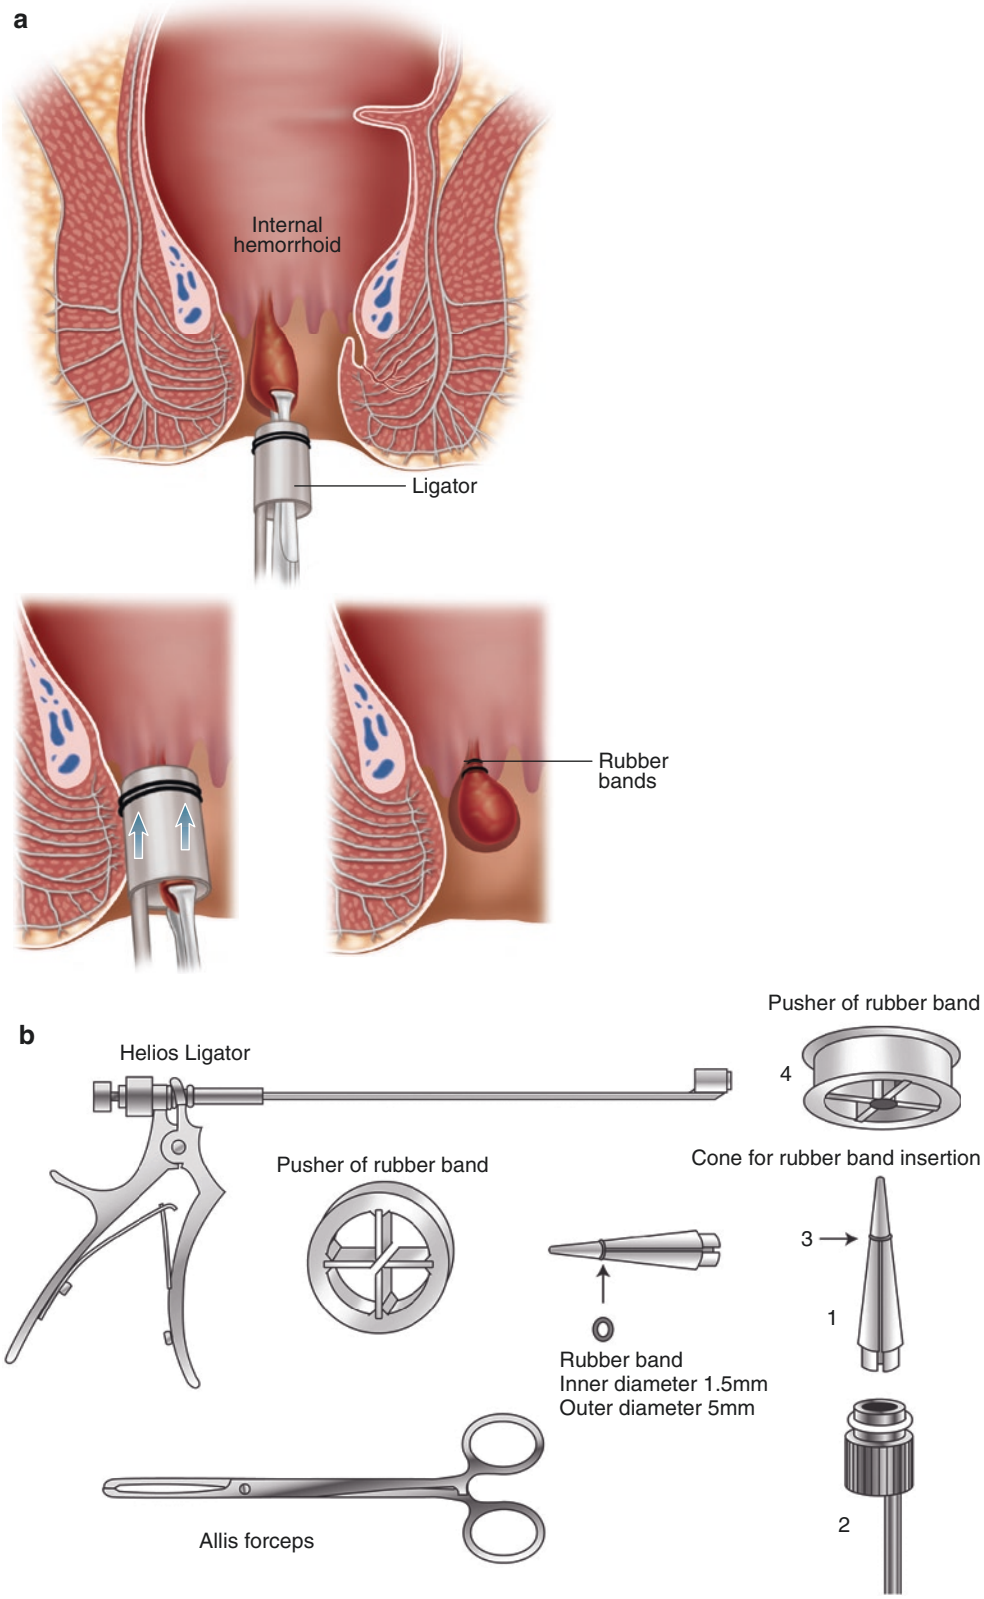

Fig. 11.5 Hemorrhoid banding – (**a**): technique and (**b**): equipment

therapy is that it is safe for patients on anticoagulation. Multiple small trials compare rubber band ligation to sclerotherapy, with differing results but overall favorable outcomes with both, leading one to conclude that they are comparable and at the discretion and preference of the surgeon [34, 35].

Thrombosed Hemorrhoid Excision

Some of the most grateful patients are those who undergo excision of a thrombosed hemorrhoid in the office setting. Optimal timing of the procedure is critical, and thus knowl-

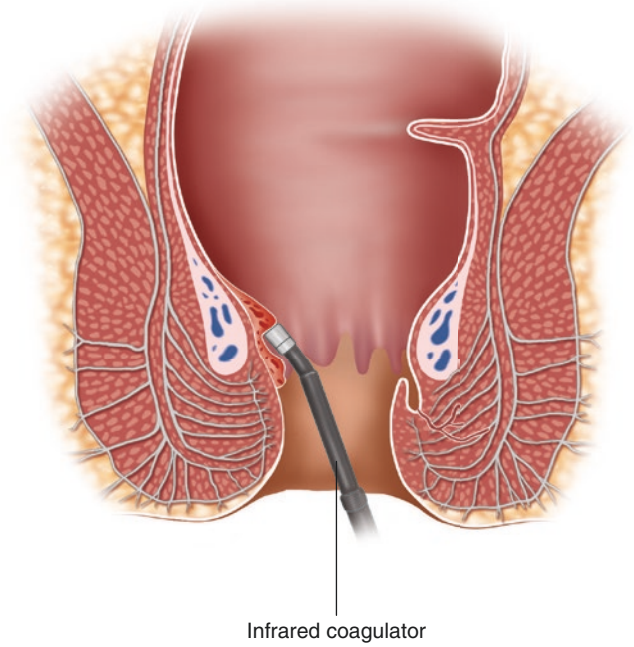

Fig. 11.6 Infrared photocoagulation technique

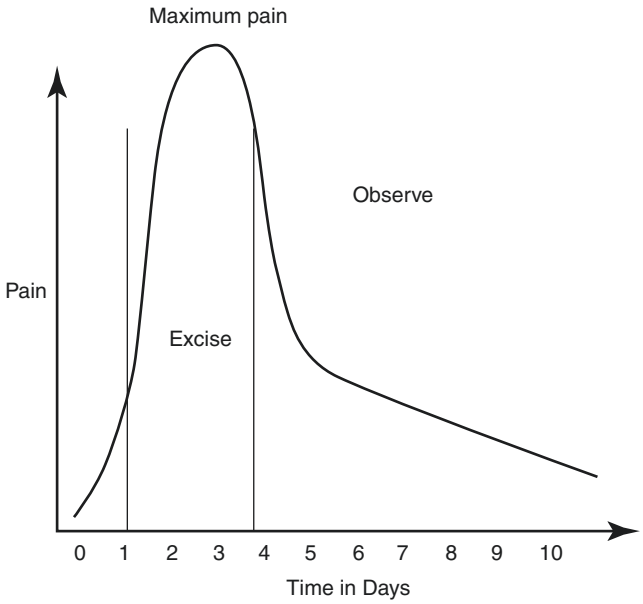

Fig. 11.8 Timing of excision of a thrombosed external hemorrhoid. (With permission from Cintron and Abcarian [101])

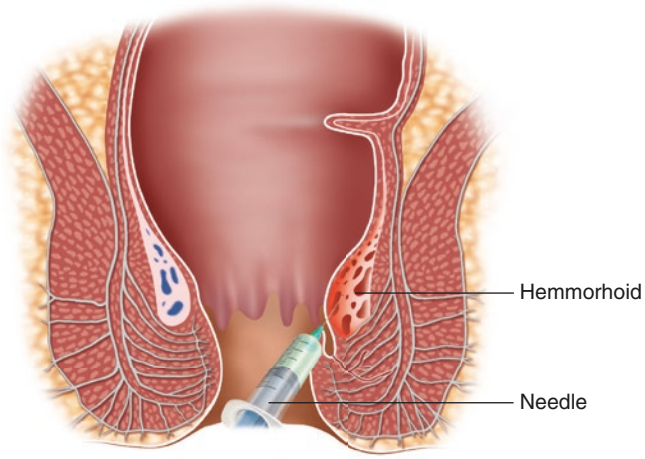

Fig. 11.7 Sclerotherapy technique

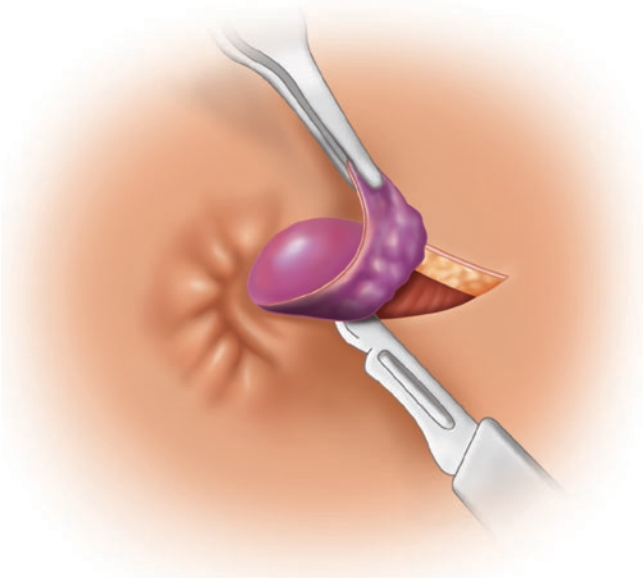

Fig. 11.9 Excision of thrombosed hemorrhoid

edge of the natural history of thrombosed hemorrhoids is important (Fig. 11.8). As most patients should start to experience spontaneous improvement within 72 hours of the onset of symptoms, excision beyond this time point may only serve to increase the intensity and duration of pain. For those not meeting criteria for excision, topical nifedipine has been shown to improve pain scores by decreasing associated sphincter spasm [36]. A small subset of patients will present with persistent pain and a palpable lump for several days to weeks, with no improvement in symptoms, and may also be good candidates for excision. Compared to incision and clot evacuation, excision of the thrombosed hemorrhoid is associated with improved outcomes, specifically decreased rate of recurrence and less pain.

To excise a thrombosed hemorrhoid, the perianal skin is cleansed with a betadine solution and allowed to dry (Fig. 11.9). Local anesthetic (1% lidocaine with or without epinephrine 1:200,000) is injected using a 27-gauge needle into the base of the hemorrhoid. Toothed forceps are used to grasp the most lateral or radial aspect of the hemorrhoid, while a fine Metzenbaum scissor (or an office cautery device) is used to meticulously dissect around the hemorrhoid and

associated clot in an ellipse shape, superficial to the sphincter muscle. Dissection in the proper tissue plane results in minimal blood loss. Care is used to prevent going unnecessarily wide on the anoderm, creating a larger wound than necessary. Pressure is held on the excision site, and silver nitrate can be used for hemostasis.

Operative Management of Hemorrhoids

Operative management of hemorrhoids is usually reserved for those patients who have failed medical management or have recurrent, persistent disease despite medical therapy or office-based procedures. Typically, only 5–10% of patients with hemorrhoid-related complaints require operative hemorrhoidectomy [37]. Additionally, operative approaches are most effective for grade III and IV internal hemorrhoids, those with a large external component, and may be the only realistic option for extensive hemorrhoidal disease or incarcerated, strangulated, or gangrenous hemorrhoids.

Excisional hemorrhoidectomy has excellent results, minimal recurrence rates, few complications and remains the gold standard in the surgical management of hemorrhoids. Excisional hemorrhoidectomies can be classified as being done in a closed (Ferguson technique) or open (Milligan-Morgan technique). Because both excisional techniques are associated with significant postoperative pain, other surgical techniques have been devised with the goal of achieving the excellent results of excisional hemorrhoidectomy while reducing postoperative discomfort. More specifically, these other primary operative management techniques include use of ultrasonic energy devices, stapled hemorrhoidopexy, and transanal hemorrhoid dearterialization.

In all operative interventions, bowel preparation and preoperative antibiotics are not required [29]. A preoperative enema can be given at the surgeon's discretion to clear out the distal rectum of stool. The anesthetic technique can be tailored to the patient and can range from local with sedation to full general anesthetic. Positioning in lithotomy, prone jackknife, or left lateral positioning is per surgeon preference. All operations begin with a thorough visual inspection of the perianal skin, followed by digital rectal exam and anoscopy to determine which hemorrhoid columns require intervention and to rule out other pathology not identified during the office examination.

Excisional Hemorrhoidectomy Closed Technique (Ferguson Technique)

First described by Dr. Lynn Ferguson of the Ferguson Clinic in the early 1950s, the closed hemorrhoidectomy technique remains the most common operation for hemorrhoids in the United States [38, 39]. An elliptical incision is made, starting at the perianal skin and continuing to the anorectal ring, dissecting the hemorrhoid tissue away from the sphincter complex (Fig. 11.10). Dissection can be completed with a scissors, scalpel, or Bovie electrocautery. Dissection is carried out beyond the enlarged internal component at which point the pedicle is suture ligated with absorbable suture and the hemorrhoid tissue amputated. The wound is then closed in a running fashion with the same absorbable suture used to ligate the hemorrhoid pedicle. The suture may be run in locking fashion to improve hemostasis, and small bites of the underlying sphincter complex may be taken to close the dead space. A few millimeters of the anal margin wound may be left open for drainage. One to three columns may be excised using this technique. Care should be taken to preserve bridges of viable skin and mucosa between excision sites to prevent stenosis [40]. Hemorrhoids may be sent as individual specimens, so that any incidental finding on final pathology can be attributed to a specific quadrant, although the likelihood of an incidental findings is only about 1% in the literature [41].

Excisional Hemorrhoidectomy Open Technique (Milligan-Morgan)

The open technique of hemorrhoidectomy is commonly used in the United Kingdom. Perioperative considerations are the same as for the Ferguson technique. The excision is also very similar, however, following suture ligation of the pedicle and amputation of the hemorrhoid bundle the wounds are left open to heal by secondary intent (Fig. 11.11). Again, one to three columns can be excised, with the same caveat regarding preservation of viable bridges of skin and mucosa. Both open and closed techniques are considered appropriate. A recent meta-analysis of 11 RCTs comparing open versus closed hemorrhoidectomy demonstrated that the closed approach was associated with decreased postoperative pain, faster wound healing, and lesser risk of postoperative bleeding. Postoperative complications, hemorrhoid recurrence, and infectious complications were similar [42]. However, multiple individual randomized controlled trials have demonstrated little difference [42–46].

Use of Energy Devices in Excisional Hemorrhoidectomy

Both the open and closed techniques have been modified to include the use of alternative energy sources, such as the bipolar diathermy and ultrasonic shears. A Cochrane review was completed to compare bipolar energy hemorrhoidectomy to standard excisional hemorrhoidectomy [47]. The authors concluded that early postoperative pain was less when the bipolar device was used; however, the difference was no longer noted at day 14. Hemorrhoidectomy completed with a bipolar energy device was also found to be faster. Use of ultrasonic shears seems to produce similar results [48].

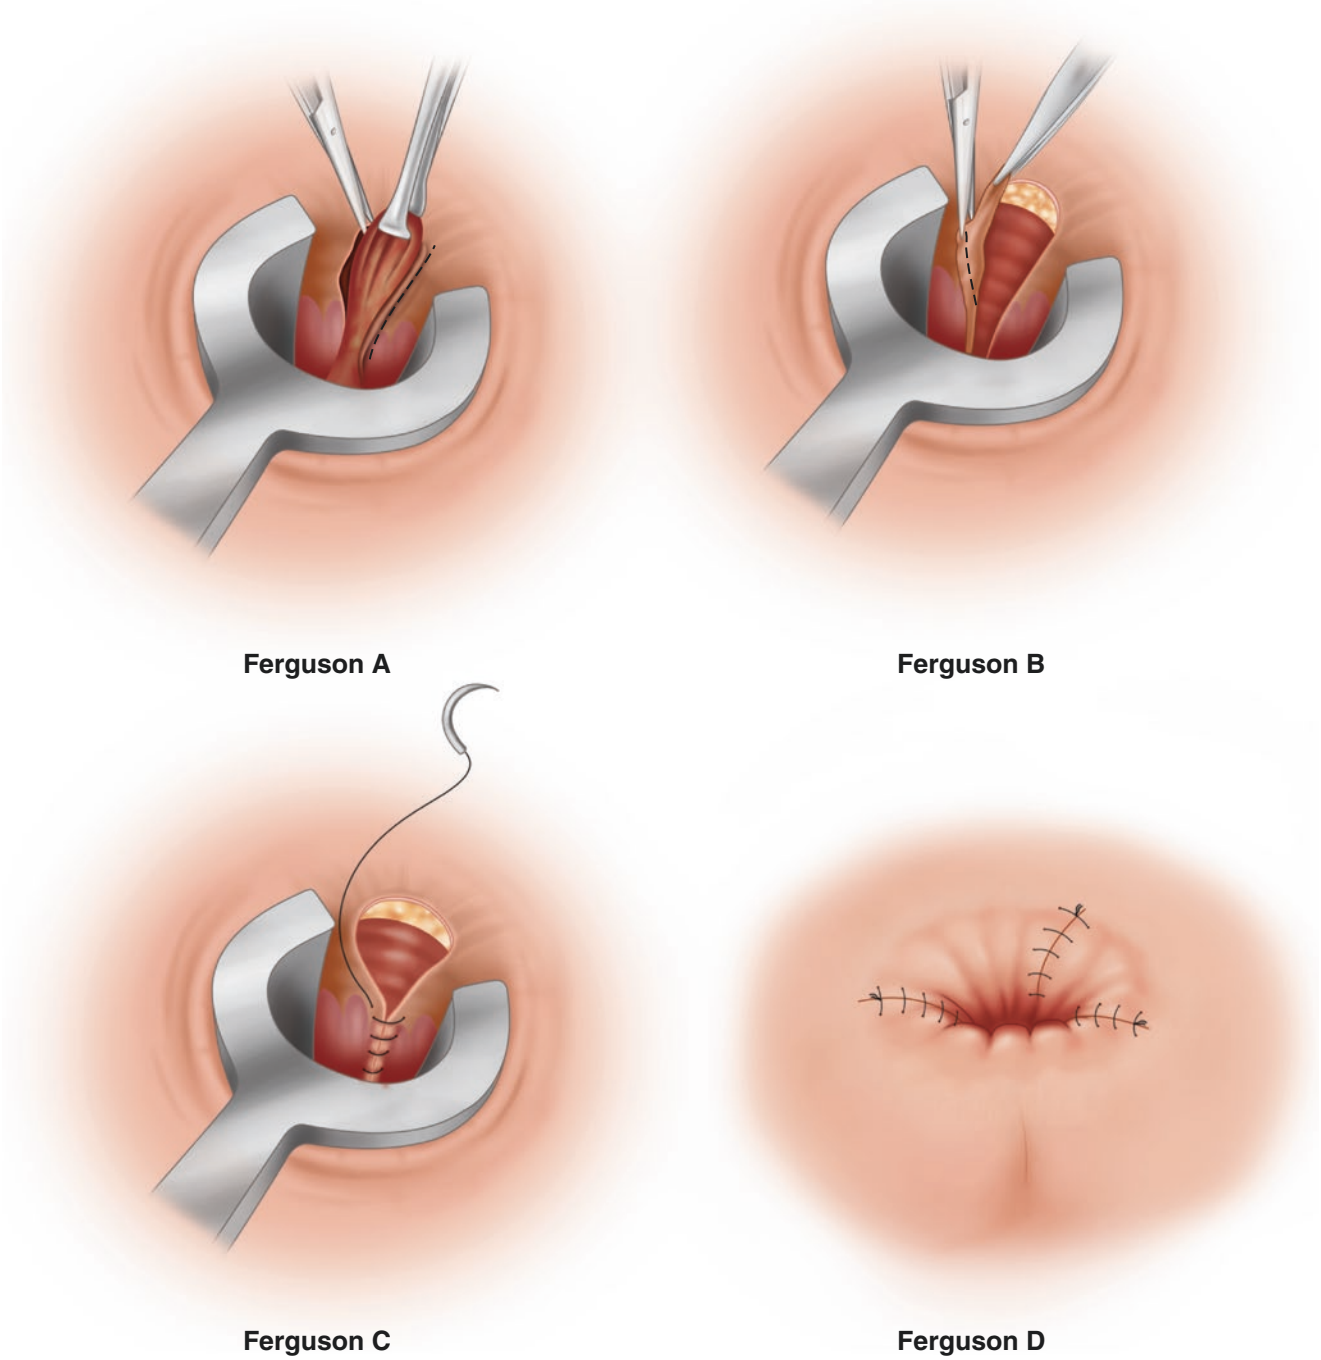

Fig. 11.10 Closed hemorrhoidectomy

When these two devices were evaluated head to head in a randomized controlled trial of patients undergoing closed hemorrhoidectomy, postoperative pain scores were similar, with no differences in clinical outcomes [49]. Other approaches including diathermy and the use of laser technology have not demonstrated improvements in pain and may be associated with higher cost [50–53].

Whitehead Hemorrhoidectomy

The Whitehead hemorrhoidectomy technique, once common in the United Kingdom, involves a circumferential excision of internal hemorrhoidal tissue and redundant anoderm just proximal to the dentate line. This procedure never gained wide acceptance in the United States, in part owing to a high incidence of postoperative complications including anal ste-

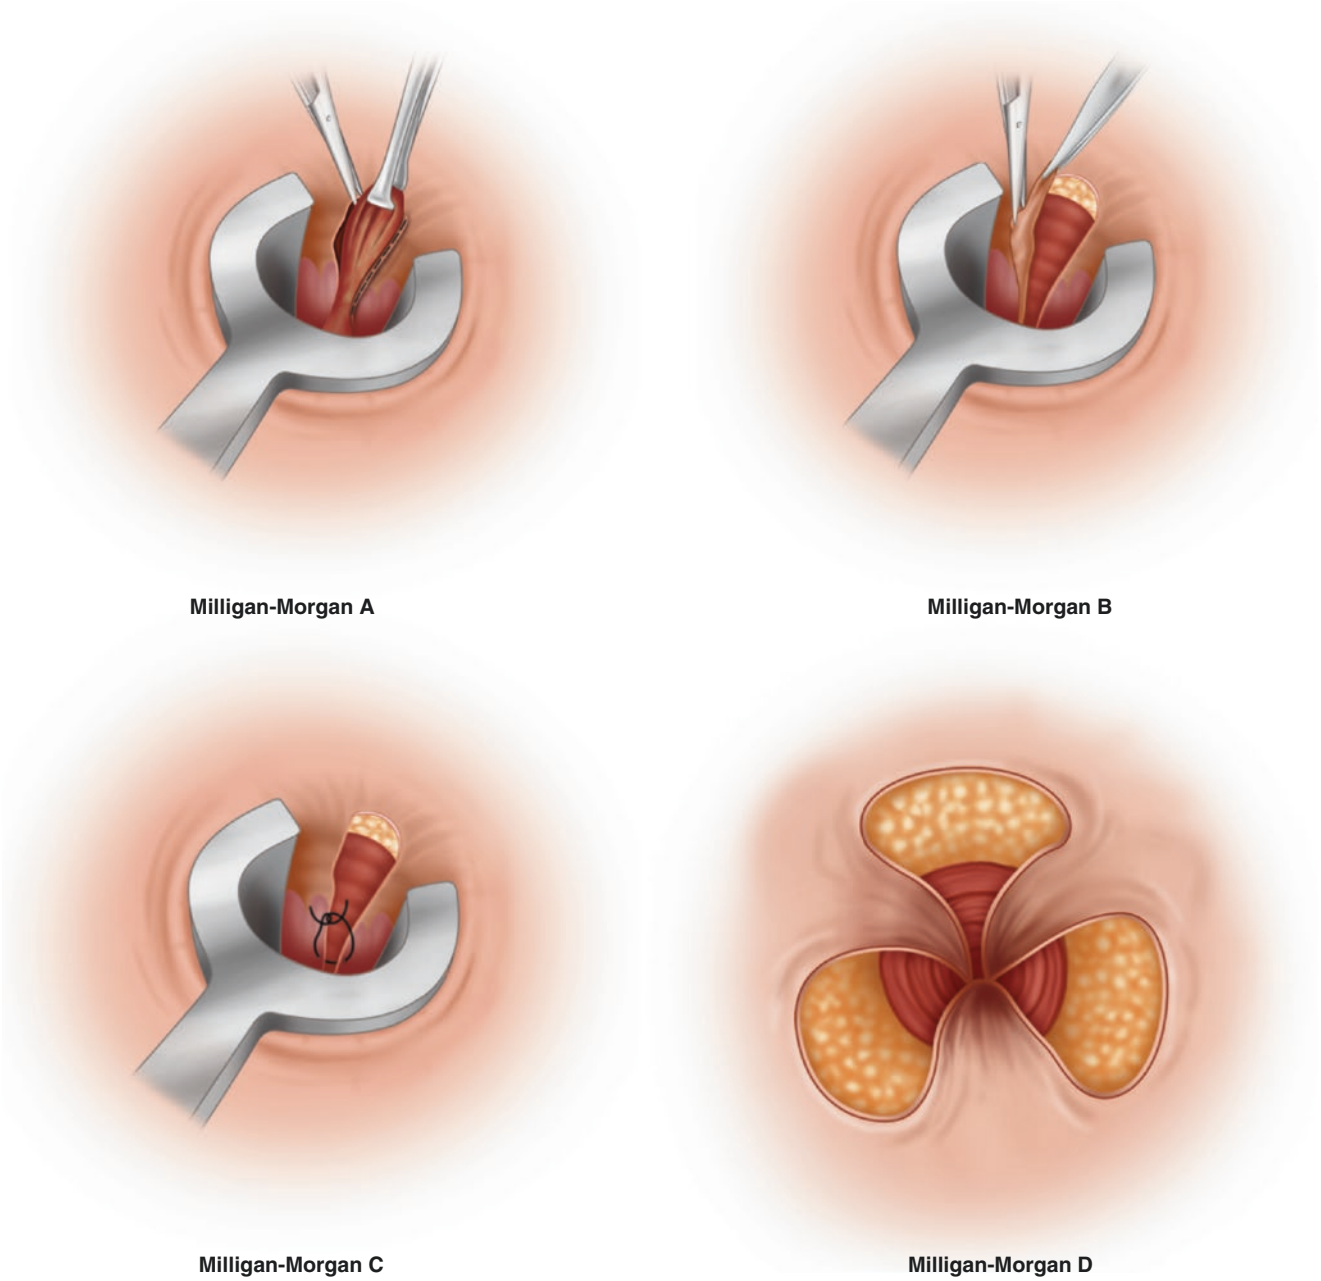

Fig. 11.11 Open hemorrhoidectomy (Milligan-Morgan)

nosis, mucosal ectropion (the "Whitehead deformity"), and disturbed continence (Fig. 11.12). Most centers have abandoned this approach.

Stapled Hemorrhoidopexy

Stapled hemorrhoidopexy, first developed in Italy, uses a circular stapling device to address circumferential internal hemorrhoids and create a mucosa-to-mucosa anastomosis. In doing so, the submucosa proximal to the dentate line is excised, resulting in removal of redundant tissue, a cephalad relocation of the anal cushions and interruption of the feeding arteries (Fig. 11.13). Although effective for internal prolapsing disease, it does not address external hemorrhoids. To perform the procedure, a translucent anoscope, provided with the circular stapler, is introduced transanally. After placing the anoscope, a purse-string suture is placed in a circumferential manner into the submucosa, approximately 2 cm above the dentate line (Fig. 11.14). The head of the stapler is then placed through the anoscope and into the rectum. The purse string is tied down around the shaft of the stapler. The stapler is slowly closed while providing traction on the purse-string. Once closed, the stapler is fired and then

Fig. 11.12 Whitehead deformity

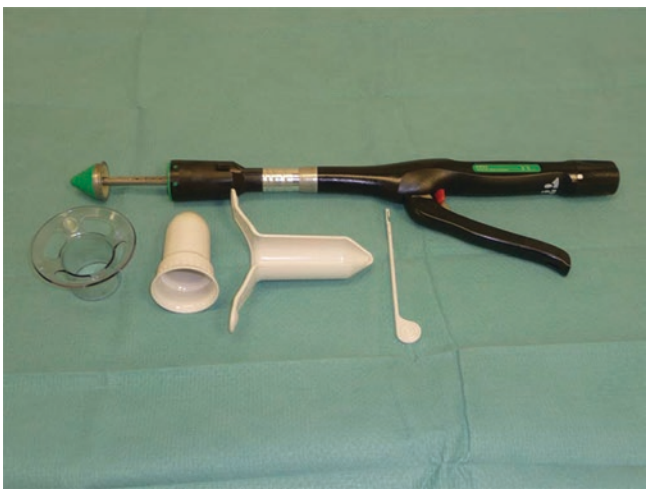

Fig. 11.13 Stapled hemorrhoidectomy. (Reused with permission Wexner and Fleshman [102]. Copyright © 2018 Wolters Kluwer)

removed along with the excised tissue. The staple line is inspected for bleeding and controlled, if present, with suture ligation. In females the vagina should be inspected and palpated prior to firing the instrument to ensure that a vaginal cuff has not been inadvertently included.

Early cohort and smaller nonrandomized trials reported stapled hemorrhoidopexy to be associated with less pain and faster recovery when compared with excisional hemorrhoidectomy. A randomized controlled trial of 777 patients undergoing either stapled hemorrhoidectomy or traditional excisional hemorrhoidectomy demonstrated less pain in the stapled group with similar complication rates. Despite these advantages of the stapled technique, the excisional hemorrhoidectomy group had significantly better quality-of-life scores than the hemorrhoidopexy group. Further, in the stapled hemorrhoidopexy group, 32% of patients reported that their symptoms had recurred compared with only 14% in the excisional hemorrhoidectomy group, and this difference was maintained at 24 months [54]. A Cochrane review of 12 trials including 1097 patients demonstrated similar findings. Additionally, patients undergoing hemorrhoidopexy were more likely to require an additional operative procedure. Lastly, patients undergoing excisional hemorrhoidectomy surgery were more likely than those undergoing stapled hemorrhoidopexy to be asymptomatic following surgery [55].

Stapled hemorrhoidopexy has been associated with several unique complications, including rectovaginal fistula, staple line bleeding, and stricture at the staple line. A systematic review of 784 articles including a total of 14,232 patients found a median complication rate of 16.1%, with five documented mortalities [56]. Between 2000 and 2009, there were 40 published cases in the literature of rectal perforation after stapled hemorrhoidopexy. Thirty-five patients required a laparotomy with fecal diversion, and one patient was successfully treated with low anterior resection. Despite surgical treatment and resuscitation, there were four deaths [57]. The severity of possible complications associated with stapled hemorrhoidopexy have deterred many from its use and reflect the importance of proper training and surgical technique.

Doppler-Guided Hemorrhoidectomy

Originally described by Morinaga in 1995 [58], Doppler-guided/assisted hemorrhoid artery ligation (HAL) uses an anoscope fashioned with a Doppler probe to identify each hemorrhoid artery. The artery is subsequently ligated and, although not initially described, is often followed by a suture mucopexy for patients with symptomatic prolapse. Potential benefits are the lack of tissue excision and less pain.

Patient preparation and setup is identical to any excisional technique. A specialized anoscope with Doppler ultrasound is introduced into the anal canal (Fig. 11.15). The Doppler and anoscope are rotated until a feeding artery is identified (Fig. 11.16). With the aid of a guide to ensure proper depth and location, the artery is suture ligated. The Doppler can be used to confirm loss of signal, indicating ablation of arterial inflow. The process is repeated until the four to six hemorrhoidal arteries have been ligated. Depending on the degree of prolapse, a suture mucopexy may be included using the same stich as the ligation. This is completed by running a continuous suture from the ligation point toward the distal anal canal, just proximal to the dentate line. The free end of the stich is then tied to the tail of the suture, pulling the hemorrhoid column into the proximal anal canal toward the ligation.

Fig. 11.15 Transanal hemorrhoidal dearterialization device

Prospective studies using HAL have demonstrated favorable short-term results [59]. A systematic review evaluating 28 studies, including 2904 patients with grade I–IV hemorrhoids, demonstrated a pooled recurrence rate of 17.5%, with the highest rates for grade IV hemorrhoids. Overall postoperative complication rates were low, with an overall bleeding rate of 5% and an overall reintervention rate of 6% [60]. In a randomized prospective trial comparing RBL with HAL for the treatment of grade II and III hemorrhoids, recurrence rates, symptom scores, complications, quality-of-life assessment, and continence score were similar. Patients had more pain in the early postoperative period after HAL. HAL was also more expensive and was not found to be cost-effective compared with RBL in terms of incremental cost per quality-adjusted life-year [61]. In respect to long-term outcomes, a recently completed meta-analysis of comparing stapled hemorrhoidectomy to HAL demonstrated a statistically significant difference in recurrence (OR 0.55; 95% CI, 0.340.90 $P = 0.02$) with increased recurrence in the HAL group [62]. A similar meta-analysis demonstrated that recurrence was highest in those with grade IV hemorrhoids [63]. When comparing HAL to excisional hemorrhoidectomy, one meta-analysis, which included 286 patients in the evaluation of recurrence, found no difference [64]. However, the data regarding long-term comparisons between excisional and HAL hemorrhoidectomy are somewhat lacking. In conclusion, HAL demonstrates favorable short-term results but may be associated with increased recurrence, especially in those with grade IV hemorrhoids.

Pain Management and Postoperative Care

Pain management after hemorrhoidectomy starts with adequate patient counseling in the preoperative setting. Setting realistic expectations for the patient can go a long way in terms of allaying their concerns and ensuring they are prepared with enough time to recuperate before planning to return to normal activity. Recovery time is variable and depends on the type of procedure, anticipated extent of surgery, as well as the patient's intrinsic tolerance and if they are on preoperative narcotics. Multimodal pain control is critical to minimize discomfort associated with surgery for hemorrhoids, while limiting narcotics.

For patients under conscious sedation, a pudendal nerve block consisting of a 1:1 mix of 1% lidocaine and 0.25% bupivacaine is most commonly used, for a total volume of 40–60 mL depending on patient weight. The addition of 1:200,000 epinephrine to one of the local analgesics will increase the maximum dose and duration of action. Although from a pharmacokinetic standpoint, the onset of lidocaine is faster than bupivacaine, under 2 minutes versus 5 minutes, and the duration of action is shorter, 1–2 hours versus 2–4 hours, the clinically observed differences between the two drugs have not been shown to be significant, with an overall time to onset between 12 and 29 seconds, with a duration of action between 6 and 7 hours [65].

Use of liposomal bupivacaine either as monotherapy or volume expanded in bupivacaine will result in improved analgesia for the first 72 hours postoperatively. A prospective, randomized, controlled double-blind study of 100 patients undergoing excisional hemorrhoidectomy demonstrated significant increase in time to first opioid use, 19 hours versus 8 hours, $p = 0.005$, with corresponding reduction in pain scores [66]. It is our practice to volume-expand a 20 mL bottle of liposomal bupivacaine with 20 mL of 0.25% bupivacaine and inject this at the onset of the procedure as a pudendal nerve block. Importantly, liposomal bupivacaine cannot be volume-expanded in lidocaine, which will competitively drive the bupivacaine out of the liposomes and lead to toxicity. While the cost of liposomal bupivacaine is far greater than conventional non-liposomal alternatives, there are no studies that have performed a cost analysis for outpatient anorectal surgery, although it has been found to be cost-effective (or at least comparable) in many other types of surgery, in part, due to decreased length of stay, which is not applicable in this setting [67–69].

Given that narcotics are associated with unfortunate side effects (such as constipation) and have been shown to increase risk of long-term addiction and contribute to the "opioid crisis" in the United States, it is best to minimize their use [70]. A pudendal nerve block is essential for postoperative pain control, regardless of whether general endotracheal or monitored anesthesia care is used. A prospective, randomized, double-blind, placebo-controlled trial of 61 patients undergoing anorectal surgery compared the use of preoperative oral acetaminophen and gabapentin and intraoperative intravenous ketamine and dexamethasone to pla-

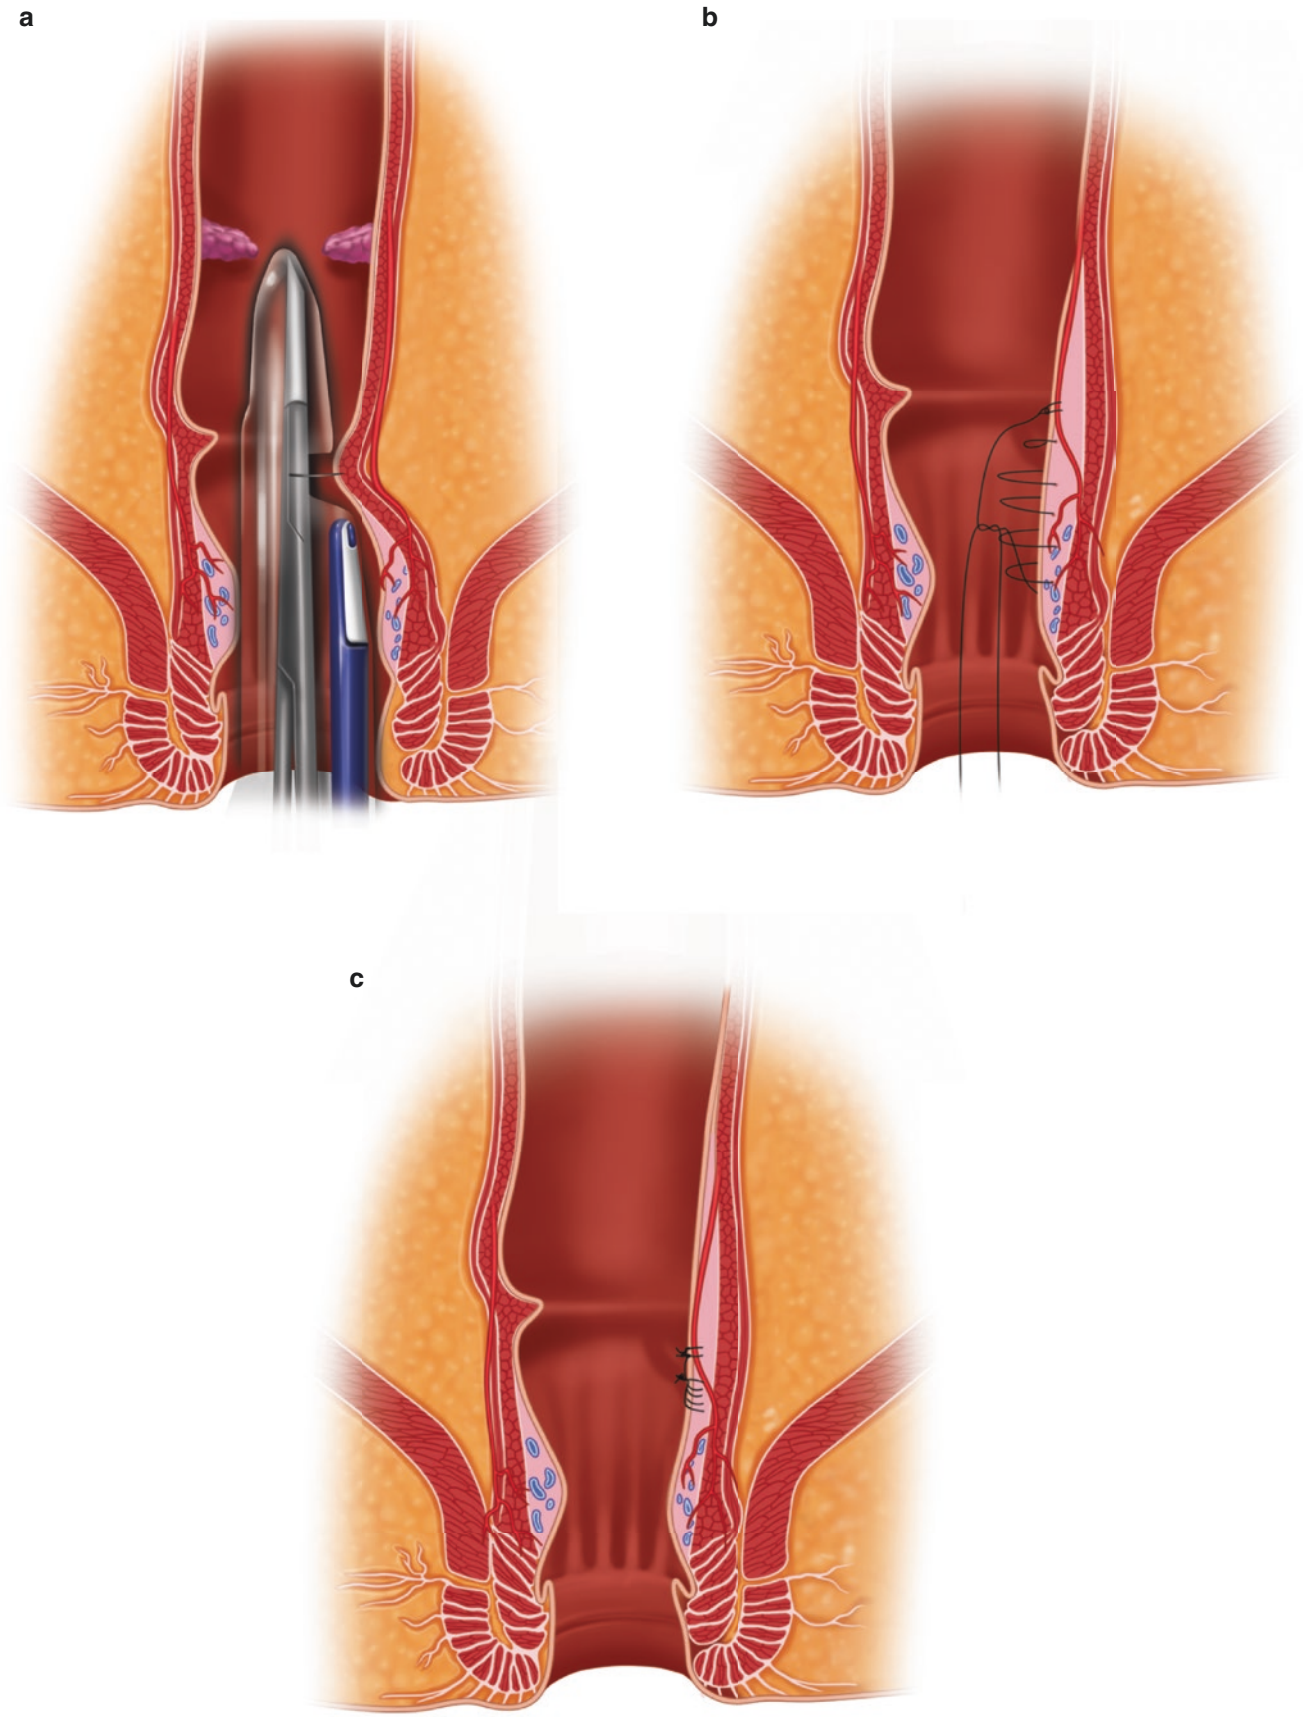

Fig. 11.16 Transanal hemorrhoidal dearterialization

cebo and found significantly decreased self-reported pain scores (50% and 40% decrease) and breakthrough narcotic use (relative risk reduction 76% and 92%) in the post-anesthesia care unit and at 8 hours postoperatively. Unfortunately, as is the case with many such studies, the trial was underpowered to detect a difference in hemorrhoid patients ($n = 17$) [71].

As for oral medications, non-narcotic medications should be used as a mainstay, with narcotic pain medication for breakthrough pain. Recommended effective Motrin dose is 600 mg TID. Acetaminophen can be used either simultaneously or alternating, at doses not to exceed 4 g/day. Diazepam is a very helpful adjunct in reducing sphincter spasm, although this has not been studied formally in the literature. Oral metronidazole has been given in the postoperative setting, although studies are mixed regarding its efficacy in terms of decreasing pain. A 2017 meta-analysis of five randomized controlled trials involving 337 patients found that the metronidazole group had significantly lower pain scores on postoperative days 1 and 4, as well as a significantly faster return to activity; however, when a sensitivity analysis was performed, the largest trial was excluded due to bias, and consequently all the observed findings were no longer statistically significant [72].

No formal guidelines exist to inform clinicians on appropriate prescribing of narcotics after hemorrhoidectomy, although a recent study of over 6200 patients in a claims database determined that a 5- to 10-day prescription is optimal for most patients, noting there was over threefold increased odds of needing a prescription refill in patients with history of opioid use. One of the major limitations of the study was that it could not determine the number of pills or type of narcotic prescribed [73]. A more recent retrospective single-institution study of 77 patients who underwent ambulatory excisional hemorrhoidectomy evaluated postoperative opioid usage to create a prospective prescribing guideline. It was determined that, to meet opioid needs for 80% of patients, the equivalent of 27 pills of 5 mg oxycodone would need to be prescribed postoperatively for home use [74]. Additionally, it is our preferred practice to prescribe narcotics that do not contain acetaminophen, such as oxycodone, to minimize risk of acetaminophen toxicity.

Topicals After Hemorrhoidectomy

Various topical preparations can be considered in the postoperative setting, as data suggest a modest benefit. A prospective, double-blind, randomized controlled trial of 66 patients with grade III–IV hemorrhoids undergoing open hemorrhoidectomy compared use of 5% topical baclofen to placebo and demonstrated a significant reduction in pain and analgesic consumption in the treatment arm at 1 and 2 weeks postop [75]. A 2010 meta-analysis of five randomized controlled trials of 333 patients using topical glyceryl trinitrate (GTN) ointment after hemorrhoidectomy demonstrated significant reduction in pain on postoperative days 3 and 7, but not on day 1. It also demonstrated an odds ratio of 3.57 for wound healing at 3 weeks postop, compared to placebo ($p < 0.0001$), without a statistically significant difference in incidence of headache [76]. A 2019 study of 40 patients found similar results with regard to postoperative pain, but there was a significantly higher rate of headache in the GTN arm [77]. Additionally, studies demonstrate modest benefits of topical lidocaine in the postoperative setting, when combined with diclofenac or nifedipine [78, 79].

Routine Postoperative Care

Following hemorrhoidectomy, in addition to pain control, patients are instructed to avoid constipation. Patients who have corrected their stool texture prior to undergoing surgery will have the best outcomes. Fecal impaction in the postoperative period can be a devastatingly painful complication and is to be avoided with rigorous attention to maintaining a proper bowel regimen. It is essential to educate patients on the constipating side effects of narcotics, and to counteract this with water intake and fiber, stool softeners, laxatives, and other adjuncts such as prune juice and probiotics. Conversely, patients are also encouraged to avoid diarrhea, whether it be due to underlying conditions (which are best optimized prior to surgery) or by overdoing it with laxatives. Frequent loose stools will be painful and irritating and may delay healing. Lastly, Sitz baths and warm or cool packs will also provide relief from pain. Most patients are familiar with these interventions from their time prior to surgery.

Complications of Hemorrhoidectomy

Urinary Retention

Urinary retention is one of the most common complications following hemorrhoidectomy and occurs at a rate of 1–15%. It is also the most common reason for failure of surgical patients to be discharged from an ambulatory setting [80]. The incidence is higher after spinal anesthesia and after HAL procedures. The risk may be mitigated with decreasing volume of intravenous fluids to less than 500 cc and through judicious use of local anesthesia [81].

Postoperative Hemorrhage

Delayed post-hemorrhoidectomy bleeding is a rare but serious complication after hemorrhoidectomy [82]. The incidence of delayed postoperative hemorrhage has been reported to be 0.9–10% [83, 84]. While some minor bleeding is expected following hemorrhoidectomy, patients who describe passage of an entire bowel movement of blood clots are likely to require and exam under anesthesia. The culprit vessel may not always be found, but if it is, it can usually be managed

with an interrupted figure of eight absorbable suture. It is also reasonable to evacuate any residual clot from the rectum and distal sigmoid via rigid proctoscopy to reduce the chances of clouding the postoperative clinical picture with ongoing hematochezia. Some data suggest that delayed bleeding is linked to risk factors such as the surgical procedure, infection, defecation with excessive straining, and number of piles [85, 86]. Interestingly, a study that evaluated 45 patients with delayed bleeding reported that male gender and individual surgeons were independent risk factors [83]. There was no significant difference in the occurrence of hemorrhage between patients who underwent a closed or open hemorrhoidectomy [43] or between conventional hemorrhoidectomy and using a bipolar energy device [87].

Fecal Incontinence

Incontinence to stool following hemorrhoidectomy can occur but is rare and may be multifactorial in nature. There may be undue stretch placed on the anal sphincter at the time of surgery, direct sphincter injury, or loss of the bulk of the hemorrhoid cushions. Proper technique which avoids the sphincter muscles should have no impact on sphincter integrity or function.

Anal Stenosis

Anal stenosis can occur following hemorrhoidectomy if excessive anoderm is removed. It is most commonly encountered following emergency hemorrhoidectomy and is usually secondary to inadequate remaining skin bridges. Treatment can involve bulk laxatives, dilation, and anoplasty (described elsewhere) [88, 89].

Special Patient Populations

Strangulated Hemorrhoids

Strangulated hemorrhoids are internal hemorrhoids that have prolapsed and become incarcerated and irreducible. Edema and thrombosis of the external hemorrhoids often accompany this condition. The incarcerated internal hemorrhoids may be beefy red, or ulcerated and necrotic, depending on the length of time of incarceration. If not necrotic, circumferential injection of local anesthetic and reduction of the strangulated hemorrhoids can be accomplished, followed by bed rest. One small randomized trial published in 1991 compared reduction followed by banding of the internal component and excision of the external thromboses with excisional hemorrhoidectomy; 13.5% of patients treated with reduction and banding went on to require excisional hemorrhoidectomy [90]. Unless the patient has prohibitive operative risk, the best option for strangulated hemorrhoids is expeditious excisional hemorrhoidectomy; in the presence of necrosis, excision is a necessity. Either an open or a closed technique can be used. If tissues are very edematous, or if devitalized tissue is present, one may consider leaving the wounds open to prevent abscess. Postoperative care is as usual after excisional hemorrhoidectomy [91].

Hemorrhoids in Pregnancy

Engorgement of the internal hemorrhoids and edema of the external hemorrhoid are common during pregnancy, possibly related to impaired venous return, constipation, and pressure on the pelvic floor. A single institution prospective study of 94 Dutch women demonstrated a 14.4% prevalence of hemorrhoidal prolapse in the third trimester and a 14.6% prevalence of thrombosis in the postpartum period [92]. Hemorrhoid symptoms almost always resolve after delivery and rarely need urgent intervention. Surgical intervention in pregnancy is reserved for strangulated hemorrhoids, or occasionally a very symptomatic external thrombosis. When necessary, operation should be performed using local anesthesia with the patient positioned in the left lateral decubitus position to avoid compression of the inferior vena cava.

Hemorrhoids, Varices, and Portal Hypertension

Rectal varices and hemorrhoids are distinct and different. Rectal varices in patients with portal hypertension provide collateral circulation for the portal system into the systemic venous circulation. Incidence of hemorrhoid symptoms in patients with portal hypertension is like that of the general population [93]. Although rectal varices are common in patients with portal hypertension, they bleed much less commonly than esophageal varices [94]. In the rare instance of bleeding from rectal varices, portal hypertension should be addressed first, whether it be by medical management of transjugular intrahepatic portosystemic shunt, or by portosystemic shunts, or even by liver transplant. Direct control methods such as sclerotherapy and suture ligation will have a higher rate of success if the portal system is decompressed and should be reserved for instances in which all other options have been exhausted [95, 96].

Hemorrhoids in Crohn's Disease

As many patients with Crohn's disease have loose stools, engorged hemorrhoids may occasionally be seen and require surgical intervention. These are specifically distinguished from Crohn-related perianal skin tags. Patient selection is very important. In the background of rectal inflammation, conservative management is indicated. Older literature describes a high rate of poor wound healing and complications with hemorrhoidectomy in Crohn's disease. Some patients with anorectal Crohn's disease describe a hemorrhoidectomy with poor outcome immediately preceding their inflammatory bowel disease diagnosis. However, in appropriately selected patients who are well controlled medically and have no rectal inflammation or other anorectal disease, a

good outcome can be attained. Wolkomir and Luchtefeld reported healing in 90% of patients who underwent hemorrhoidectomy in the setting of well-controlled ileocolonic Crohn's disease [97]. Karin reported on a group of 13 patients with Crohn's disease without rectal involvement who had symptomatic grade 3 hemorrhoids. All underwent transanal hemorrhoidal dearterialization with good outcomes. At 18 months, ten patients were without hemorrhoid-related symptoms [98].

Hemorrhoids in the Immunocompromised Patient

Anorectal pathology is increasingly seen in immunocompromised patients, including those with medically induced immunosuppression, such as solid organ transplant recipients and patients receiving steroids or chemotherapy, as well as those with disease-induced immunosuppression, including human immunodeficiency virus (HIV). One must recall that this population is heterogeneous. For those in whom the immunocompromise can be expected to resolve, conservative management should be pursued aggressively until immunity is normal or nearly so. For those with an ongoing degree of immunocompromise, medical management should be the primary approach, reserving direct intervention only after medical failure and with careful consideration of the implications of complications in this population [91]. RBL and excisional hemorrhoidectomy have been shown to be safe in HIV-positive patients on highly active antiretroviral therapy with acceptable CD4 counts [99, 100].

Conclusion

In conclusion, hemorrhoidal disease is common and frequently misdiagnosed. Knowledge of associated symptoms along with anorectal and hemorrhoid anatomy is critical in securing the diagnosis and selecting the appropriate treatment (Fig. 11.17). Minimizing straining and improving hydration and fiber intake are the first step for patients with symptomatic hemorrhoids. Most office procedures are best suited for symptomatic grade I–III internal hemorrhoids or thrombosed external hemorrhoids. One's armamentarium should include a variety of techniques for symptomatic hemorrhoids to optimize outcomes and provide individualized therapy. Excisional hemorrhoidectomy continues to provide the most consistent results, while others, possibly less painful surgical interventions, are associated with higher recurrence rates. Complications of hemorrhoid surgery are rare and include urinary retention, bleeding, infection, stenosis, incontinence, and recurrence. Special considerations include pregnant patients, as well as those with Crohn's disease, the immunocompromised, or those with portal hypertension.

Anal Fissure and Anal Stenosis

12

V. Liana Tsikitis and Slawomir Marecik

Key Concepts

- Acute anal fissures (symptoms <6 weeks) are typically treated first with nonoperative, conservative management with high healing rates.
- Calcium channel blockers have similar efficacy rates with topical nitrates and fewer side effects. They are considered first line of treatment for chronic fissures.
- Botulinum toxin injection has slighter higher efficacy in addressing symptomatology than topical therapy, and it is considered second line of treatment for chronic anal fissures.
- Lateral internal sphincterotomy (LIS) has superior healing rates than pharmacologic treatment for chronic anal fissures; however, there is an increased risk for permanent minor incontinence. Open and closed techniques of LIS yield similar healing rates.
- Anocutaneous flaps represent a safe surgical alternative for anal fissures with decreased anal sphincter tone. In addition, advancement flaps can be used in combination with botulinum toxin injection and LIS for expediting primary wound healing.
- Ninety percent of anal stenosis cases are a result of inappropriately performed hemorrhoidectomy.
- Mild anal stenosis can frequently be managed with nonoperative treatment.
- Moderate and severe anal stenosis will require surgical treatment.
- Sphincterotomy, stricturotomy, and stricturectomy should be followed by reconstructive procedures reintroducing the epithelial or mucosal coverage into the anal canal.
- Reconstructive options involve the rectal advancement flap and several flaps utilizing the anoderm and perirectal skin.
- Management of anal stenosis in Crohn's disease should be based on optimization of medical therapy combined with dilations; however, a significant number of patients will require diversion.

Anal Fissure

Definition, Clinical Presentation, and Etiology

An anal fissure is a linear tear of the anal mucosa, usually extending from the dentate line to the anal verge. Even though anal fissures are encountered frequently, there are no population studies that elucidate their exact incidence (Fig. 12.1). The chief complaints from patients with an anal fissure include anal pain and bleeding associated with defecation. Most patients with anal fissures will seek consultation due to the severity of pain and negative impact on quality of life [1].

Anal fissures affect all age groups, and the majority of fissures (90%) occur at the posterior anal midline (90%) [2–4]. The incidence of anterior midline fissures is higher in female patients (10–25%) than male patients (1–8%) [2–4]. The incidence of concomitant anterior and posterior fissures is 3% [4]. Atypical fissures including lateral fissures should raise concern for inflammatory bowel disease, tuberculosis, human immunodeficiency virus (HIV), or syphilis (Fig. 12.2).

Acute anal fissures are thought to be secondary to anoderm trauma due to either constipation with hard stools or frequency from diarrhea. The pain is described as most severe during the act of defecation although it may last several hours following a bowel movement. Although constipation and hard stools are commonly considered the culprit, only 13% of patients with fissuring disease report constipa-

tion [2]. Chronic fissures are persistent, long-lasting fissures that continue for more than 6 weeks. In particular, the persistently high internal sphincter tone leads to chronicity of fissures, and they can cause pain even after a local anesthetic is applied [1]. Chronic fissures may be found at an outpatient clinic examination, although examination and visualization

Fig. 12.3 Acute fissure with clear edges and no signs of chronicity of sphincter hypertrophy. (Courtesy of Richard P. Billingham, MD)

may be difficult due to pain and internal sphincter spasm. Inspection classically reveals indurated edges, visible sphincter muscle at the base, associated hypertrophic papilla proximally, and a sentinel tag distally (Fig. 12.3).

It is speculated that the lack of normal activity of nitric oxide synthase (NOS) is responsible for the chronicity of long-standing fissures. One study aimed to compare the presence of NOS in patients with and without chronic anal fissures. Internal sphincter biopsies were taken from patients with chronic anal fissures at the time of lateral internal sphincterotomy and from patients that were undergoing abdominoperineal resections that acted as the control group. Internal sphincter specimens from patients with chronic fissures contained little or no NOS compared to the internal sphincters from the abdominoperineal resection specimens [5]. In addition, the increased internal sphincter tone associated with anal fissures is thought to cause local ischemia which prevents the fissure from healing. When the topography of the inferior rectal arteries was examined using postmortem angiography, the anoderm is supplied by the inferior rectal arteries after traversing the internal sphincter, and it clearly illustrated that the arterial perfusion is inversely related to the pressure of the internal sphincter [6]. High tonicity of the internal sphincter muscle will lead to lower perfusion of the anal canal, suggesting the fissure represents a nonhealing ischemic ulcer. Likewise, cadaver studies have demonstrated a paucity of arterioles in the posterior midline of the anal canal, also explaining the propensity for the posterior location of fissures [7, 8].

Anal fissures can also occur in women during labor and delivery due to shear forces and local trauma. In fact, 11% of chronic fissures are associated with difficult or instrumented deliveries and are most common in the anterior midline [3]. Interestingly, these chronic fissures are not associated with

increased sphincter tone, but normal or even low pressures. It is important to distinguish the etiology of chronic fissures, so treatment is appropriately tailored [9].

Medical/Pharmaceutical Treatment

Topical Agents

First-line treatment of anal fissures consists of conservative medical treatment including stool softeners, psyllium fiber and other bulking agents, sitz baths, and the application of topical analgesics such as lidocaine gel for pain control. Most studies show healing rates of 16–31% in acute and chronic fissures with conservative management [3]. The application of local lidocaine does not increase fissure healing rates when compared to placebo; however, lidocaine can provide symptomatic pain relief [4, 10]. In addition, maintenance therapy with fiber decreases the risk of fissure recurrence [11].

The goal of medical treatment of anal fissures is to decrease the internal sphincter tone and allow healing. Topical nitrate use leads to healing of chronic anal fissures in about 50% of patients and demonstrates a 13.5% improvement in healing over placebo; however, recurrence rates are high [4]. In particular, close to 50% of the patients who had their fissures healed with nitrates will experience a recurrence. Commonly used topical nitrates include isosorbide dinitrate and glyceryl trinitrate. However, these nitrates are rarely used today due to their unpleasant side effects, primarily headaches [3, 4].

Application of topical calcium channel blockers including nifedipine and diltiazem has been associated with healing close to 90% of chronic anal fissures [12]. In addition, a double-blinded, multicenter, randomized trial comparing the application of nifedipine (treatment group) to hydrocortisone and lidocaine (control group) found that the nifedipine treatment healed acute fissures within 21 days in 95% of patients compared to 50% in the control group [13]. In this study, anal manometry confirmed that nifedipine decreased the resting anal pressure by 30% compared to the control group [13]. Data suggest that the cure rate of anal fissures is higher with three times' daily application of calcium channel blockers and with a 3-month treatment duration [14].

Botulinum Toxin Injection

When conservative management with topical ointment fails, a second-line treatment still under the medical management umbrella is the injection of botulinum toxin (Botox). Interestingly, Botox injection has better results when used as a second-line treatment [3, 15]. Treatment with Botox has healing rates ranging from 27% to 96% [3]. The most common side effect related to Botox injection is temporary incontinence, particularly to flatus, that can occur in up to 18% of patients [3]. Multiple dosages (ranging from 20 to 100 international units (IU) or more) have been described, and varied injection sites have been proposed [3, 4]. One advantage of Botox injection over topical nitrates and calcium channel blockers is that it does not require a frequent application schedule and does not cause similar unpleasant side effects [4, 16]. However, its efficacy is questionable with one meta-analysis showing that Botox injection had no significant advantage over nitrate topical application or placebo [10]. Another meta-analysis comparing Botox to sphincterotomy reported that Botox has lower healing rates but also lower rates of incontinence [17].

A Cochrane review of 77 studies and 5031 participants showed that nitrates are marginally more efficacious than placebo (48% healed versus 35%) in healing fissures [18]. Botulinum toxin injections and calcium channel blockers were equivalent to nitrates in efficacy but had fewer side effects [18]. No arms of medical therapy compared favorably to surgical treatment; however, they all carry a lower risk of permanent incontinence [10, 18].

Operative Treatment

Anal dilation is possibly the oldest treatment for anal fissures and is only mentioned here for historic purposes. There is substantial variance in the surgical technique with a wide range of outcomes. A 2011 Cochrane review examining seven randomized controlled trials comparing anal dilation to sphincterotomy reported that anal dilation was less effective and resulted in higher rates of incontinence (OR: 4.03, 95% CI: 2.04–7.46) [19]. More recently pneumatic balloon dilation has been described for anal fissure therapy. In one study, a 40-mm-diameter and 60-mm-long anal balloon was inserted into the anal canal after adequate lubrication and was positioned with 10 mm protruding from the anus. The balloon was rapidly inflated to a 20 psi pressure (1.4 atm) and maintained in situ for 6 min. The balloon was then deflated and removed. The fissure-healing rates were 83.3 percent in the pneumatic balloon dilatation and 92 percent in the lateral internal sphincterotomy group. At anal manometry, mean resting pressure decrements obtained after pneumatic balloon dilatation and lateral internal sphincterotomy were 30.5 and 34.3 percent, respectively. At 24-month follow-up, the incidence of incontinence, irrespective of severity, was 0 percent in the pneumatic balloon dilatation group and 16 percent in the lateral internal sphincterotomy group ($P < 0.0001$) [20].

Lateral Internal Sphincterotomy (LIS)

Lateral internal sphincterotomy (LIS) is considered the gold standard for treatment of chronic anal fissures with multiple randomized studies showing its superior effectiveness in

treating the symptomatology when compared to conservative medical management [21–32]. LIS has healing rates of 88–100%, but it can be associated with incontinence rates of 8–30% [4]. This incontinence can be transient (less than 2 months) or prolonged (over 2 months) in 3–7% of patients [3]. However, these incontinence rates are reported with traditional LIS, when the sphincterotomy is carried up to the dentate line. Such a traditional sphincterotomy has a lower rate of recurrence and a higher risk of permanent incontinence when compared to the "tailored" sphincterotomy [33], which is defined as a sphincterotomy to the apex of the fissure. The "tailored" sphincterotomy has been shown to preserve more of the sphincter and lowers incontinence rates [19, 34]. Older randomized trials comparing traditional and tailored sphincterotomy showed statistically higher healing rates with the traditional technique, with relatively similar reported incidences of minor incontinence (<3% incontinence rate) [35, 36]. Accordingly, the tailored sphincterotomy is as the preferred surgical approach which provides symptom relief and decreased risk of permanent incontinence. LIS may be considered as first-line surgical treatment in patients without prior obstetrical injury, inflammatory bowel disease, prior anorectal operations, or sphincter weakness [4]. In particular, patients with chronic anal fissures and without underlying fecal incontinence may benefit from LIS as the first line of treatment.

Technique

LIS is performed with either an open or closed technique. In the open technique, an incision is made distal to the dentate line exposing the intersphincteric groove. The surgeon then elevates and divides the internal sphincter muscle to the height of the fissure and closes the wound with an absorbable stitch. In the closed technique, the intersphincteric groove is not exposed but delineated. A narrow-bladed scalpel, flat side adjacent to the muscle, is introduced through the skin in either right- or left-lateral position of the intersphincteric groove, and the tip is advanced submucosally to the dentate line. The sharp edge of the knife is turned toward the internal sphincter muscle, and the muscle is divided, releasing the tension and creating a palpable defect. The skin opening can be left open or closed with a chromic stitch. In a recent Cochrane review comparing the open and closed techniques, no difference in outcomes including persistence of the fissure or fecal incontinence was demonstrated between the two techniques (Figs. 12.4 and 12.5) [19].

Outcomes

Reported recurrence rates range from 0% to 15% after LIS, which are usually attributed to insufficient length of the division of the internal sphincter muscle [3]. LIS can be repeated and offered as a treatment of recurrent fissures and performed on the contralateral side of a prior sphincterotomy site [4]. There is a paucity of data regarding recurrent fissures after LIS. A recent study including 57 patients evaluated repeated LIS for recurrent fissures with a mean follow-up of 12.5 ± 4.2 years. They reported a 98% healing rate and a 4% minor incontinence rate including incontinence to flatus and seepage. The authors used the modified Cleveland Clinic Incontinence Questionnaire to report patients' symptoms, and 2 female patients out of 57 reported varied incontinence to flatus and seepage [37]. Overall, one should consider LIS as the standard surgical treatment for chronic anal fissures with increased sphincter tone when medical management has failed.

Local Advancement Flaps

Local advancement flaps are the first line of surgical treatment for chronic anal fissures associated with normal or low anal pressures. These patients are usually female patients that have developed fissures after a prolonged and difficult vaginal delivery. These flaps are usually anocutaneous flaps (dermal V-Y or house flap) which have been described using a variety of techniques (see below in the "Anal Stenosis" segment). Giordano et al. demonstrated a 98% healing rate after anorectal advancement flap surgery independent of anal tonicity [38]. At a 6-month follow-up, there was no reported fissure recurrence or fecal incontinence [38]. Interestingly, the authors reported a 6% rate of fissure formation at a new site [38]. A smaller study showed similar successful results after local advancement flap surgery for fissures in the setting of hypotonicity with a median follow-up of 7 months [39].

Anocutaneous flaps have been combined with sphincterotomy or Botox injection to simultaneously address the chronic nonhealing wound and the underlying sphincter hypertonicity [4]. One randomized study allocated 50 patients to receive LIS, 50 patients to receive V-Y advancement flap, and 50 patients to receive a combination of LIS and V-Y flap (see diagram in "Anal Stenosis" segment). At the 1-year follow-up, healing rates for patients who received LIS, V-Y advancement flap, and a combination of LIS and V-Y flap were 84%, 48%, and 94% ($p = 0.001$), and recurrence rates were 4%, 22%, and 2% ($p = 0.01$), respectively [40].

Fissurotomy and Fissurectomy

Fissurotomy and fissurectomy are not considered standard treatment options for anal fissure. Chronic fissures frequently present with subcutaneous tracts that extend distally from the chronic fissure to the sentinel tag. Fissurotomy involves incising and dividing that tract to expose the chronic underlying cavity and release the perianal skin, resulting in widening of the anal canal. The wound remains open to heal by secondary intention. One prospective trial of 109 patients undergoing fissurotomy had resolution of symptoms in 98% of patients, with the other 2% requiring subsequent sphinc-

terotomy [41]. In contrast, fissurectomy is defined as the excision of the chronic fissure wound with excision of the sentinel pile, if present. In a recent Cochrane review on operative procedures for fissure in ano, the authors commented on two studies which compared fissurectomy with sphincterotomy [19]. These studies comprised of total of 162 patients and found that sphincterotomy was significantly less likely to result in treatment failure compared to fissurectomy (OR 8.07 [1.42–45.84]). One of the two studies concluded that fissurectomy is not a procedure of choice because of its asso-

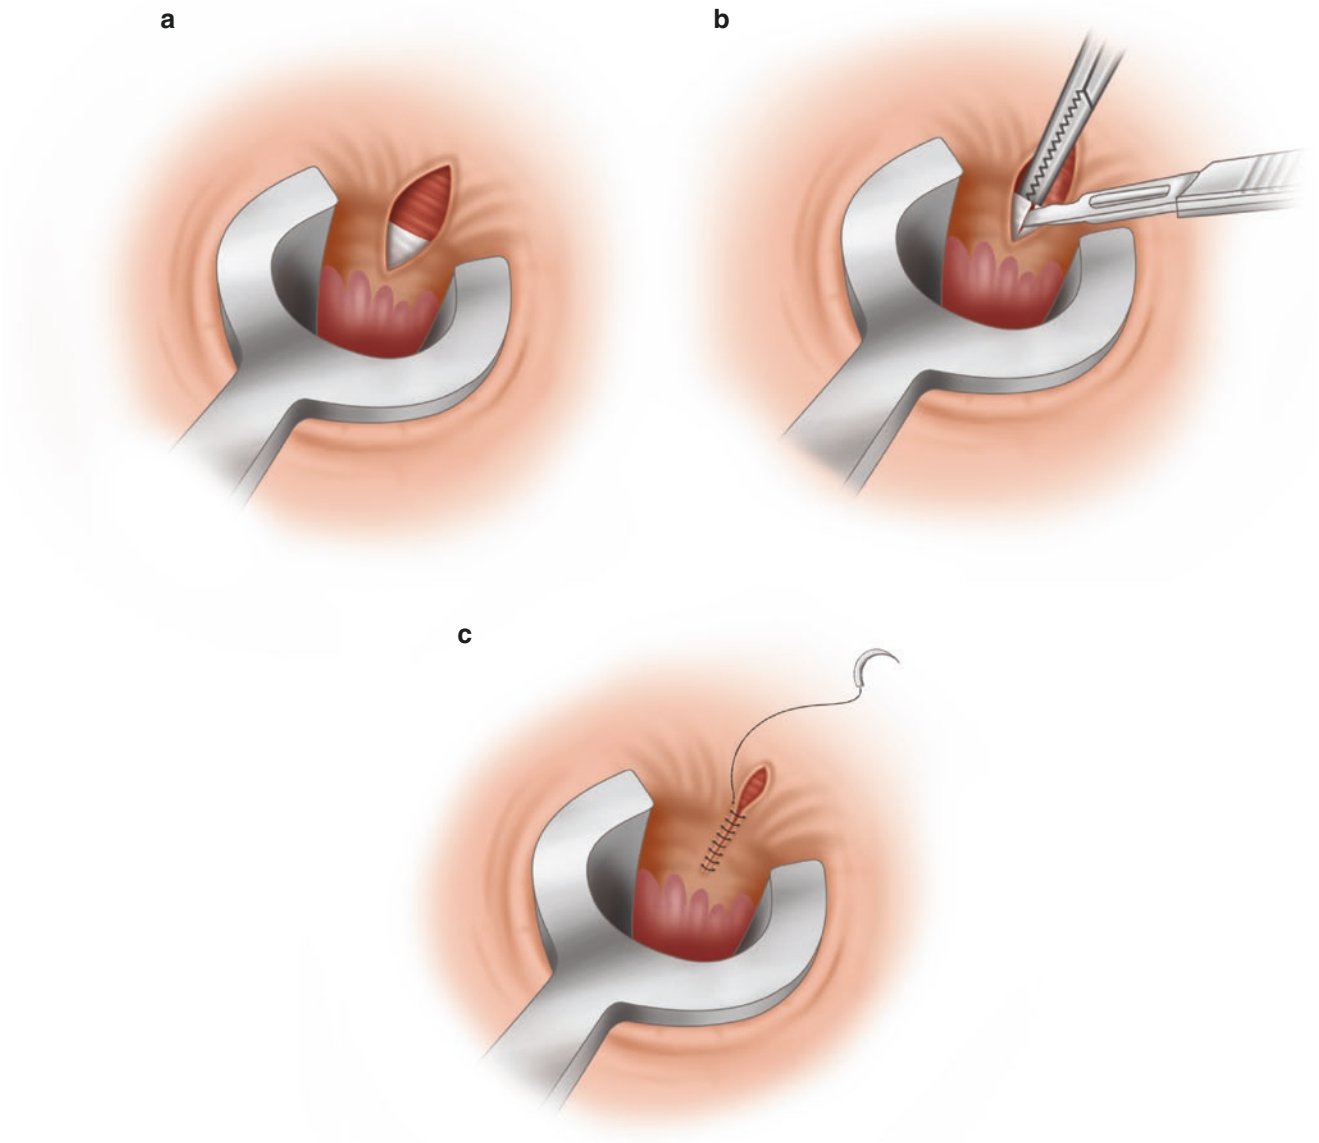

Fig. 12.5 Open lateral internal sphincterotomy. (**a**). Radial skin incision distal to the dentate line exposing the intersphincteric groove. (**b**). Elevation and division of the internal sphincter. (**c**). Primary wound closure

ciated recurrence risk (3%) and the high rate of incontinence (6%) [42]. Another study reported that fissurectomy, in combination with isosorbide dinitrate cream, resulted in 100% healing within 10 weeks without recurrence and without incontinence complaints [43]. A third study showed that fissurectomy with concurrent Botox injection led to 100% improvement of symptoms with objective wound healing in 93% of patients [44].

Atypical Fissures

Atypical fissures are most commonly seen in patients with Crohn's disease and patients with sexually transmitted diseases. Fissures in Crohn's patients usually present as deep, painful ulcerations and are treated with Crohn's medical therapies. Crohn's fissures are rarely treated surgically because of perceived poor wound healing that may lead to significant perianal deformity and potentially to incontinence. Multidisciplinary care is instrumental in addressing anorectal Crohn's pathology, and optimal medical management may lead to resolution in more than half of the cases [45, 46]. Treatment of atypical fissures associated with sexually transmitted diseases is dictated by identifying the causative organism after a biopsy of the fissure. HIV-related fissures are the most commonly encountered and may present either as deep, broad-based ulcers or as typical appearing fissures. These fissures are not associated

with internal sphincter hypertonicity. Short-term successful treatment options include surgical debridement and intralesional steroid injection; however, in the long term, optimizing antiretroviral therapy is instrumental for improving symptomatology [47].

Anal Fissure, Conclusion

Anal fissures are common and can be effectively treated with conservative medical management. When fissure symptomatology is long-standing (more than 6 weeks), topical calcium channel blockers in combination with sitz baths and the use of psyllium fiber or other bulking agents are the first lines of treatment. Botulinum toxin injection can be added when medical management fails to provide a resolution of symptoms. LIS is considered the standard surgical treatment for chronic anal fissures with a hypertonic internal sphincter and can be considered first-line treatment for patients that have no underlying fecal incontinence. Advancement flaps remain an option for patients with symptomatic chronic anal fissures with associated hypotonicity and/or compromised continence.

Anal Stenosis

Introduction, Definition, and Types

Anal stenosis is an uncommon but potentially serious condition characterized by abnormal narrowing of the anorectal junction, anal canal, or the anal margin. It occurs when the physiologic capacity of the anal canal is lost and the pliable tissues are replaced with fibrotic connective tissue [48]. This leads to an abnormally tight and inelastic anal canal and can also involve the internal anal sphincter [49]. Anal stenosis commonly results from the loss of anodermal coverage distal to the dentate line and less frequently can occur in the proximal anal canal [50].

Anal stenosis can be classified as congenital, primary, or secondary [51]. Congenital stenosis is related to developmental abnormalities, which are frequently associated with imperforate anus, anal atresia, or Hirschsprung disease. Conversely, primary stenosis occurs later in life and is related to rare involutional (senile) changes. Lastly, secondary anal stenosis is the most common presentation. Historically, it has been connected to an improperly performed surgical hemorrhoidectomy, in particular a now almost abandoned technique proposed by Whitehead [52]. Anal stenosis can also, however, be encountered after any anorectal procedure or disease process resulting in repetitive trauma or excessive destruction of anoderm and hemorrhoidal tissue.

Incidence and Causes

Post-hemorrhoidectomy (secondary) anal stenosis or stricture is present in 1.5–4% of cases with some recent reports quoting even higher incidence of 19% [53–55]. Hemorrhoidectomy accounts for approximately 90% of all anal stenosis cases [41, 42]. One of the more common scenarios occurs during excessive removal of acute, swollen, and partially necrotic grade IV hemorrhoids while failing to preserve adequate anoderm. Secondary anal stenosis following a pull-through procedure can occur in up to 16% of cases and occurs most often following mucosectomy and/or anastomotic dehiscence [56, 57]. Pull-through procedures or sagittal anorectoplasties performed on children in order to treat congenital anal stenosis can lead to secondary anastomotic anal stenosis [58, 59]. Stapling procedures for hemorrhoids (PPH) have also been associated with scarring and stenosis in the area of the anorectal junction [60]. Finally, Crohn's disease can lead to stricture formation at many levels [61, 62], often with transmural disease frequently involving the internal sphincter. Stricture at the anorectal junction occurs when deep fissures of the rectal mucosa converge at the anorectal ring. More distal strictures of the anal canal are related to fissuring and fistulizing disease involving the anus and perianal region or simply from chronic inflammation caused by chronic diarrhea. The potential causes of anal stenosis are summarized in Table 12.1.

Symptoms

Symptoms of anal stenosis include difficult, painful, or incomplete evacuation, fecal impaction, constipation, decrease in stool caliber, tenesmus, bleeding, overflow diarrhea, fecal seepage, and incontinence.

Evaluation

Initial diagnosis of anal stenosis can frequently be made in the office during physical examination, although anatomic findings may not directly correlate with the severity of patient symptoms. Findings can reveal narrowing of the anal opening with common circumferential fissure formation [51]. However, the true extent and severity of the stenosis often has to be investigated and identified with the patient under anesthesia to avoid unnecessary pain or discomfort. An exam under anesthesia will also enable the physician to differentiate between the anatomical and functional cause of the stenosis and allow for biopsy of any suspicious lesions [63]. Relaxation of the anus during anesthesia is characteristic for functional stenosis, while the persistence of stricture points to anatomical stenosis caused by the scarring of the anoderm and potentially the underlying internal sphincter. A thorough

Table 12.2 Classification of anal stenosis

Severity	Location	Extent
Mild: Exam can be completed with a finger or medium Hill-Ferguson retractor	*Low:* At least 0.5 cm distal to the dentate line	*Localized*: One level or quadrant of the anal canal
Moderate: Dilation needed to examine with a finger or medium Hill-Ferguson retractor	*Mid*: Within 0.5 cm distal and proximal to the dentate line	*Diffuse*: More than one level or quadrant
Severe: Unable to examine with little finger or small Hill-Ferguson retractor, unless forcefully dilated	*High*: At least 0.5 cm proximal to the dentate line	*Circumferential*: Entire circumference

evaluation of the anorectum will allow for determination of the degree, extent, and level of the stricture, circumferential distribution of fibrosis, and any sphincter involvement.

Classification

Based on the above findings, the severity of stricture can be classified and appropriate treatment chosen. The most commonly used Milsom and Mazier classification is presented in Table 12.2 [50]. This classification divides the stenosis into mild, moderate, and severe and low (65% of patients), mid-level (18.5% of patients), and high (8.5% of patients). In addition, stenosis can be "diaphragmatic" (after inflammatory bowel disease, characterized by a thin strip of constrictor tissue), "ringlike" (annular, lesions <2 cm), or "tubular" (length > 2 cm).

Treatment

The treatment of anal stenosis is based on patient symptoms and varies depending on the severity, location, and cause of the stenosis. Inflammatory and infectious etiology should always be treated with appropriate medical therapy first.

Nonoperative Treatment

This option is typically used for patients with mild and occasionally moderate stenosis (as an initial step) and is based on dietary modifications, stool softeners, and "bulking therapy" with dietary fiber supplementation [49]. Assuring that the stool is soft enough to pass through the stenosis, it allows for the natural, repetitive stretch of the anal canal by a fecal bolus. At a minimum, this can prevent further stricture formation. In many cases, this therapy is successful and can lead to effective widening of the anal canal lumen [64].

If the bulking therapy is not successful, or the patient experiences a significant amount of pain during elimination, digital or mechanical dilation can be performed [51]. This can be attempted in the office with the use of local anesthetic gel and a set of Hegar dilators, followed by at-home dilations. Alternatively, the patient can undergo the first dilation under anesthesia (with digital, Hegar, or pneumatic technique), followed by regular gradual dilations at home. A set of metal or plastic dilators can be acquired for between $15 and $100. Historically, candles or other similarly shaped household objects have also been used.

Any dilation under anesthesia should be performed carefully and follow two main principles. The first is to allow for only minimal trauma to the already strictured anoderm and to avoid creation of deep fissures. The second principle requires no disruption of the underlying internal sphincter muscle. If the dilation procedure cannot meet the above principles, it should be avoided, and the patient should be advised of other corrective techniques described later in the text.

Aggressive dilation with deep fissure creation and trauma to the internal sphincter will likely lead to a brief improvement in symptoms. However, in the long term, it will also lead to worsening of the anoderm and sphincter fibrosis [51]. Dilations can be successfully performed in patients with Crohn's disease, postradiation stenosis, or anastomotic strictures [49]. They are routinely used following pull-through procedures for Hirschsprung's disease in children [65]. It is important to identify any anastomotic strictures as early as

possible. In fact, it is the author's routine practice to check for them during the rectal exam within the first 2 weeks after surgery. Early recognition of not-yet fibrotic strictures allows for early, frequent digital dilations in the office or home, thereby avoiding the need for forceful mechanical dilation later.

Dilations of chronic and fibrotic strictures require compliant and highly motivated patients. Approximately half of patients with anal Crohn's stenosis will respond to medical therapy and dilations, while the other half will require proctectomy or proximal diversion [66, 67]. Dilations are more effective for shorter strictures. Pain related to dilations is a major factor that can limit the effectiveness of the therapy. Sphincter damage leading to fecal incontinence is a major concern after repeated dilations [68]. If the stenosis is refractory to safe dilations, other surgical options should be considered.

Anal stenosis is often associated with anal fissure disease, which can be a result of or cause for the stenosis. For this reason, it is important to first address the fissure, as described earlier in this chapter. Lastly, it is important to note that because many patients initially present relying on laxatives, enemas, suppositories, and even manual disimpaction maneuvers, this can lead to additional trauma of the already stenotic anal canal in the long term [51, 68].

Surgical Treatment

Operative treatment is reserved for severe and persistent moderate anal stenosis, as well as for rare refractory cases of mild symptomatic stenosis [49–51, 54, 63, 68]. Sphincter function evaluation with anorectal manometry and pudendal nerve motor latency can also be attempted before the surgical correction if indicated; however, it will not likely change the course of treatment and may be either painful or difficult to perform. Endoanal ultrasound is not typically an option.

All corrective cases are performed under general anesthesia or under sedation with local anesthesia allowing for sufficient retraction and exposure of the anal area. The main challenge is to provide the initial access to the strictured anal canal, which will frequently require using a small-size Hill-Ferguson retractor. Often, a gentle pneumatic or Hegar dilation is necessary to open the lumen. Any suspicious areas should be biopsied to rule out malignancy since chronic wounds have a higher propensity for malignant transformation. The extent and radial distribution of the scar should also be ascertained since further treatment will be determined by these findings [50]. The internal sphincter involvement, and its fibrosis, is evaluated for possible functional stenosis, which may require lateral internal sphincterotomy [51]. Any fibrotic stenosis of the internal sphincter muscle should be addressed by concomitant sphincterotomy (unilateral or bilateral) to improve chances of successful outcome [63].

The Lone-Star retractor is frequently used to bring the anus into the effective operating field. Release or excision of the scar tissue enables further access into the anal canal.

Reconstruction of the anodermal defect can then be performed with a fragment of a healthy rectal wall (commonly referred to as rectal mucosa), anoderm of the anal verge, or the perianal and gluteal skin including the underlying subcutaneous tissues.

Transverse Closure Following Excision of Scar (With Possible Sphincterotomy)

For short strictures involving the internal sphincter, an incision or excision of the scar with internal sphincterotomy can be attempted. This will create a diamond-shape defect. Transverse closure of this wound can then be attempted, as long as there is no excessive tension on the tissues [69]. Absorbable and long-lasting 2-0 and 3-0 sutures should be used (e.g., Vicryl). If there is too much tension on the edges of the defect, the patient should be considered for a Y-V advancement flap (see below) [69]. Simple stricture release without any reconstruction attempt can lead to temporary improvement in symptoms but will likely result in stricture recurrence [49].

Rectal Advancement Flap

Advancement of the healthy rectal tissue is primarily reserved for proximal and mid-anal canal stenosis [70–72]. It is performed as a modification of Martin's anoplasty following the incision or excision of the scar and optional concomitant internal sphincterotomy (preferably in the lateral position) [73]. In the literature, this is described as "rectal mucosal flap"; however, this term is a misnomer. The flap is often not created, but rather the rectal wall is stretched to cover the defect. And if the flap is created, to prevent ischemia of the flap, the dissection should also involve the deeper tissues, including one or both layers of the muscularis propria of the rectum (potentially including some fragments of the distal internal sphincter) or even a thin layer of the mesorectal tissue, which can fill in the sphincterotomy defect. One of the important stipulations of this technique is to advance the flap only to the level of the intersphincteric groove, thus preventing mucosal ectropion creation. A potential defect distal to the intersphincteric groove is usually left open for secondary healing. Rahkmanine reported very good results with this technique [74] (Fig. 12.6).

Y-V Advancement Flap

This procedure, as with the techniques described below, is used for mid- and distal anal stenosis [48, 75–77]. It involves the advancement of the anoderm or the perianal skin into the anal canal. After gentle dilation of the anus, a small- or medium-size Hill-Ferguson retractor is used for the expo-

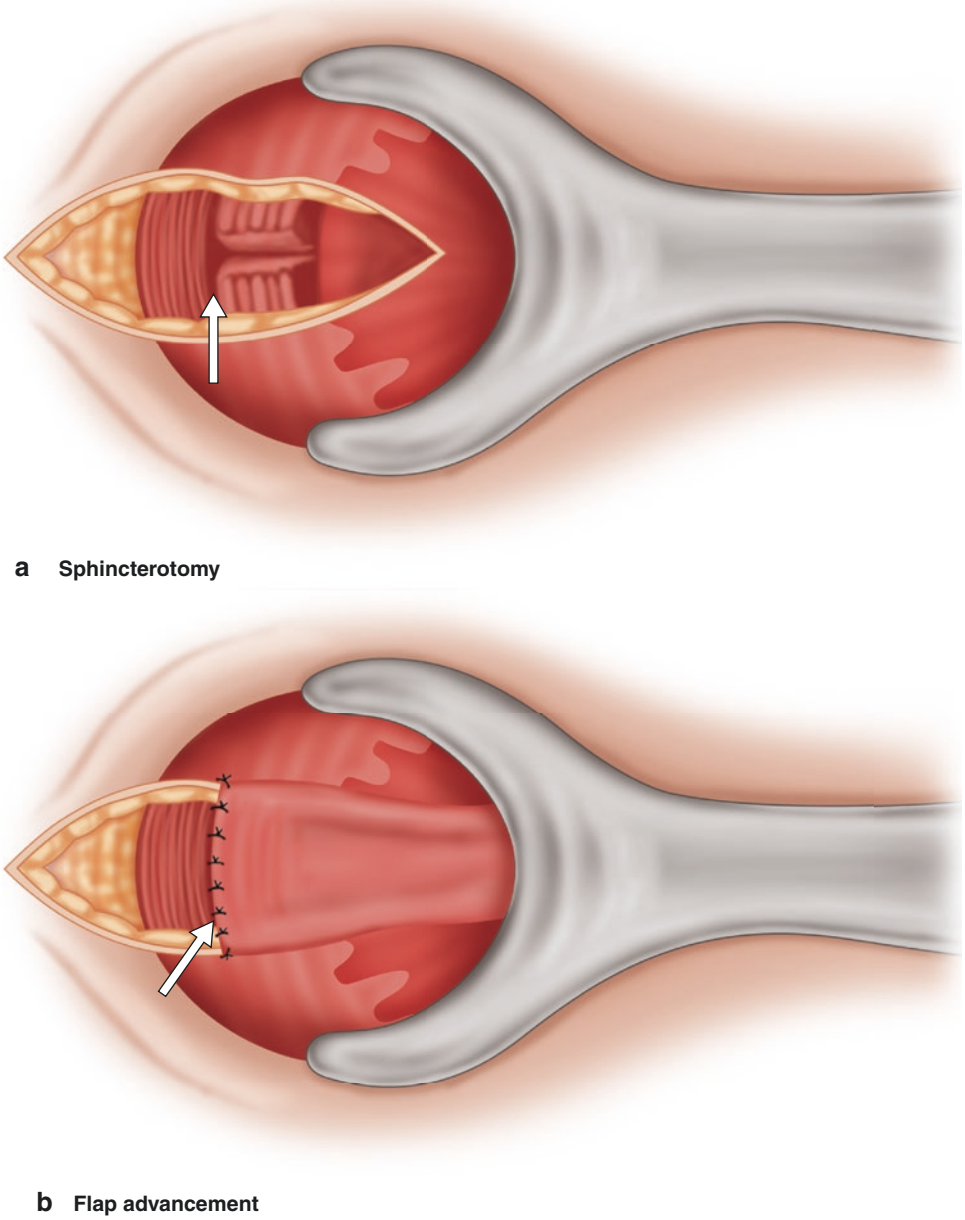

Fig. 12.6 Rectal advancement flap

sure. The scar is longitudinally incised or removed, and concomitant internal sphincterotomy can then be performed. The vertical limb incision of the Y is extended proximally, beyond the stenosed area, into the anal canal. Subsequently, two incisions constituting the oblique limbs of the Y are created, starting at the distal end of the defect and extending into the anal margin, for a total length of at least 5 cm. The created V flap should include the underlying subdermal tissue. In thinner patients, it can also include the subcutaneous layer of the external sphincter muscle in order to provide adequate blood supply and mobility. The flap is then stretched proximally into the anal canal. The tip of the V flap is anchored to the internal sphincter and the anal canal mucosa at the proximal end of the defect. The edges of the flap are sutured to the corresponding edges of the defect. Long-lasting absorbable sutures are used. The V-Y flap can be used to cover no more than 25% of the anal circumference and can be performed bilaterally (similar to most advancement flaps). It should be noted that the tip of the flap is prone to ischemia. Healing rate between 64% and 100% has been reported (Fig. 12.7) [75–78].

V-Y Advancement Flap

This technique involves the creation of a triangular island flap using the skin, anoderm, and subdermal tissue, with the proximal base of the flap directly adjacent to the defect from the scar excision (and potentially the sphincterotomy) [50]. The foundation can also involve the subcutaneous layer of

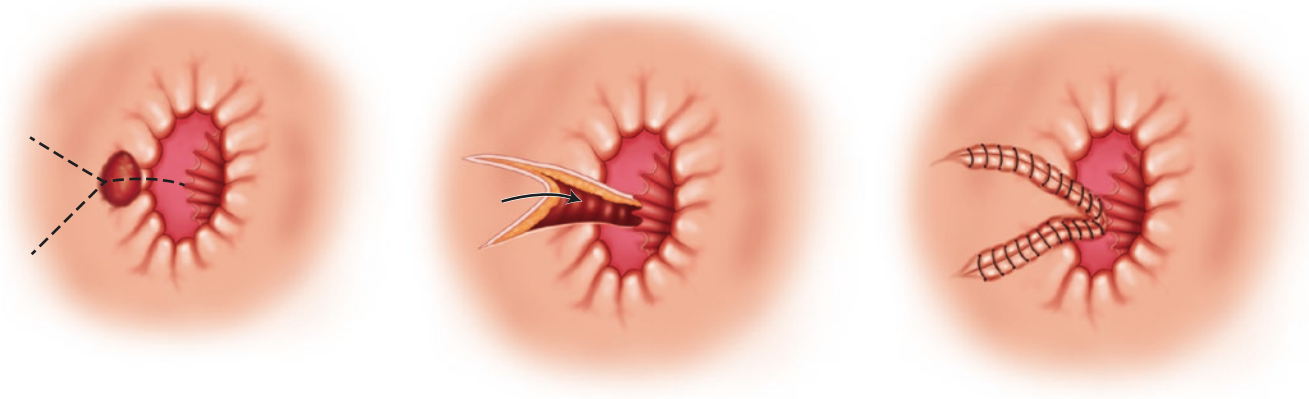

Fig. 12.7 Y-V advancement flap

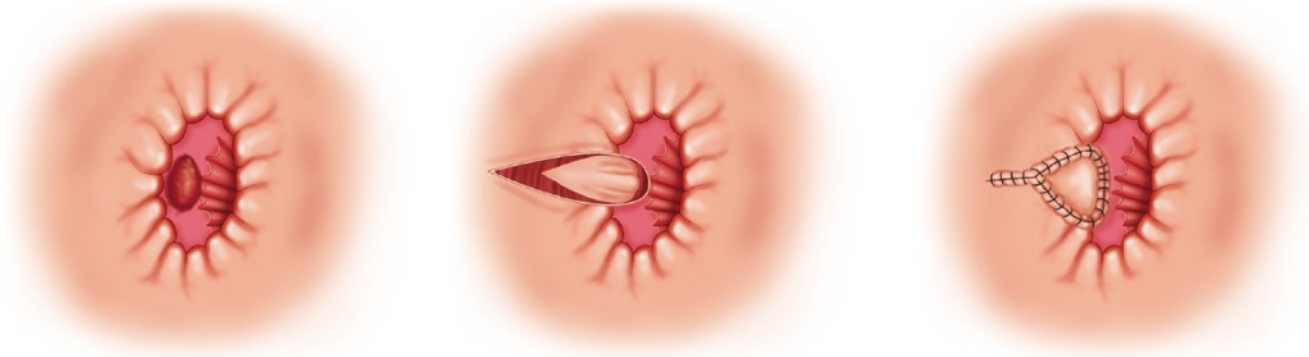

Fig. 12.8 V-Y advancement flap

the external sphincter [79]. The tethering of the flap is only dependent upon its deeper layers, while all edges are free. The flap is then advanced into the resulting defect and sutured circumferentially, while the donor site is closed. This effectively pushes the flap into the anal canal. This technique was initially developed as the treatment for anal ectropion but later became an option in treating anal stenosis (Fig. 12.8) [80].

Diamond (Rhomboid) Flap

This technique, described by Caplin and Kodner, involves advancement of the rhomboid skin and subcutaneous flap into the defect formed by stricturotomy in the distal anal canal [81]. It can also include the fibers of the subcutaneous layer of the external sphincter to increase its thickness and reach. The flap is moved into the defect, while attached by its deeper layers which provide the vascular supply. It is then sutured circumferentially to the surrounding tissues. The donor site defect is closed, effectively pushing the flap into the anal canal. Excellent healing rates after diamond anoplasty have been reported (Fig. 12.9) [76, 78, 81].

House Flap

This technique was first described by Christensen et al. [82]. The house flap anoplasty involves proximal advancement of the perianal skin into the area of the stricturotomy, located distally to the dentate line. The concept is similar to the V-Y flap or diamond flap techniques; however, the formation of a wider flap allows for more effective treatment of the stenosis. In order to accomplish this, the initial longitudinal incision through the stenosed area is supplemented by two transverse incisions of equal length at both ends, centered on the longitudinal incision. This may also involve the internal sphincter. Alternatively, the scar can be excised in the form of a square. Subsequently, a house-shape flap is created using the adjacent skin and subcutaneous tissue. Occasionally this can include the subcutaneous layer of the external sphincter for better vascularity and further reach. The base of the (house) flap equals the length of the transverse incisions, and the height of the house walls equals the length of the defect. The flap is moved into the defect, while only tethered by its deeper layers, which provide the vascular supply. It is then sutured circumferentially to the surrounding tissues while the donor site defect is closed, thus effectively pushing the

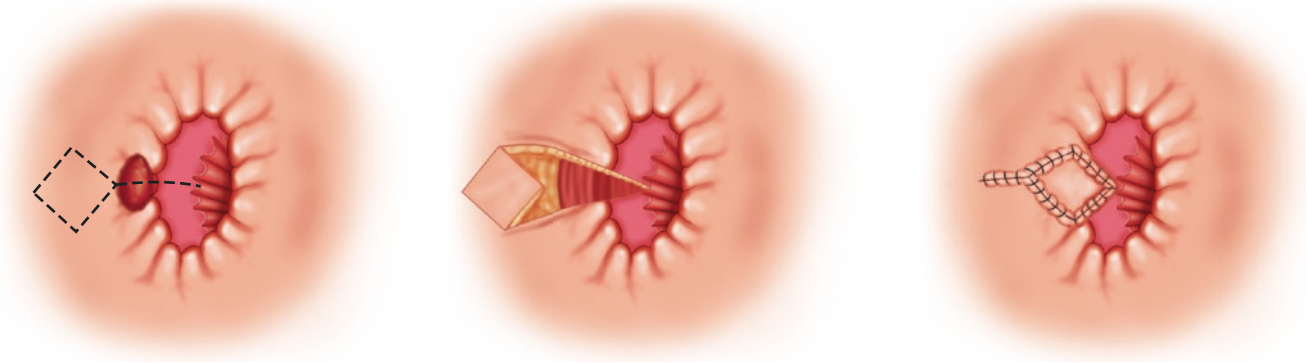

Fig. 12.9 Diamond (rhomboid) flap

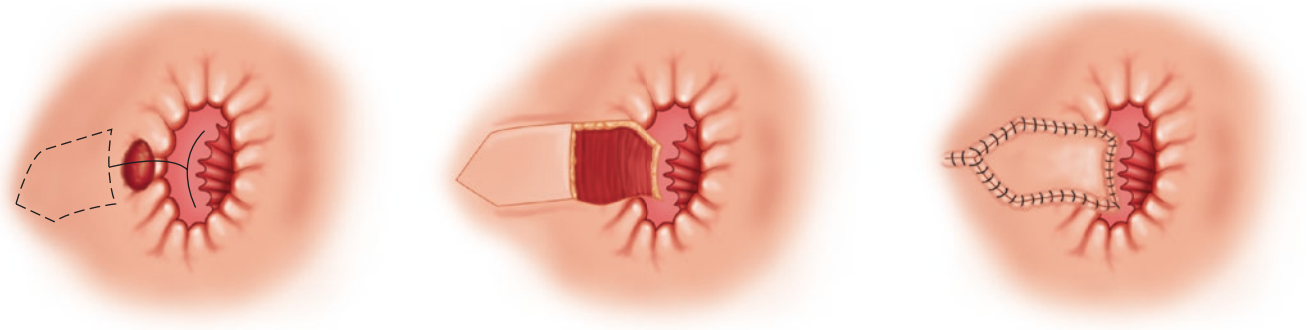

Fig. 12.10 House flap

flap into the anal canal. Clinical improvement or healing of the stenosis was reported in more than 90% of patients (Fig. 12.10) [83–85].

U Flap (Island Flap Anoplasty)

This technique was developed by Pearl et al. and can also be used in the treatment of ectropion as well as distal fistula in ano [86]. The U flap provides a wide-base island flap that can cover a large area of anodermal defect, similar to the previously described techniques. The important difference, however, is that the donor site in this technique is not closed but is left open for secondary healing. Initially, wet to dry gauze application is required to allow the area to granulate. Dry gauze can then be used to allow the wound to epithelialize. Of 25 patients treated with this flaps (20 for anal stenosis and 5 for mucosal ectropion), 16 reported excellent and 7 reported good results [86].

Rotational S Flap

This technique is used most often to cover larger defects resulting from the excision of perianal Paget's or Bowen's disease. The rotational S flap (S-plasty) can also be used to effectively move a significant amount of perianal skin into the anus in order to cover a large defect after circumferential excision of the stenotic scar in the distal anal canal. In this technique, two full-thickness, well-vascularized cutaneous flaps with an appropriate amount of underlying subcutaneous tissue (sometimes as fascio-cutaneous flaps) are created by the S-shape incision and centered around the anal opening. The flaps are subsequently advanced, rotated into the distal anus along the incision, and sutured to the non-strictured rectal mucosa, as well as to the corresponding edges of the defect (Fig. 12.11) [87, 88].

Technical Aspects

Reconstructive flap procedures are performed after mechanical bowel preparation. A complete bowel preparation may be difficult to accomplish in patients with anal stenosis. Frequently, a prolonged 1–2-day bowel preparation is required in addition to a roughage-free diet for several days prior to the procedure. If the patient is found to have a large amount of liquid stool in the colon immediately before the procedure, an ad hoc colonoscopic washout and aspiration can be performed.

The mechanical bowel preparation can be supplemented with oral antibiotic administration. This is in line with current recommendations for proctectomy cases, since the anas-

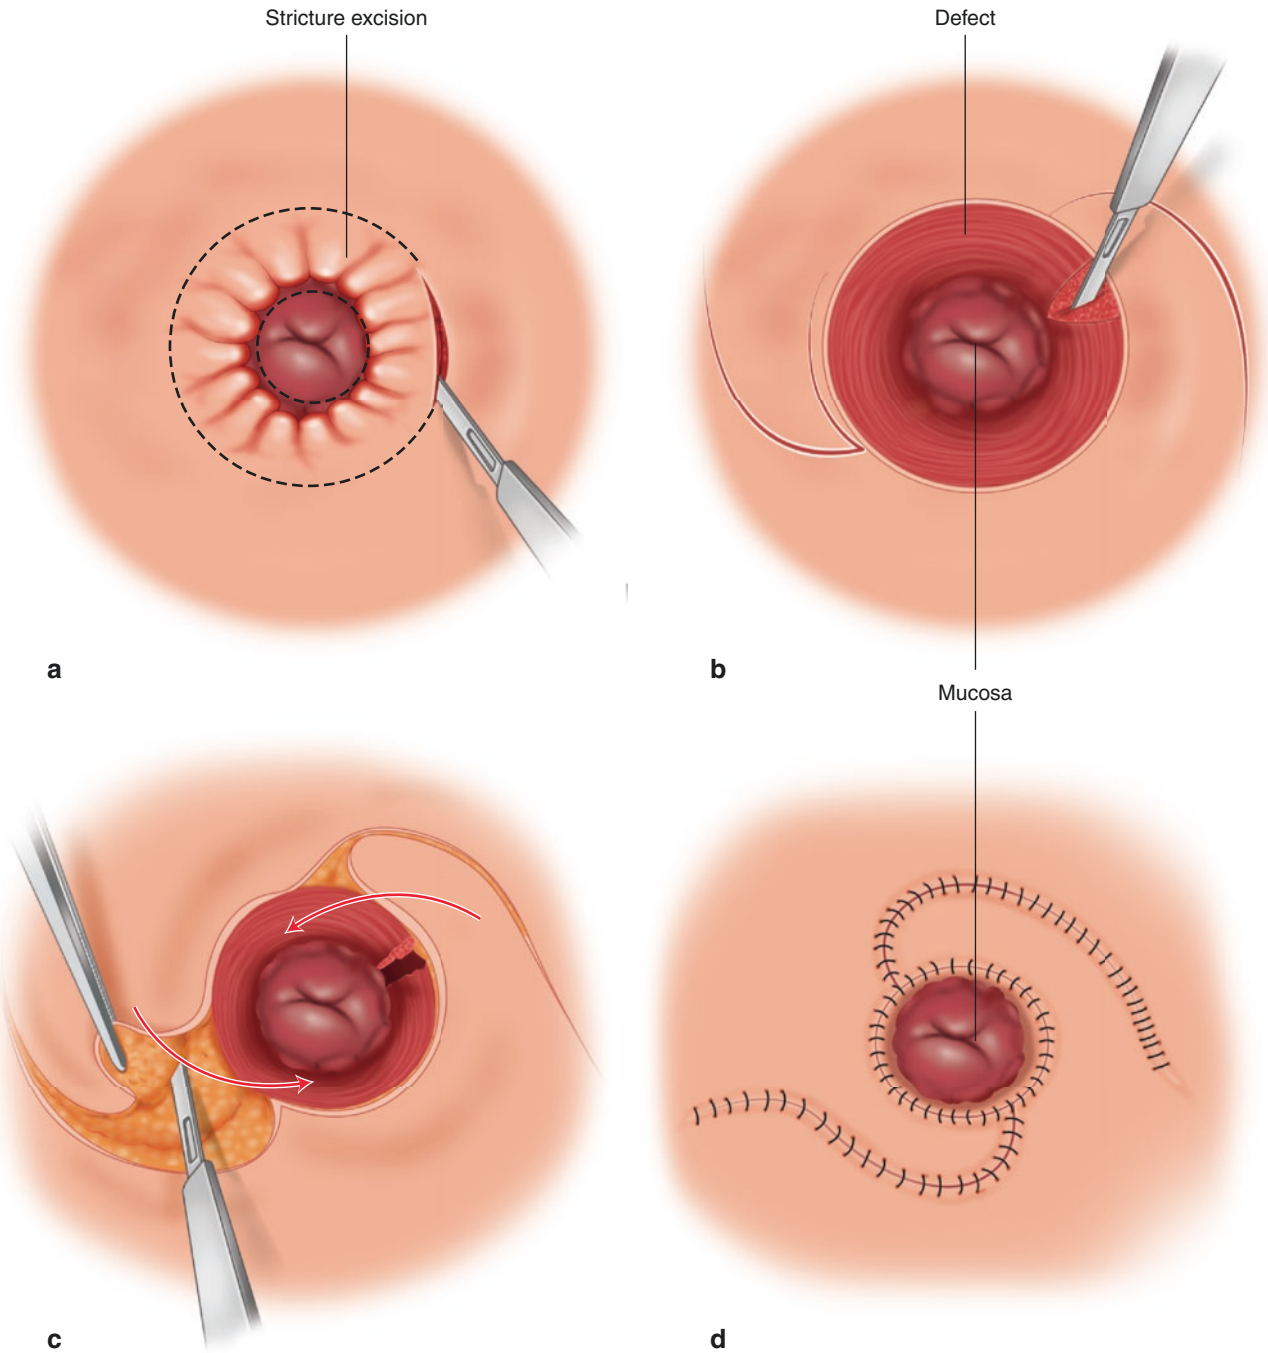

Fig. 12.11 Rotational flap (**a**) scar excision, (**b**) internal sphincterotomy, (**c**) flap creation, (**d**) flap fixation in place

tomosis (suture line) is created in the flap cases. Perioperative antibiotics are given. In cases with large amount of contamination, a low-concentration chlorhexidine solution jet irrigation can be used (Irrisept®). The choice of post procedure antibiotics (IV, oral, or none) is dependent upon the complexity of the case, bowel preparation, and surgeon preference.

Most of the flap procedures are performed with the patient in the prone jackknife position, with the exception of posterior rectal advancement flaps. The buttocks are initially taped apart and the Lone-Star retractor can be useful. Low wattage cautery and sharp knife dissection are used.

In the current era of effective hemostasis, hemostatic epinephrine solution injection is primarily reserved for cases of stubborn bleeding from the scar tissue. Alternatively, epinephrine-soaked gauze application can be utilized. Additionally, injection of epinephrine into the flap can lead to ischemia of its terminal parts, whereas injection into the dissected tissues can disturb the surgical planes or even decrease the effective space in an already tight anal canal.

Excision of the scar requires precision and should avoid thermal injury to the underlying healthy tissues. Frequently a thin layer of the scar can be infiltrated with saline or epinephrine solution and removed sharply.

It is important that the minimal amount of absorbable suture material is used, typically 2-0 Vicryl for strength and 3-0 Vicryl or Chromic for tissue approximation. Occasionally, a few non-absorbable strength sutures can be placed. Care should be taken to avoid dead space formation underneath the flaps.

In selected cases, the flap reconstruction can be protected using a diverting ostomy, most often created with laparoscopic assistance at the end of the procedure. Tenuous repairs with poor bowel preparation and negative predictive healing factors can be the determinants for prophylactic diversion.

Flap Aftercare

The majority of flap procedures are performed on an outpatient basis. Patients are instructed to not sit directly on the repair site. Showering or rinsing with water is recommended, particularly when soiling with stool occurs. The wounds should then be covered with dry dressings to prevent tissue maceration. Wet to dry dressings are suggested for the open wounds.

Close follow-up is necessary to observe for any flap ischemia, suture line breakdown, granulomas, or wound dehiscence. Localized dehiscence is not uncommon but can be effectively monitored and treated in the office setting and by thorough wound care. Not healed wound dehiscence can lead to chronic fissures, especially when associated with flap ischemia. Patients should be seen in the office within 5 days from surgery in order to check on wound healing and to reinforce the aftercare instructions.

Postoperative bowel rest can be beneficial and is frequently used by surgeons for complex and repeat repairs. Pharmacological bowel rest with antimotility and narcotic agents can be used; however, the consequences of subsequent stool buildup, fecal impaction, and its effect on the healing wound should be carefully weighed. Today, an available option is total or peripheral parenteral nutrition (TPN or PPN), which can often be administered in the home setting via the PICC line or Medline®, respectively. This route of nutrition can be effectively combined with a liquid diet high in fat and protein to provide sufficient nutrition during the first 1–2 weeks of healing. The cost of this approach is more favorable compared to the option of protective diverting ostomy (author's observation).

Alternatively, patients can be restarted on a soft high-fiber diet with an appropriate amount of water to bulk up the stools and prevent constipation (similar to the bowel regimen for the fissure patients). Local antibiotic ointments (e.g., triple antibiotic ointment) can be used for topical application.

Postoperative pain control can be provided by intraoperative injection of liposomal bupivacaine (e.g., Exparel®) as well as oral analgesia (e.g., nonsteroidal anti-inflammatory drugs (NSAIDs), acetaminophen, Lyrica®). Stool softeners are recommended during opioid analgesia. Diarrhea should be prevented, since liquid stool appears to be more detrimental to flap repairs than bulky or firm stool.

A successful flap procedure rarely requires further dilation maneuvers. However, if recurrent stricture formation is identified, dilations should be performed.

Choosing the Right Procedure

The ideal procedure should be simple, effective, and free from serious morbidity and should restore the anal function for a good long-term outcome. Unfortunately, there is no one-fits-all solution. The choice of procedure should also depend on the surgeon's comfort level. The involvement of the scar tissue needs to be determined. Repair of the stenosed anoderm will fail if the concomitant internal sphincter fibrosis is not addressed. Conversely, the lateral internal sphincterotomy will not be successful if the problem of the concomitant anodermal stenosis is not corrected [63].

Not every stenosis needs correction. Patients with asymptomatic stenosis found during digital rectal exam should only be instructed about dietary modifications and the potential need for dilations should symptoms occur. The possibility of underlying malignancy must also be excluded.

The simplest form of anoplasty involves longitudinal incision of the involved tissue with transverse closure of the resulting diamond-shape defect in a Heineke-Mikulicz fashion. This approach can be utilized for stenosis at different levels in the anal canal and performed more than once around the circumference. It is reserved for small areas of stenosis, has a high chance for restenosis, and may require additional dilations [69]. For proximal and mid-anal stenosis, rectal advancement flaps should be considered.

Mid and distal anastomosis can be successfully treated with Y-V flaps; however, the tip of the flap can be at risk for ischemia if significant tension is applied. If the Y-V flap cannot reach into the desired location without excessive tension; it can be converted into the diamond island flap [69]. Insufficient release of the stenosis with one diamond flap can be addressed by a repeated procedure on the contralateral site.

For scenarios that require advancement of a larger amount of tissue in both transverse and longitudinal aspects, the V-Y, house, and U flap (island flap anoplasty) are more appropriate. They can also be performed bilaterally. Circumferential excision of the distal anoderm is best addressed by the rotational S-plasty or larger skin flaps, based on the named vascular pedicles [79, 87–89].

It is extremely difficult to comparatively interpret the results of many case series involving various reconstructive procedures. The only randomized study by Farid compared the house flap, rhomboid flap, and Y-V anoplasty in anal stenosis patients. The average operative times were the longest in the house flap group (62 min) and the shortest in the Y-V anoplasty (35 min). The anal caliber at 1 year was the largest in the house flap group, together with the highest quality of life score and a significant improvement of symptoms ($p < 0.05$) [83]. Helpful summaries of the flap procedures with their respected outcomes have been presented by Brisinda and Shawki [48, 54].

Few complications have been reported with most of these techniques. They can include infection, flap failure, recurrence of the stenosis, fecal incontinence, and impaction [54]. In cases where no satisfactory results can be obtained using the abovementioned procedures, a diverting colostomy remains the last resort option.

Anal Stenosis in Crohn's Disease

Anal stenosis in Crohn's disease is common and does not frequently manifest itself clinically due to the liquid nature of stools in this patient population. The stricturing, fistulizing, and fissuring nature of the disease, with subsequent healing attempts, can lead to the possibility of anal stenosis at any level of the anal canal and frequently involves the anorectal junction. Poor wound healing, constant inflammation, and scar tissue formation pose a significant challenge for the possibility of surgical correction.

In a study of 224 patients with anorectal complications of Crohn's disease, 65 patients presented with anal stenosis, and 4 patients went on to develop anal stenosis during the study [67]. Most of these patients specifically indicated that anal stenosis was their only complaint, and only a small number of patients from this group required absolutely no surgical intervention. Another 16 patients underwent mechanical dilatation, and 17 patients ultimately underwent proctectomy or diverting stoma within a mean follow-up of 19 months. In another study of 44 patients with anal stenosis secondary to Crohn's disease, 75% underwent mechanical dilatation and 43% eventually required proctectomy [66]. Brochard reported successful healing in Crohn's-related anorectal stricture in 59% over the course of 8.9 years [90].

These results highlight the significant risk of loss of bowel continence in patients with Crohn's disease and anal stenosis. Some authors have suggested that manual anal dilatation may result in further scarring and progressive stenosis or incontinence and should thus be avoided in patients with Crohn's disease [51, 61, 68].

Prevention

Avoidance of several crucial mistakes during hemorrhoidectomy, which is the procedure responsible for 90% of all stenosis cases, should decrease the chance of this complication occurring. In particular, overzealous removal of all abnormal hemorrhoidal tissue should be avoided, and the mucocutaneous bridges of viable tissue should be preserved (>1 cm strips). Some of the remaining abnormal hemorrhoidal tissue can be incorporated into the closure suture line, thus eliminating the need to remove it altogether.

Other devascularization techniques (suture ligation, supplemental rubber band ligation) can also be used to address the remaining engorged hemorrhoidal tissue. Three-quadrant hemorrhoidectomy can often be replaced by two-quadrant excision, with the addition of limited resection or rubber banding of the third remaining hemorrhoidal pedicle. Often, the remaining smallest third pedicle is so devascularized after the two other columns are removed that no resection is needed. Techniques of vascular plexus resection with preservation of the anoderm or hemorrhoidopexy can also be utilized.

Finally, treatment of acute grade IV hemorrhoidal disease should be done with caution, since the majority of the anoderm is abnormally swollen at the time of the resection and will return to normal after the acute process is resolved. Injection of a local anesthetic before the resection of the hemorrhoid or a skin tag artificially "inflates" the tissues. In the end, this can result in excessive resection. In many cases, the rectal mucosa can be anchored to the internal sphincter at the level of the dentate line, or even more distally, thereby avoiding the need to close each wound in the vertical fashion. Similarly, some of the remaining anoderm of the anal verge can be anchored into the sphincter in order to prevent its outward retraction.

Resection of the hemorrhoidal tissue in the anterior or posterior midline can lead to poor wound healing, fissure formation, and anal stenosis and thus should be avoided if possible. Care should be taken to minimize the thermal injury to the non-resected tissues in the anal canal.

Anal Stenosis, Conclusions

Anal stenosis is a rare but serious problem, which every colorectal surgeon will encounter. Prevention of this complication is crucial among any surgeon who is addressing the anorectal pathology. Appropriately performed hemorrhoidectomy should minimize the risk of anal stenosis. Conservative management is reserved for mild stenosis cases. Several surgical options for moderate and severe stenosis include sphincterotomy, stricturotomy or stricturectomy, and appropriate flap anoplasty.

Cryptoglandular Abscess and Fistula

13

Eric K. Johnson and Greta Bernier

Key Concepts

- Anorectal abscess should be treated with surgical drainage, not antibiotic therapy.
- At least one-third of cryptoglandular abscesses will progress to fistula.
- Anal fistula in the typical patient should be evaluated with examination under anesthesia. Subsequent management will be dictated by anatomic findings in the operating room.
- Priorities of management are control of sepsis, maintenance of continence, and cure without recurrence, generally in that order.
- While there are many new and emerging methods of treatment, the surgeon should be critical of the published literature and base their informed consent discussion on their observed results over time. Most studies would indicate that at least 12 months of follow-up is required to determine success.

Introduction

Anorectal abscess and fistula-in-ano are commonly encountered in a colorectal surgery clinic. It is imperative for the surgeon to fully understand the pathophysiology of this disease process, the anatomy of the anal canal and pelvis with respect to cryptoglandular abscess and fistula, and how to appropriately individualize care for each patient.

As stated by Dr. Herand Abcarian, "It is difficult if not impossible to accurately assess the incidence of anorectal abscesses because they often drain spontaneously or are incised and drained in a physician's office, emergency room or surgicenter" [1]. Similarly, our estimates do not account for those treated with antibiotics alone in the primary care setting. This is further complicated by the misdiagnosis of many common anorectal pathologies as "hemorrhoids," both by patients and referring physicians.

The incidence of anorectal abscess is documented as 8.6–20 patients per 100,000 people, with males being more affected than females at an incidence of 2.4–3:1 and presentation at a mean age of 40 years [2–4]. The most common etiology is cryptoglandular, accounting for 90% of anorectal abscesses, although both abscess and fistula can arise from a multitude of etiologies, including Crohn's disease, obstetric injury, fissure, and infectious etiologies such as tuberculosis, sarcoid, and HIV. These etiologies are outside the scope of this chapter but will be discussed in further detail in subsequent chapters.

Cryptoglandular Pathophysiology

Cryptoglandular abscess and fistula-in-ano arise from glands at the dentate line, nestled between the anal papilla and the columns of Morgagni. These glands extend into the submucosal space, internal sphincter, intersphincteric space, and external sphincter to varying degrees. When bacteria and debris become inspissated in these glands, an infection develops, and this will track along the course of the gland or follow to the path of least resistance from its origin (Fig. 13.1) [5, 6]. This theory was described and popularized by Eisenhammer in the 1950s [5].

Cryptoglandular Abscess

As described above, anorectal abscesses occur in multiple spaces in the pelvis and are so classified by these locations: perianal, ischiorectal, intersphincteric, and supralevator

(Fig. 13.2). Another classification, horseshoe abscess, describes an abscess that courses posteriorly through the deep postanal space to involve the bilateral ischiorectal spaces.

Both perianal abscesses and ischiorectal abscesses typically present with perianal pain, swelling, and fluctuance, with possible spontaneous drainage of purulent fluid. Intersphincteric abscesses typically do not have any external manifestations but rather present as intense anal pain, such that the patient will often not tolerate a digital rectal exam, without any other clear pathology to account for these symptoms such as a fissure, thrombosed hemorrhoid, sexually transmitted infection, or malignancy. Supralevator abscesses may arise from cephalad extension of a cryptoglandular origin but, however, are more commonly associated with an intraabdominal process such as diverticular disease, malignancy, or Crohn's disease. Perianal and ischiorectal abscesses represent the majority of anorectal abscess, 65–80% [7, 8]. Ramanujam et al. further described the incidence of each subtype of anorectal abscess in their evaluation of 1023 patients presenting over a 5.5-year period. In their series, perianal abscesses accounted for 42.7% of anorectal abscesses, ischiorectal for 22.7%, intersphincteric for 21.4%, and supralevator for 7.3%.

Diagnosis

History and physical examination are generally sufficient to diagnose perianal and ischiorectal abscesses. Imaging adjuncts, such as CT scan, MRI, fistulogram, and endoanal ultrasound, are not indicated for the patient with classic uncomplicated presentation, without diagnostic dilemma or comorbidity, and a fluctuant area is appreciated on examination [3, 9]. Imaging may be beneficial in the workup of those with an unclear diagnosis, such as those with isolated intersphincteric abscess or those that have other complicating factors, such as history of malignancy, radiation, Crohn's disease, prior anorectal operations, or trauma, or those with concern for complex abscesses such as horseshoe or supralevator extension. Imaging adjuncts may also be useful in select cases for management of associated fistula-in-ano, as discussed later in this chapter.

Treatment

The primary treatment for anorectal abscess is expeditious incision and drainage. Perianal and ischiorectal abscesses should be drained through the skin overlying the area of fluctuance. If the abscess cavity is large, the incision should be made over the area of the cavity that is closest to the anal verge. With this technique, if the patient develops a resultant fistula-in-ano, the tract will not be unnecessarily long. This consideration is important, as approximately one-third of acute anorectal abscesses persist as a fistula-in-ano [8, 10, 11].

Intersphincteric abscesses and supralevator abscesses require special considerations both for effective drainage and to avoid iatrogenic injury. Intersphincteric abscesses typically require internal drainage at the dentate line via sphincterotomy if there is no external area of fluctuance.

The route of drainage is of particular importance for supralevator abscesses. Those that arise from an intraabdom-

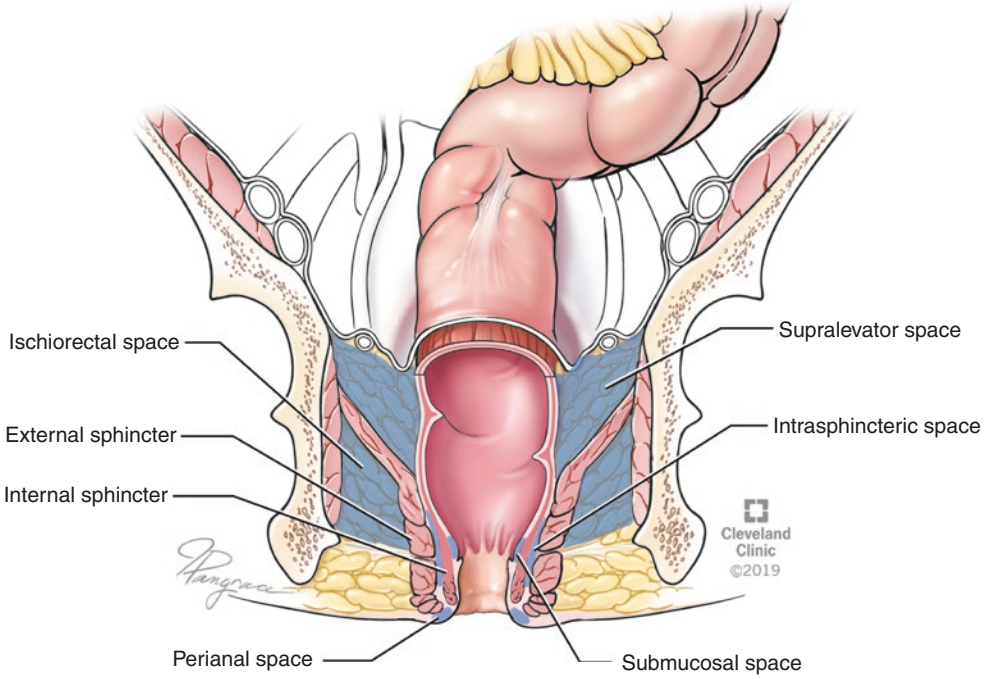

Fig. 13.3 Image showing different potential spaces for abscess formation, with emphasis on appropriate drainage route for supralevator abscess. (Reprinted with permission, The Cleveland Clinic Center for Medical Art & Photography © 2009–2020. All Rights Reserved)

inal source should be drained either transabdominally using interventional radiology assistance or transrectally, while those arising from cephalad extension of a cryptoglandular source via the intersphincteric space should be drained transrectally. Those that arise from a cephalad extension of an ischiorectal abscess should be drained transcutaneously. These principles are important in order to avoid iatrogenic creation of a suprasphincteric fistula (Fig. 13.3).

Another special case is drainage of the horseshoe abscess. As stated previously, these typically arise from extension of an ischiorectal abscess via the deep postanal space. In order to adequately drain these abscesses, there must be both bilateral transcutaneous ischiorectal drainage and posterior drainage via division of the anococcygeal ligament to access the deep postanal space. Other examples of a horseshoe abscess include those arising from a perianal abscess extending through the superficial postanal space, those extending through the anterior perianal space, or a supralevator abscesses coursing through the posterior supralevator space (Fig. 13.4).

Acute Fistula Management

By definition, 100% of anorectal abscesses of cryptoglandular etiology will have a path from the dentate line to the drained abscess cavity. At the time of acute abscess presentation, 30–70% of patients will have an identifiable tract [8, 12–14]; however, this tract is not mature and will only become a fistula tract in ~30–35% of patients. There is also a risk of creating a false passage while attempting to identify a fistula tract in the setting of acute inflammation. If a tract is identified, some advocate for primary fistulotomy at the time of abscess drainage to reduce recurrent abscess or need for second operation were a fistula to develop. And while some have shown a decrease in both abscess recurrence and fistula formation with primary fistulotomy [12], this approach results in occasionally unnecessary sphincter division in patients who would not have ultimately developed a chronic fistula. In addition, inflammation from the concomitant abscess will make it more difficult to discern the degree of muscle involvement, precluding appropriate surgical judgment, thereby potentially increasing the risk of incontinence [12, 15]. Given this controversy and potential risks, it is not generally recommended to definitively manage this tract at the time of abscess drainage.

Incision and drainage in the clinic instead of the operating room is preferred as it expedites the time to control of sepsis. In order to perform this procedure in clinic, the provider must have an adequate setup with anesthetic, instruments, patient positioning, and an amenable patient. In many cases, patients will tolerate in office drainage. This can be facilitated by injecting a wheal of anesthetic at the intended site of drainage, decompressing the cavity through the wheal with a larger needle prior to injecting additional anesthetic, and then completing drainage via a small incision. Complex perianal abscesses, such as those that are deep/nonpalpable, those that are associated with tissue necrosis, and those inpatients who are intolerant of a bedside procedure, are better managed in the operating room.

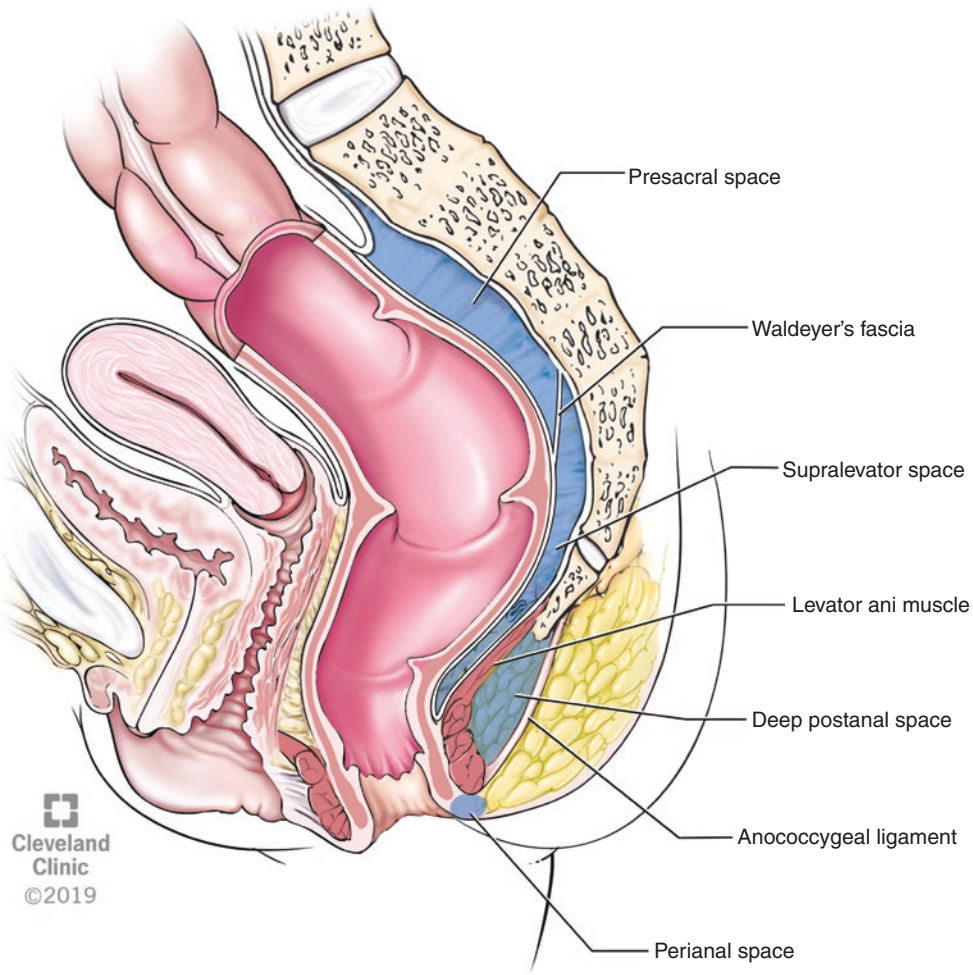

Fig. 13.4 Sagittal image showing potential abscess spaces. (Reprinted with permission, The Cleveland Clinic Center for Medical Art & Photography © 2009–2020. All Rights Reserved)

Post-drainage Care

After transcutaneous drainage, packing the abscess cavity is not recommended as wounds left unpacked are more manageable to care for with less pain and faster healing [16–18]. A catheter, such as a mushroom-tip catheter, may be placed in an abscess cavity to promote drainage and to maintain the external opening. This is of particular help in those with large or deep abscess cavities to ensure adequate drainage of the cavity and to minimize the size of external incision. Warm water soaks (i.e., sitz baths) for 10–15 minutes two to three times per day and external gauze for drainage are all that are required for wound care.

Post-drainage Antibiotics

Traditionally antibiotics were recommended only for those with extensive cellulitis, signs of sepsis, or immunocompromised state [19]. While we lack definitive evidence to direct antibiotic therapy, in general, a broad-spectrum antibiotic that offers gram-negative and anaerobic coverage while providing additional coverage of typical gram-positive skin-associated bacteria is adequate. Typical oral regimens would include augmentin alone, trimethoprim-sulfamethoxazole alone, and a quinolone combined with metronidazole. In a patient with prior history of methicillin-resistant *S. aureus* infection, use of trimethoprim-sulfamethoxazole or clindamycin will often cover a community-acquired form of the infection. This is more controversial in recent years as there is data to suggest post-drainage antibiotic treatment may decrease fistula formation. Ghahramani et al. randomized 307 patients to operative drainage with or without postoperative ciprofloxacin and metronidazole. They found a significant decrease in fistula formation from 30% in the control group to 14.1% in the antibiotic group ($P < 0.001$) [20]. Likewise, Lohsiriwat found a decrease in fistula formation from 48% to 17% in those that received antibiosis vs. those that didn't, respectively [11]. In a subsequent meta-analysis, Mocanu et al. found a 36% decreased rate of fistula formation in those with post-drainage antibiotics than those who received no antibiotics or placebo [21]. These studies are not uniformly reproducible, as there are similar studies which showed no protective effect of antibiotic treat-

ment with fistula formation [10, 22]. Given this inconclusive evidence, guidelines still recommend against routine antibiotics [19].

Without plans for post-drainage antibiotics, it is not necessary to send a bacterial culture, as this data would not be actionable. If antibiotics are planned, then a bacterial culture at the time of drainage may help guide antimicrobial selection, in particular when treating a patient with history of drug-resistant bacteria such as MRSA.

Anal Fistula

Presentation/Symptoms

As previously discussed, anorectal abscess persists as an anal fistula in approximately 30–35% of patients. Interestingly, this rate increases in nondiabetics and those less than age 40, with no significant difference identified based on sex, smoking status, HIV status, or administration of perioperative antibiotics [10, 11]. Patients with fistula-in-ano present to the colorectal surgery clinic with a wide range of complaints, including "hemorrhoids," history of anorectal abscess with spontaneous or surgical drainage, external bump that becomes irritated and bleeds, chronic external drainage, and cyclical perianal pain and swelling that is relieved with expression of fluid. Given the variety of complaints in patients with fistula-in-ano as well as those of any anorectal patient, a good physical exam is of the utmost importance to appropriate diagnosis, medical decision-making, and patient counseling.

Classification

The most common etiology of fistula-in-ano is cryptoglandular progression. The course of the offending gland through the sphincter complex or the path the bacteria travels through the tissues as its path of least resistance determines the type of resultant fistula. Fistulas are categorized based on degree of sphincter involvement: subcutaneous/submucosal (2–3%), intersphincteric (24–45%), transsphincteric (30–60%), and suprasphincteric (2–20%) [23–25].

Subcutaneous or submucosal fistulas begin at the dentate line and course just deep to the anoderm without any sphincter involvement. Intersphincteric fistulas track through the internal sphincter alone before traveling through the intersphincteric space to reach the perianal skin. Transsphincteric fistulas travel through both the internal sphincter and external sphincter and are further subdivided based on degree of external sphincter involvement. Those fistulas involving 30% or less of the external sphincter are considered low transsphincteric fistulas, whereas those involving more than 30% of the external sphincter are termed high transsphincteric fistulas. This is of particular importance in the decision regarding sphincter-dividing vs. sphincter-sparing techniques and risk of postoperative fecal incontinence. This will be discussed in further detail in a later section. Suprasphincteric fistulas begin at the dentate line, course through the internal sphincter, travel cephalad in the intersphincteric space, and cross the skeletal muscle above the external sphincter to enter the ischiorectal space.

A fifth class of anorectal fistula is also described: the extrasphincteric fistula. These fistulas do not arise from a cryptoglandular origin and do not involve the sphincter complex. These fistulas arise from an intraabdominal source such as diverticulitis or malignancy, are associated with a separate etiology of fistulizing disease such as Crohn's disease, or may arise from iatrogenic injury or inappropriate drainage of a supralevator abscess. Extrasphincteric fistulas are mentioned here to fully understand the classification of fistula-in-ano; however, their management will be discussed in another chapter (Fig. 13.5).

Neither the location of the initial abscess cavity nor the location of external opening of a fistula tract can predict the degree of sphincter involvement. The internal opening can be somewhat reliably predicted for cryptoglandular fistulas based on the location of the external opening following Goodsall's principle. Overall this principle correctly corresponds to actual patient disease in ~80% of those with cryptoglandular fistula [26]. This is most accurate for posterior and intersphincteric fistulas, 91% and 93%, respectively, than for anterior and transsphincteric fistulas, 69% and 68%, respectively (Fig. 13.6) [27].

In this principle, any external opening involving the posterior half of the anoderm (posterior to the transverse anal line) will curve medially to involve an internal opening in the posterior midline. External openings involving the anterior half of the anal verge (anterior to the transverse anal line) will correspond to a radially located internal opening. Exceptions to this rule include posteriorly arising fistula tracts that extend anteriorly in their curved path prior to communicating with the perianal skin.

Preoperative Imaging for Fistula Characterization

As mentioned previously, there are several imaging adjuncts that may be used to define a fistula tract, such as CT scan, MRI, fistulography, and endoanal ultrasound. The majority of patients with uncomplicated cryptoglandular disease are diagnosed with fistula-in-ano based on symptoms and physical exam findings alone, and there is no additional benefit to adding imaging in the initial workup. Gonzalez-Ruiz et al. demonstrated 93% ability to identify internal fistula opening

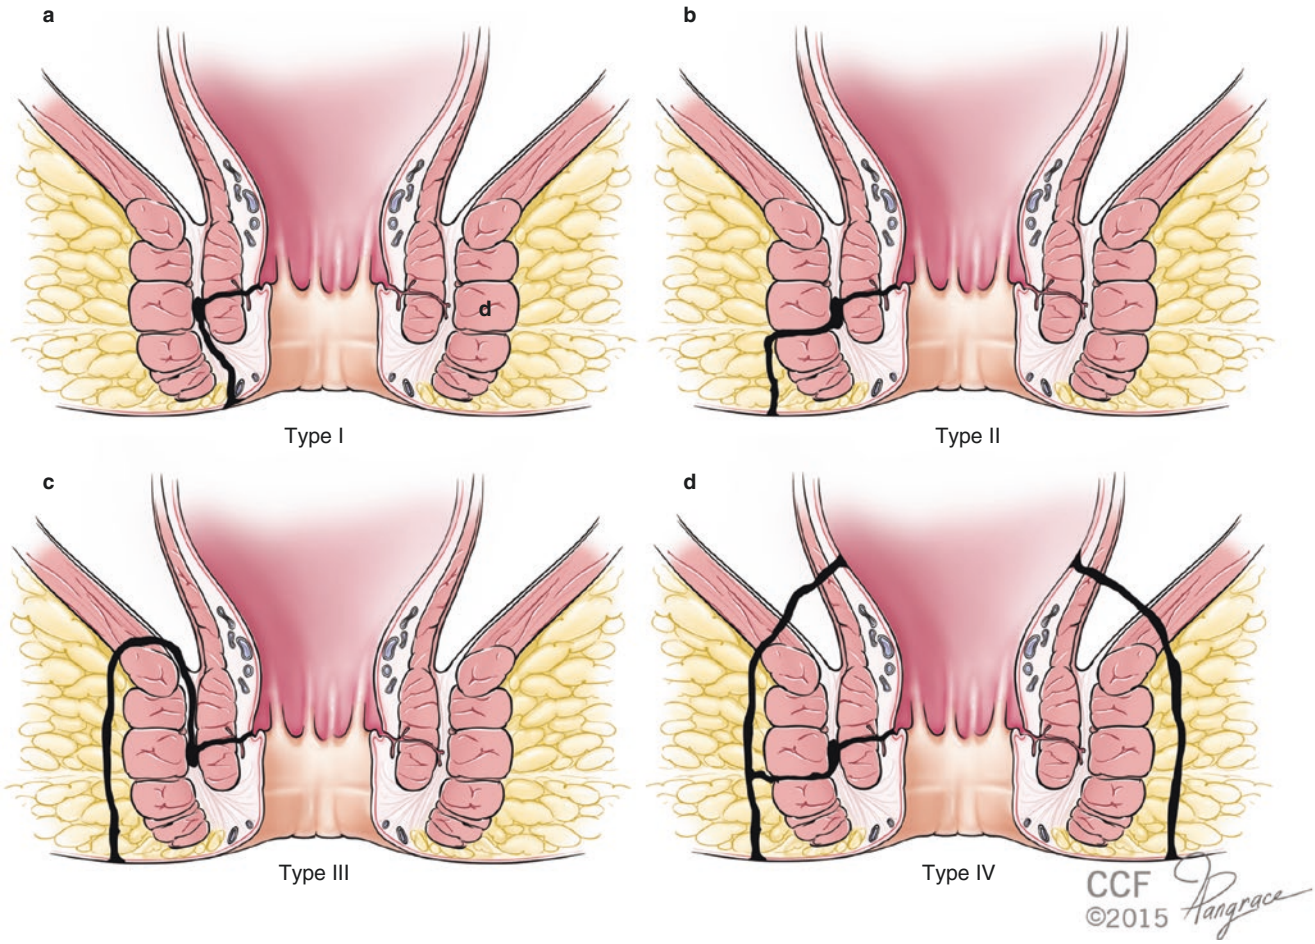

Fig. 13.5 Cross-sectional images showing the anatomy of various fistula tracts. Type 1, intersphincteric; type 2, transsphincteric; type 3, suprasphincteric; type 4, extrasphincteric, combined transsphincteric/extrasphincteric. Fig. 13.6 Goodsall's rule, which has come into question more recently. It still remains a decent guideline for determining the location of an internal opening. (Reprinted with permission, The Cleveland Clinic Center for Medical Art & Photography © 2009–2020. All Rights Reserved)

with direct palpation [26]. Imaging is reasonable to consider for those with non-cryptoglandular disease, such as Crohn's, those with recurrent disease or history of prior fistula operation, and those in whom the tract was not readily identifiable on examination under anesthesia.

The imaging modality selected is highly dependent on surgeon preference, comfort with interpretation, access to certain modalities, and, in the case of ultrasound, surgeon skill.

Fistulography

Fistulography is performed by injection of water-soluble contrast into the external fistula opening followed by plain X-ray or fluoroscopy imaging. A modified technique described by Pomerri et al. may also be used during which contrast is placed into the rectum via a Foley catheter [28]. With this method, the authors were able to identify 100% of primary tracts, 74.2% of internal openings, 91.8% of secondary tracks, and 87.8% of abscesses. Despite relative accuracy, both fistulography techniques have been surpassed by

other modalities, due to the lack of radiologist expertise, anatomic information provided with plain X-ray alone, and discomfort to the patient [29]. These may still have a role for those without access to more advanced 3D imaging options.

Computed Tomography (CT)

Standard computerized tomography (CT) is typically not a helpful modality to evaluate fistula characteristics [30]. CT may be helpful, as previously stated, in the evaluation of complex abscess cavities, including supralevator abscesses, or to define aberrant anatomy from prior surgery, prior infection or inflammatory disease, or congenital aberrancies. CT with fistulography, however, does have the ability to characterize a fistula tract with relatively good accuracy [31]. Proponents of this technique cite the increased availability of CT and decreased cost as compared to MRI. There is also no interobserver variability. Negatives of this modality include exposure to radiation, procedural cannulation of the fistula tract which often requires surgeon presence in radiology, and decreased accuracy as compared to MRI. CT fistulography is less accurate at fistula classification (73.1% vs. 92.7%, $p < 0.001$) and identification of internal opening (68.2% vs. 85.3%, $p < 0.001$) as compared to MRI, with similar ability to identify secondary extensions and similar correlation with intraoperative findings [31].

Magnetic Resonance Imaging (MRI)

The use of MRI to evaluate anal fistulas was first described in the 1992 by Lunniss et al. [32]. In the initial reports, MRI was highly accurate, sensitive, and concordant with operative findings [33, 34]. Many consider MRI the preferred imaging modality to characterize anal fistulas given its accuracy, reproducibility, and no need for instrumentation of the fistula tract by the radiologist or surgeon, which leads to improved patient tolerance [29]. MRI is also preferred due to its ability to both localize abscesses and characterize fistulas with depiction of the surrounding anatomy.

A more important determination may not be which modality to use, but when to use imaging. In a study of 136 patients undergoing preoperative 3T MRI, Konan et al. identified an 83.1% concordance with operative findings; however, the contribution of that finding to clinical evaluation was only significant in 33.8% of patients [35]. Applicable and treatment changing information was more common in those with complex fistulas (54.4% vs. 5.2%, $p < 0.001$) and with external opening >2 cm from the anal verge (47.1% vs. 10.2%, $p < 0.001$) and when a horseshoe fistula was present (66.7% vs. 30.6%, $p = 0.021$). This again supports the earlier assertion that imaging adjuncts are unnecessary with straightforward cryptoglandular disease.

MRI can be performed with either an endoanal coil or a body coil. There was initial support for the endoanal coil with studies showing improved accuracy as compared to an external coil [36]. This technique however is poorly tolerated by patients and has decreased ability to delineate anatomy further from the anal verge. In addition, with improvements in MRI technology with both 1.5 Tesla and 3.0 Tesla magnets, body coil MRI findings surpassed endoanal coil MRI in concordance to surgical findings [37, 38].

Endoanal Ultrasound (EAUS)

While MRI is currently considered the gold standard for fistula evaluation, cost and access are often prohibitive for patients. In these situations, endoanal ultrasound provides a reasonable alternative for preoperative evaluation. Endoanal ultrasound is similar to MRI in ability to accurately identify internal opening, each with rates of 80–90% accuracy [37, 39, 40]. Endoanal ultrasound is less accurate at identifying secondary extensions, 67–80% vs. 90% [37, 39, 40]. Notably there is no difference between these two modalities in evaluation of simple fistula tracts [40]; however, most would argue that neither adjunct is indicated for the simple fistula tract.

Injection of dilute hydrogen peroxide into the fistula tract via the external opening is often used as an ultrasonic contrast agent during endoanal ultrasound to improve visibility of fistula. Peroxide contrast enhancement increases identification of internal openings, accuracy of fistula classification, and ability to identify supralevator extension and abscess [41–44].

Endoanal ultrasound remains an accurate and cost-effective modality for fistula evaluation. However, given the poor patient tolerance, variability of accuracy based on operator skill, and limited view of anatomy further from the anal canal, MRI continues to be the standard of care for preoperative imaging assessment when available and when indicated in select patients. One advantage of ultrasound is that it can be performed as an adjunct in the OR, which may have immediate impact upon treatment.

Treatment Strategies

There are three main goals in management of fistula-in-ano: (1) control of sepsis, (2) definitive repair of fistula without recurrent disease, and (3) maintenance of continence [45, 46]. The first step in treatment is rectal exam under anesthesia, to evaluate the fistula, surrounding anatomy, and degree of ongoing infection and to classify the fistula with respect to sphincter involvement.

There is little to no role for medical management alone without surgical management in the treatment of cryptoglandular fistula-in-ano. Exceptions to this include those that are minimally symptomatic and have other comorbidities precluding surgical management. In these patients, control of sepsis remains a goal of treatment which may require placement of a draining seton as described below. They must also

Fig. 13.7 Image showing malignant degeneration/transformation in a chronic fistula tract

be monitored long term due to the rare but documented incidence of malignant degeneration of chronic anal fistula (Fig. 13.7) [47]. Medical management is well described for fistula-in-ano related to Crohn's disease, as will be discussed in the following chapter.

Intraoperative Fistula Identification

The first step in surgical management is intraoperative identification and characterization of the fistula. Even in those with preoperative imaging, these findings are merely guidance and must be confirmed with intraoperative findings. To this end, rectal examination under anesthesia is performed. The authors prefer monitored anesthesia care with sedation and prone jackknife position; however, this procedure can be performed in high lithotomy or under general anesthesia depending on surgeon preference and patient comorbidities.

The procedure begins with digital rectal exam and anoscopic exam both to palpate internal opening and rule out other anal canal pathologies previously unidentified during examination in clinic. The external opening is gently probed with a blunt-tipped fistula probe. These probes can be single or double armed, straight or curved, and malleable or non-malleable, depending on both surgeon preference and the limitations of the individual fistula tract. The probe is passed along the tract until it communicates with the internal opening. This can be facilitated by palpation of the internal opening with the opposite hand at the time of probe passage to guide direction. The probe should move smoothly and without significant force through the fistula tract, so as to avoid creation of a false passage.

A commonly encountered situation is that in which the fistula probe passes through the sphincter complex but does not pass through the mucosal opening. While tempting to "pop through" this final layer of mucosa, inaccurate identification of the internal opening leads to increased risk of recurrent fistula, and therefore this should be avoided [48].

It can be challenging to identify the internal opening in some patients. Intraoperative hydrogen peroxide or methylene blue may be injected via the external fistula opening to aid in identification of the exact site of internal opening. In a study by Gonzalez-Ruiz et al., internal openings were accurately identified in 83% of cases when methylene blue or hydrogen peroxide injections were used [26]. Even if the internal opening is identified, it may be difficult to pass the probe if there is significant angulation or branching or if you encounter unexpected complex anatomy. In these cases, the surgeon may choose to gently probe the internal opening outward to attempt to connect with the externally passed probe.

Alternatively, intraoperative ultrasound with or without hydrogen peroxide contrast enhancement may be used. Just as with preoperative endoanal ultrasound, the surgeon may choose to add hydrogen peroxide as ultrasonic contrast enhancement. Some show that the addition of hydrogen peroxide significantly increases the ability to identify internal opening (94%) and determine curvilinear vs. linear anatomy (85%) [49, 50]. Others found endoanal ultrasound with hydrogen peroxide and endoanal ultrasound alone were equivocal in identifying internal opening, primary tract and secondary tract, although both were still highly accurate at 90 and 86%, 81 and 71%, and 68 and 63%, respectively [51].

It is important to remember that, like any ultrasound, endoanal ultrasound is highly user dependent. These aforementioned degrees of accuracy are in the hands of experienced users. If a surgeon is anticipating use of this modality in the operating room, then it is advised to initially perform endoanal ultrasound intraoperatively on all fistula-in-ano patients, whether simple or complex, to improve their skill and interpretation.

Other techniques have been described to aid in internal opening identification and complete probe passage. One such technique describes partial fistulectomy or fistulotomy from the external opening to the level of the external sphincter followed by traction on the transsphincteric portion of the fistula to identify dimpling of the anal mucosa at the site of

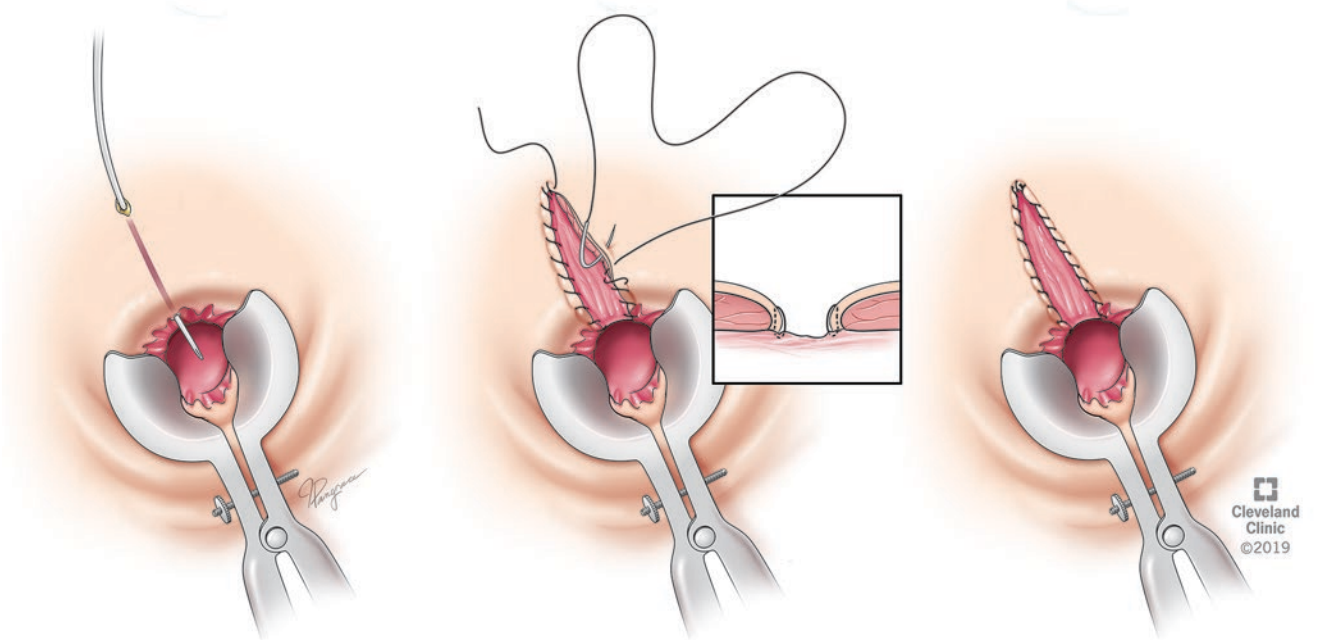

Fig. 13.8 Image showing a simple fistulotomy with marsupialization of the wound edges. (Reprinted with permission, The Cleveland Clinic Center for Medical Art & Photography © 2009–2020. All Rights Reserved)

internal opening [52]. These techniques should be used with caution as they may interfere with appropriate and definitive treatment in the future. Occasionally, one should abandon the procedure if an internal opening is not identified, preserving a future opportunity to identify the fistula tract without injury to the anal canal or sphincter complex.

Once clearly identified, fistulas are commonly classified as simple or complex based on the risk for incontinence after a sphincter-dividing operation. Complex fistulas are described by the American Society of Colon and Rectal Surgeons Standard Practice Task Force (SPTF) as involving more than 30% of external sphincter (high transsphincteric, suprasphincteric, and extrasphincteric), anterior location in a female, multiple tracts, recurrent fistula, preexisting incontinence, local irradiation, and Crohn's disease [53]. Fistulas that clearly fall in the simple classification may be treated with definitive sphincter-dividing surgery at the time of initial presentation. All others should undergo a sphincter preserving technique, typically beginning with placement of a draining seton.

Fistulotomy

Fistulotomy is generally safe in simple fistulas with recurrence rate of 0–9% and incontinence rate between 0% and 37% [24, 48, 54]. The wide range in findings is likely due to variable inclusion criteria of simple vs. complex fistula type in these studies of patients undergoing fistulotomy. Overall, in appropriately selected patients, fistulotomy is safe and has low risk of recurrence and resultant incontinence. For this reason, it is the only surgical option recommended for simple fistulas.

Fistulotomy entails laying open the fistula tract including all secondary tracts for complete and adequate drainage. In some situations, fistulotomy of the primary tract with counter-drainage of the secondary tract/s will provide a reliable result but can simplify healing and postoperative care (Fig. 13.8). This is most easily performed by dividing the tissue overlying the fistula probe with electrocautery. The underlying fistula tract is debrided with electrocautery or curetting. Marsupialization of the wound edges after fistulotomy has been shown to decrease overall resultant wound size, shorten time to healing (6 weeks vs. 10 weeks, $p < 0.001$), and reduce incidence of postoperative bleeding (36% vs. 46%, $p < 0.05$) [55, 56].

Concomitant fistulectomy was initially theorized to improve healing by removal of the dense fibrotic tissue of a chronic fistula. This technique, while having similar recurrence and incontinence rates as compared to fistulotomy, also carries with it increased wound size, increased size of postoperative sphincter defect, and increased time to healing [45, 57, 58]. Therefore, we do not recommend fistulectomy over fistulotomy for simple fistula-in-ano. Fistulectomy may have a role for chronic blind ending sinus tracts, especially one that does not cross the sphincter complex and travels cephalad into the ischiorectal space, for which fistulotomy is not feasible. A drain may be placed in this scenario to facilitate fluid drainage, in particular for tracts that are narrow and penetrate deeply into the tissues.

Fig. 13.9 Transsphincteric fistulotomy into the deep postanal space in a patient who failed sphincter-sparing management. This individual did not have any alteration in continence after healing, which is a relatively common result in this setting

While fistulotomy is typically reserved for low lying and simple fistulas, the modified Hanley procedure [59] (posterior midline fistulotomy into the deep postanal space using primary fistulotomy or a cutting seton combined with counter-drainage of bilateral horseshoe tracts) has been associated with successful treatment of deep postanal space/horseshoe fistulas that would generally be considered as complex (Fig. 13.9). It is the opinion of the authors that this procedure should be reserved for failures of sphincter-sparing approaches; however, despite the significant amount of external sphincter divided, incontinence rates are relatively low.

Setons

The word seton originates from *seta*, the Latin word for bristle. In fact, the earliest described setons were horsehair or "seta equina." These setons were used to drain infection and fell out over time. Currently there are many materials that may be used as a seton: nonabsorbable sutures, vessel loops, Penrose drains, silastic catheters, rubber bands, wire, electrical cable tie, etc. The main differentiation between setons is not the material chosen but the goal of treatment. Setons are characterized as draining setons or cutting setons.

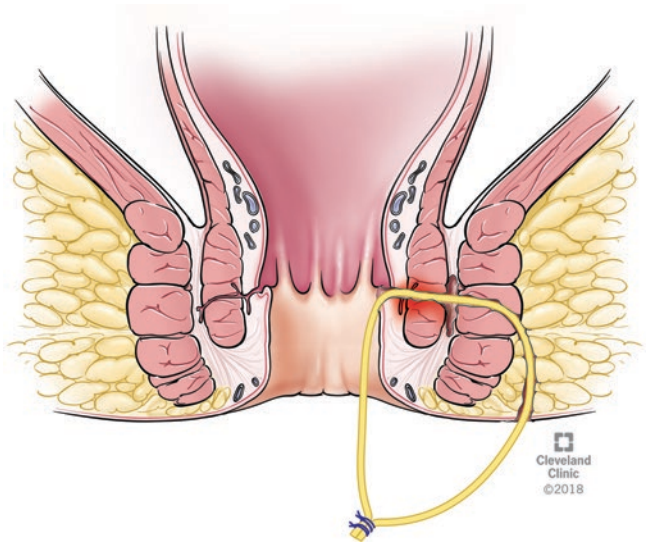

Fig. 13.10 Loose seton placed through a transsphincteric fistula. (Reprinted with permission, The Cleveland Clinic Center for Medical Art & Photography © 2009–2020. All Rights Reserved)

Draining Seton

A draining seton is secured loosely to itself (Fig. 13.10) such that there is no significant tension on the involved tissues. This type of seton is placed if there is complex disease with significant sphincter involvement or significant inflammation such that degree of sphincter involvement cannot be accurately elucidated. The goal of a draining seton is adequate drainage and sepsis management, as well as tract maturation, which is necessary for some types of complex repairs. This procedure is very well tolerated and carries with it very little risk.

Cutting Seton

A cutting seton is placed similarly to a draining seton; however, it is secured tightly to itself such that there is tension and compression on the involved tissues. Successful placement requires division of the anoderm overlying the fistula tract. The seton is then serially tightened in clinic and slowly "cuts" through the intervening tissues until it falls out, leaving intact scar behind and preventing a tissue defect from developing. The time to healing, thereby time to extrusion of seton, may last weeks to months and is dependent on the amount of tissue to be divided. Setons are tightened as frequently as every other day or as infrequent as just once postoperatively. Recurrence rates are low with this procedure (0–10%); however, there remains a significant risk of incontinence, reported between 0 and 67% [60–66]. This observed variability in incontinence rates is attributed to differing surgical techniques, duration of follow-up, and variable surveillance records in follow-up.

Ritchie et al. evaluated a large series of patients ($n = 1460$) and concluded a rate of incontinence of 12% after cutting seton [65]. This rate was based on all included manuscripts; however, one-third of manuscripts did not include a

description of incontinence, and when these are excluded, average incontinence rate increases to 32%. Likewise, several large studies used only medicated cutting setons. When these studies are excluded, incontinence rate rises to 22%. Incontinence rate also increases with more proximal location of the internal opening.

In a review by Vial et al., authors compared rates of recurrence and incontinence with or without division of the internal anal sphincter [66]. They identified similar recurrence rates between preserved and divided internal anal sphincter (5% vs. 3%) and significant difference in rates of incontinence (5.6% vs. 25.2%). These authors concluded that division of internal anal sphincter was not necessary to improve recurrence rate and worsened postoperative function and should therefore be avoided when using a cutting seton.

Overall, cutting setons have high enough incontinence rates to recommend preferential use of other sphincter-sparing approaches for complex fistulas, unless in the setting of recurrent disease with exhaustion of other options or when the anatomy is not amenable to other options.

Loose Seton as Definitive Treatment and External Anal Sphincter-Sparing Seton

Loose draining setons were traditionally seen as a mechanism for sepsis control and bridge to definitive repair in cryptoglandular anal fistula; more recent studies show promising results with the use of draining seton as definitive repair. The mechanism for this treatment is not fully understood; however, proponents of this technique cite eventual erosion of the seton such that the internal opening migrates distally out of the high pressure zone, allowing ultimate healing [67]. Emile et al. reported ~10% recurrence rate with risk of incontinence of 3% [68]. Risks for recurrence include previously recurrent fistula, supralevator extension, and anterior fistula. In their multicenter review of 200 patients undergoing loose seton placement for definitive management of fistula, Kelly et al. identified 100% initial clearance of fistula, with overall 6% recurrence rate and 96% patient tolerance [69]. In their described technique, setons were changed electively every 3 months until the fistula resolved. The median number of seton replacement for each patient was 3 (range 1–8, mean 2.84).

In a recent study by Omar et al., 60 patients with complex anal fistula were randomized to conventional drainage seton or external anal sphincter-sparing seton using a rerouting technique [70]. They identified persistence or recurrence rates of 13% and 3% for conventional and external sphincter-sparing techniques, respectively ($p = 0.35$), and no difference in physical, social, or sexual activities ($p = 0.7$, 0.59, 0.67). Importantly they identified significant decrease in time to healing from 103 ± 47 days in the conventional group, as compared to 46 ± 18 days in the external sphincter-sparing group ($p < 0.0001$). These studies are promising for the use of loose draining seton as a means of definitive treatment and warrant further investigation.

Fibrin Glue

The use of fibrin glue for obliteration of an anal fistula tract was first described in the 1990s as a means to treat complex anal fistulas without impairment of incontinence [71]. In this initial series, Hjortrup et al. reported a 50% success rate, which they argued was reasonable given the procedure's repeatability, ease of performance, and minimal patient risk. With this procedure, the primary fistula tract is identified and debrided, followed by injection of fibrin glue (Fig. 13.11). While none have been associated with change in recurrence rate, variations to this procedure include the use of preoperative setons, degree of tract debridement, use of intra-adhesive antibiotics, and suture closure of internal or external openings [72]. Since this initial study, success rates remain variable at a range of 14–94% [72–76]. Healing rates decrease with increasing fistula complexity [76, 77]. Given the variable success rates, fibrin glue is not recommended as a first-line treatment for complex fistula-in-ano; however, with low risk of complication or incontinence, it is a reasonable second-line treatment or alternative when other surgical options are not feasible [19, 29].

Fistula Plug

The anal fistula plug was developed with similar goals to fibrin glue treatment: fistula healing by obliteration of the tract without sphincter division and resultant risk of incontinence. This procedure entails identification of primary fistula tract, passage of a biologic or synthetic plug through the fistula tract, and securement of this prosthesis to the internal opening with successful obliteration of the internal opening (Fig. 13.12a–c). The first study describing the use of graft material as an anal fistula plug, as compared to fibrin glue, occurred in 2006 by Johnson et al. [78]. In this initial series of 15 patients with bioprosthetic mesh plug, they observed an 87% closure rate. Based on this promise, commercially available plugs were created, all with the same goal: creating a scaffolding in which native tissue could grow to close a fistula tract. Subsequent studies observed widely variable success rates of 24–88% [79–82]. Decreased success was attributed to many things: inadequate tract debridement, excessive tract debridement, inadequately secured plug, and presence or lack of preoperative seton, none of which have been shown to be significant factors of success. These mixed success rates as well as increased cost have kept fistula plug from becoming a widely accepted first-line treatment for complex fistula-in-ano [19, 29].

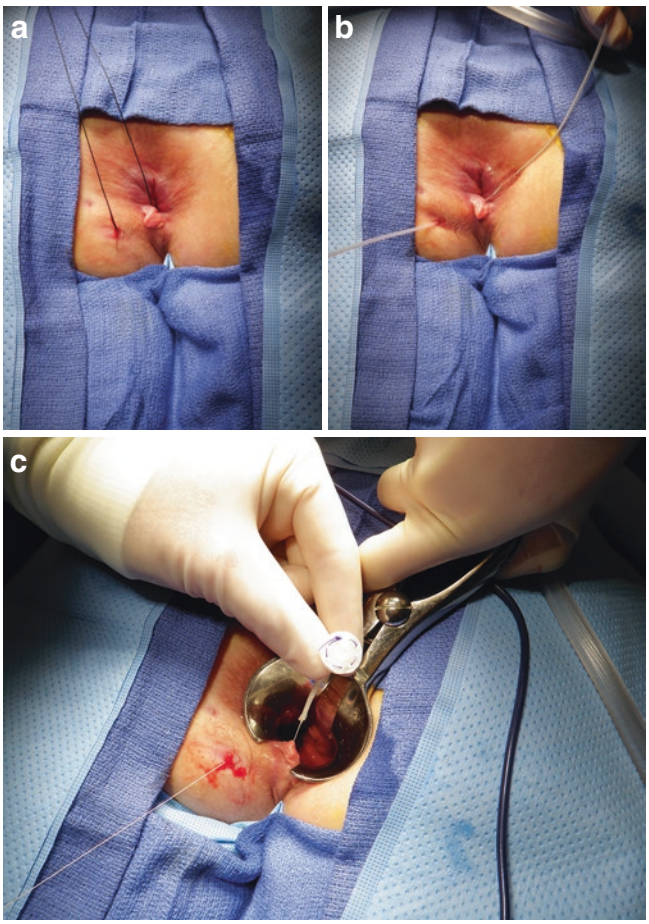

Fig. 13.12 (**a**): Transsphincteric fistula with silk suture (marker suture) placed through the tract. This will be used to pull the fistula brush through the tract. (**b**): Fistula brush being pulled through the tract to gently debride granulation tissue. (**c**): Fistula plug being pulled retrograde through the tract

While its role as a solitary treatment for complex fistula is limited, some have evaluated the role of fistula plug as an adjunct to other complex repairs, such as endorectal advancement flap (ERAF) and ligation of intersphincteric fistula tract (LIFT), as discussed below.

Endorectal Advancement Flap (ERAF)

Endorectal advancement flap entails debridement or excision of the fistula tract and mobilization of a wide-based mucosal/submucosal rectal flap, followed by coverage of the internal opening after removal of overlying tissues and suture closure of the internal opening (Fig. 13.13a–d). Based on its reproducible reasonable success rates of 60–100% [83–91], endorectal advancement flap has been accepted as a first-line treatment option for complex anal fistulas. Keys to successful flap survival include adequate blood supply, via the wide-based submucosal plexus, and lack of tension, requiring adequate length of mobilization. There is variability regarding degree of circular muscle (internal sphincter) included in the mucosal and submucosal flap, with a direct correlation between degree of muscle involvement and flap viability [92]. Importantly, however, there is an inverse relationship between degree of muscle involvement and subsequent incontinence. Recurrence is associated with smoking, recurrent disease, Crohn's disease, prior horseshoe abscess, and elevated BMI [93–97]. Contraindications include Crohn's disease, undrained sepsis, persistent secondary tracts, fistula diameter greater than 3 cm, malignancy or radiation-related etiology, and anorectal stricture [98]. Recently, Yellinek et al. evaluated flap configuration and did not show significant difference in recurrence between rhomboid designed flap (64%) and elliptical flap (62%) [99]. Likewise, there is no change in success between standard curette debridement and fistulectomy excision of fistula tract[86]. Repeat endorectal advancement flap is feasible and carries with it good success rates; however, it is also associated with a higher rate of recurrence than initial ERAF repair [100, 101].

Importantly, while this procedure does not directly divide sphincter muscle, incorporation of sphincter fibers in the advancement flap to varying degrees does lead to worsening continence in up to 35% of patients [86, 102].

Both anal fistula plug and fibrin glue have been suggested as adjuncts to endorectal advancement flap to improve success. Studies evaluating addition of fibrin glue to ERAF unfortunately revealed higher rates of failure than with flap alone [93, 103]. Likewise, advancement flap closure over a

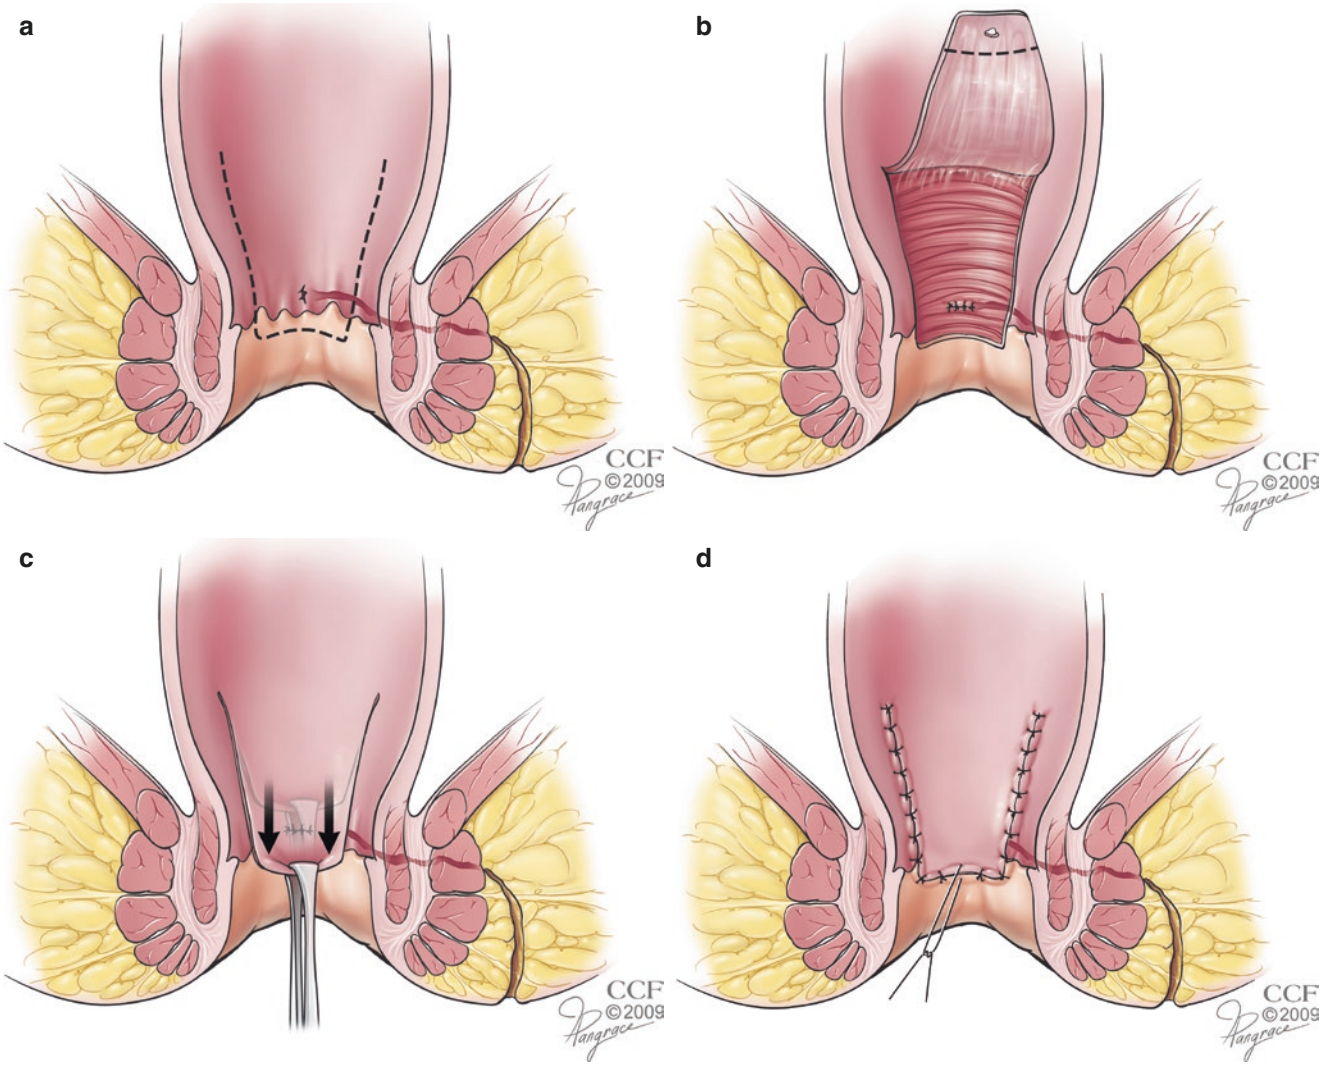

Fig. 13.13 (**a**): Dotted line represents the outline of intended tissue flap harvest. (**b**): Mucosal/submucosal flap raised with appropriate dimensions as well as area at the tip, intended for excision. (**c**): Flap being stretched into place after closing the internal opening at the muscular level. (**d**): Completed endorectal advancement flap. fistula plug does not confer improved healing as compared to fistula plug alone. It may be beneficial to incorporate platelet-rich plasma with ERAF [104]; however, additional studies are required.

An alternative flap design is described using a dermal advancement flap instead of a mucosal flap (Fig. 13.14), which carries with it the theoretical decreased risk of mucosal ectropion. Such flaps can be fashioned in a "house" or "diamond" configuration or as V-Y advancement of perianal skin. Studies evaluating this therapy are heterogeneous, making it difficult to make definitive recommendations. Overall, this procedure is safe and has low to moderate rates of incontinence (10–20%) [92, 105] and moderate rates of success (50–70%) [98, 106–109].

Ligation of Intersphincteric Fistula Tract (LIFT)

Similar to ERAF, ligation of intersphincteric tract (LIFT) is now widely accepted as a first-line treatment for complex fistula-in-ano due to reasonable success rates and sphincter preservation [19]. LIFT was developed as a "total sphincter preserving" technique in 2007 by Rojanasakul et al. [110]. This procedure entails dissection of intersphincteric space until the mature fistula tract is encountered and subsequently divided and doubly ligated (Fig. 13.15a–d). The internal and external wounds are debrided and left open to drain. In the initial description in 2007, authors reported 94.4% healing rate with 0% rate of incontinence [110]. A subsequent retrospective observational study of 251 patients by the initial authors reported 87.7% rate of healing [111]. Limitations

include lack of reporting on complications, specifically changes to continence, and varied patient population (55.8% low transsphincteric, 10.8% intersphincteric, 6.0% high transsphincteric, 25.5% semihorseshoe ischioanal, 2.0% horseshoe ischioanal). As many studies of sphincter-sparing techniques include only complex fistula-in-ano, it is important to consider that the patient population in this review was comprised of 66.6% simple anal fistulas. Overall, rates of success range from 61% to 94% with rare instances of change in continence [112–117]. Interestingly, recurrence was associated with shorter fistula tract ($p < 0.01$) [117]. When the LIFT procedure fails, it most often results in drainage via the intersphincteric incision as a persistent intersphincteric fistula which can subsequently be managed with simple fistulotomy [118–120]. Madbouly et al. randomized 70 patients to LIFT or endorectal advancement flap (ERAF) [121]. Authors observed initial success rates of 94% and 91% for the LIFT and ERAF groups, which fell to 74% and 66% after 1 year follow-up, respectively, emphasizing the importance of length of follow-up and risk of late failure. A recent meta-analysis of the topic indicates that results from ERAF and LIFT are quite similar [122].

Fig. 13.14 Anocutaneous advancement flap (from outside to inside). Can be used when creating an endorectal advancement flap leading to a mucosal ectropion

Variations of the LIFT technique have been suggested: BioLIFT, LIFT plus, LIFT-PLUG, LIFT + ERAF. The BioLIFT incorporates a bioprosthetic graft placed in the inter-

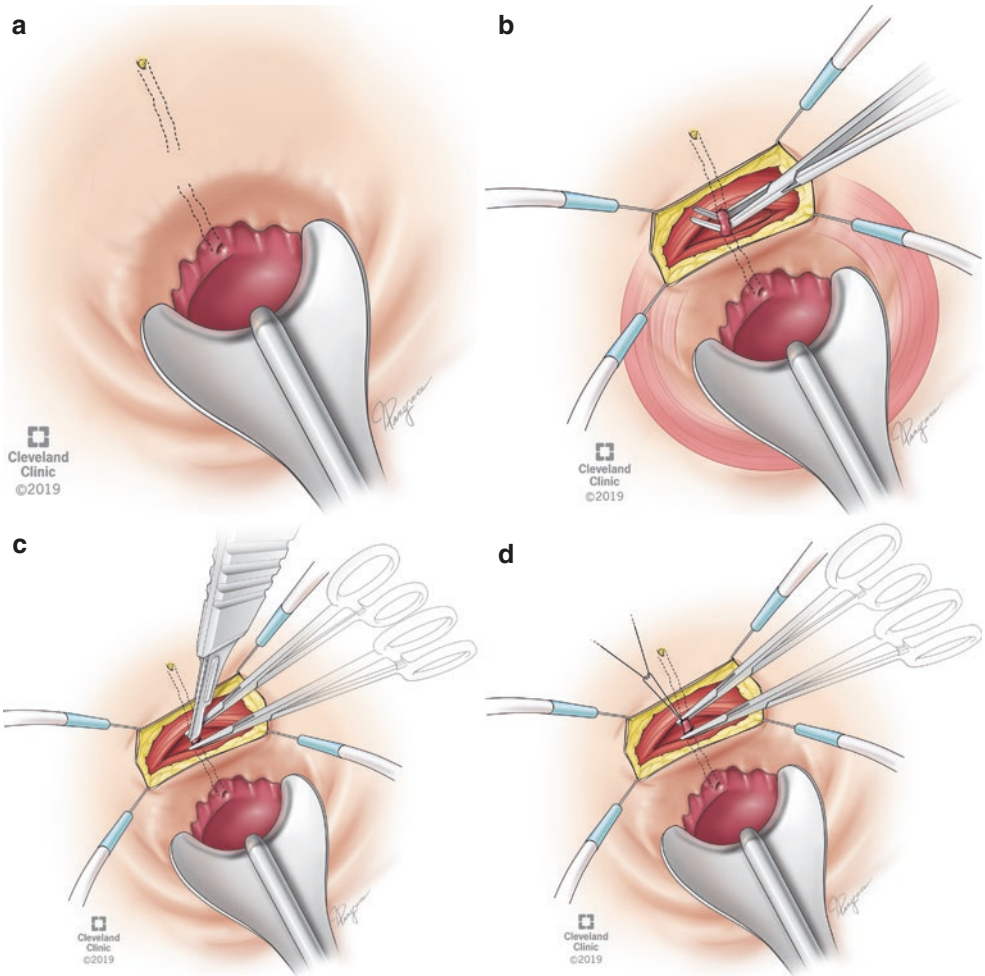

Fig. 13.15 (**a**): Transsphincteric fistula tract, illustrating the intersphincteric portion of the tract prior to incision for LIFT. (**b**): Intersphincteric incision with isolation of the intersphincteric portion of the tract. (**c**): Division of the intersphincteric portion of the tract. sphincteric plane with the goal of decreasing communication between the two portions of the fistula tract. Concern regarding this procedure surrounds the risk of additional intersphincteric dissection to accommodate the prosthesis as well as the cost of the bioprosthetic. Lau et al. evaluated LIFT and BioLIFT and found similar success rates of 80.2 and 81.9%, respectively [123]. Thus far, BioLIFT cannot be supported as an advantage based on the cost and equivocal results.

Han et al. evaluated traditional LIFT procedure with the LIFT-PLUG procedure [124]. In this operation, a bioprosthetic plug is passed through the previously debrided external sphincter tract via the intersphincteric incision and secured in place. These authors observed shorter healing time (22 days vs. 30 days, $p < 0.001$) and higher primary healing rate (94.0% vs. 83.9%, $p < 0.001$) in the LIFT-PLUG group than the standard LIFT group, respectively.

The LIFT plus procedure incorporates a partial fistulotomy of the distal tract external to the external sphincter to promote external drainage. LIFT plus may confer an advantage over LIFT with success rates of 85% vs. 81% (0.0529) as observed by Sirikurnpiboon et al. [125]. Overall, with the current data available, none of these three techniques can be confidently recommended over standard.

Novel Surgical Therapies

Fistula Tract Laser Closure (FiLaC™)

Closure of an anal fistula tract using radially emitting laser probe was first described in 2011 and subsequently in 2014 as a novel technique to heal simple and complex anal fistulas without risk to continence [126–128]. In its initial description, the authors described mechanical tract debridement with endorectal advancement flap, followed by laser treatment of the tract with a radial fiber connected to a diode laser [126]. Subsequent descriptions did not include endorectal advancement flap. Success rates were reported at 77–82% in these initial small series with no instances of incontinence. Since then, additional studies observed a decrease in primary success rates of 33–71% [129–131]. In those with primary failure, secondary success was achieved in some with repeat-FiLaC™, fistulectomy with sphincter repair, or primary fistulotomy that was possible due to distal migration of the tract after FiLaC™. Increased success was associated with intersphincteric-type, short fistula tract (<30 mm) and history of prior seton. One study to date has described minor mucous or gas incontinence at a rate of 1.7% during their median 25.4-month follow-up [131].

Video-Assisted Anal Fistula Treatment (VAAFT)

Meinero and Mori first described the video-assisted anal fistula treatment (VAAFT) procedure in 2006, with which they observed promising success with 74% primary closure rate and 87% overall healing after 1 year of follow-up [132]. This procedure is characterized by direct visualization of the primary fistula, secondary tracts, and internal opening. A Karl Storz fistuloscope is passed through the external opening to the internal opening with continuous glycine-mannitol irrigation. Once the internal opening is identified, it is marked with a stay suture. A unipolar electrode is inserted into the fistuloscope to fulgurate the fistula walls including the openings to any secondary tracts. This is followed by debridement of necrotic material with a brush and finally closure of the internal opening, traditionally with surgical stapler, absorbable suture, or advancement flap. The closure may be further enforced by fibrin glue injection just beneath the prior internal opening. This procedure is similar in many ways to the FiLaC™ procedure but, however, has the additional benefit of direct visualization.

Garg et al. evaluated VAAFT with a meta-analysis of 8 studies including 786 patients [133]. The authors identified a 76% success rate, 16.2% complication rate, and no reports of worsening level of continence. In a subsequent meta-analysis by Emile et al. of 788 patients across 11 studies, rates of success remained high at 86.8% after medial follow-up of 9 months [134]. Complication rate remained low at 4.8% observed. Interestingly, recurrence rates varied by type of internal opening closure. Staple closure was the lowest at 15.3%, followed by suture closure 17.7%, and lastly recurrence was highest with advancement flap closure. VAAFT is a promising technique in the growing field of fistula management.

Fistulotomy with Primary Anal Sphincter Reconstruction

Fistulotomy was previously only regarded as an appropriate treatment for simple anal fistula given the increasing risk of incontinence with increasing fistula complexity. In recent years, there have been several promising studies evaluating the role of fistulotomy with primary sphincter reconstruction (Fig. 13.16a–c). These studies reveal high success rates (91–96%) and low incontinence rates (2–13%), with the post-defecation soiling being the most common type of de novo incontinence [135–138]. Risks of recurrent disease and incontinence were significantly increased in those with prior recurrent fistula, complex fistula, presence of secondary tracts, and prior seton drainage. In this technique, a primary fistulotomy is performed, with or without fistulectomy, followed by end-to-end primary sphincteroplasty with dissolvable sutures. Proponents of this technique argue its favorable success and complication profile as compared to many of the other surgical options for complex anal fistulas.

Stem Cell Therapy

There has been a lot of excitement regarding autologous stem cell therapy in the treatment of fistula-in-ano. In a phase

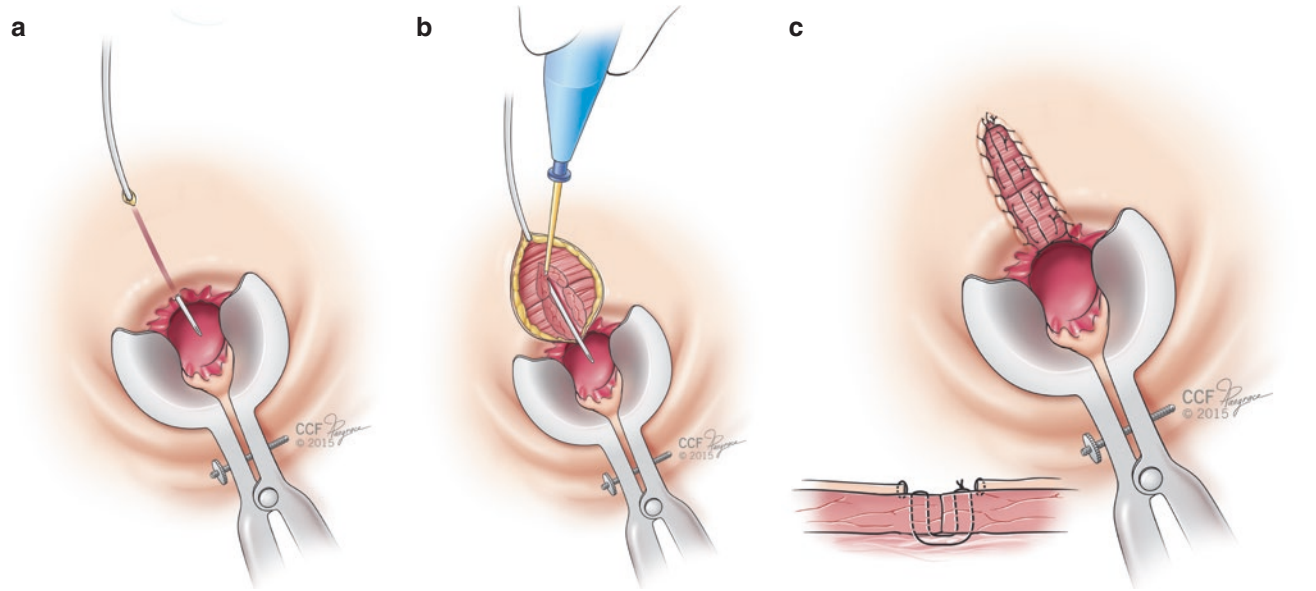

Fig. 13.16 (**a**): Transsphincteric fistula with indwelling probe prior to fistulotomy. (**b**): Fistulotomy performed over probe. There is an appreciable amount of external sphincter being divided. All Rights Reserved)

II clinical trial, Garcia-Olmo et al. randomized 35 patients to fibrin glue alone or fibrin glue with 10 million adipose-derived stem cells [139]. Their study observed a 4.43 increased relative rate for healing (CI 1.74–11.27, $p < 0.001$) in those with adipose-derived stem cells in addition to fibrin glue (71% healing vs. 16%). Unfortunately, healing rates decreased from 71% to 62.5% in the stem cell group at 1-year follow-up. In their phase III trial, Herreros et al. on behalf of the FATT collaborative group performed a multicenter, randomized, single-blind clinical trial of 200 patients over 19 centers [140]. Participants were randomized to the following treatments after uniform closure of the internal opening: 20 million stem cells, 20 million stem cells with fibrin glue, and fibrin glue alone. There was no significant difference between groups at both 24–26-week and 1-year follow-up, ~40% and ~50%, respectively. The authors pointed out that the results were much more promising at their pioneer center, with healing rates at 24–26 weeks of 54.56%, 83.33%, and 18.18% for the stem cell alone, stem cell + fibrin glue, and fibrin glue alone groups, respectively ($p < 0.001$). Additional studies are ongoing regarding stem cell therapy including combinations with fibrin glue, plasma-rich protein, and coated fistula plugs [141–143].

Over the Scope Clip (OTSC® Proctology)

In 2012, Prosst and Ehni described the use of a clip to close the internal opening, using the OTSC® Proctology device. In this procedure, a super-elastic nitinol clip is placed with a specialized endoscope over the internal fistula opening. Initial small series observed success rates of 60–93% healing rates, with decreased healing in those with prior fistula operations. Discomfort from the clip was reported as minimal by study participants; however, the clip did require removal with the OTSC® Proctology clip cutter in the majority of cases [144–148]. This is a promising device; however, there is inadequate evidence to support its routine acceptance. Additional studies are required evaluating success, risks for failure, complication, and device cost.

Recommendation

There are a few main take-home points to consider in the management of acute anorectal abscess and anal fistula. In a patient with demonstrable abscess on physical exam, surgical drainage is the standard and can often be done in the office under local anesthesia with careful technique. Antibiotics are reserved for special circumstances including cellulitis and sepsis. Cure and preservation of continence are the overriding goals in the management of anal fistula, with continence perhaps taking precedence. A patient's quality of life would generally be better with an indwelling loose seton as opposed to living with significant incontinence. It is important to be aware of the multitude of methods that can be used to treat anal fistula. Failure rates of sphincter-sparing approaches are significant, and when one method fails, it is often useful to proceed to another. The importance of informed consent cannot be overemphasized. Failure rates should be discussed, expectations set at the onset, and patients well aware of their alternatives.

Rectourethral and Complex Fistulas: Evaluation and Management

14

Jan Rakinic and W. Brian Perry

Key Concepts

- Rectourethral fistula (RUF) is an uncommon but potentially devastating condition which may significantly impact a patient's quality of life.
- Treatment of prostate cancer is most common etiology.
- Up to 45% of simple RUF may heal with fecal diversion alone.
- Ultimate repair may be quite complex, involving a multispecialty team approach over the course of several procedures.
- Surgical repair with interposition of well-vascularized tissue has good outcomes, though radiation confers higher risk for permanent fecal or urinary diversion.

Introduction

Rectourethral fistula (RUF) is an uncommon but potentially devastating condition which may significantly impact a patient's quality of life. Ultimate repair may be quite complex, involving a multispecialty team approach over the course of several procedures. This chapter discusses acquired rectourethral fistulas in adults; congenital RUFs which are typically found and treated in the neonatal period are not covered in this chapter.

Etiology

The vast majority of acquired RUF are iatrogenic following treatment of prostate cancer, which is more frequently multimodal than in past years. Inflammatory bowel disease and pelvic infections may also cause primary RUF, though far less frequently. Traumatic pelvic injuries from vehicular trauma, other trauma with pelvic fracture, or battle-related instances may also lead to RUF. Kucera reported three soldiers with complex penetrating perineal injuries who required RUF repair in a staged manner over several months, illustrating the complex nature of these injuries and their management [1].

RUF complicates radical retropubic prostatectomy in 1–6% of cases, regardless of whether the procedure was performed open, laparoscopically, or robotically. The prostatic urethra is separated from the anterior rectal wall only by Denonvilliers' fascia and capsule of the prostate, making it vulnerable to damage and fistulization. Many of these RUFs result from unrecognized rectal injury or failed rectal repair at the index operation and typically occur at the vesicourethral anastomosis. The incidence of rectal injury at prostatectomy has been reported from 0.1% to 9% [2, 3]. In one review, 54% of patients who developed an RUF had an overt rectal injury. Other non-ablative risk factors for RUF include age, prior transurethral resection of the prostate, bacterial prostatitis, previous hormonal therapy, and a perineal operative approach [4].

The addition of radiation to the treatment of prostate cancer contributes significantly to RUF formation. Ionizing radiation leads to microvascular injury, mucosal ischemia, and tissue fibrosis. Prior to 1997, less than 4% of RUF had received radiation; from 1998 to 2012, more than 50% involved some form of radiotherapy [5]. When used as stand-alone primary therapy, the rate of RUF for external beam radiotherapy (EBRT) is about 1%, and, for brachytherapy, about 3% [6, 7]. Combining the two modalities increases the risk regardless of the order or isotopes employed. The rate of RUF after newer modalities such as cryosurgery and high-intensity focused ultrasound (HIFU) is around 2% currently [8].

The incidence and complexity of RUF increase markedly during salvage therapy for a biologically or histologically confirmed prostate cancer recurrence after EBRT. Regardless of the salvage method employed – prostatectomy, cryosurgery, HIFU, or BT – rates of RUF range from 3% to 6% to as high as 60% [9–11]. These RUFs are among the most complex, with large fibrotic connections in a field of poor-quality tissue. Concomitant urethral and rectal strictures as well as sexual and urinary dysfunction are common [5].

Iatrogenic RUF may also occur following low rectal resections for rectal cancer or salvage resections for anal cancer; these patients have often also received pelvic radiation. Secondary rectal cancer following EBRT is a concern, occurring 5–15 years posttreatment [12]. Rectal biopsies, especially anteriorly, may be the final precipitating event in the formation of RUF and should be performed with great care in this situation [13]. Other elective rectal and anal surgeries can rarely lead to RUF, including fistulotomy and stapled hemorrhoidopexy. [14]

Clinical Presentation

RUFs due to a complication of prostatectomy typically present with the first 2–4 weeks after surgery [15]. Radiation-associated RUF can present up to 14 years after the last radiotherapy dose, supporting the role of long-standing tissue damage in these patients. Patients with RUF may present with fecaluria, pneumaturia, and pelvic or bladder pain. The passage of urine per rectum on attempted urination is often reported. Recurrent urinary tract infections are common. In one series, over 80% had preexisting erectile dysfunction [16].

Diagnostic Evaluation

Physical examination will often reveal a defect in the anterior rectal wall 5 to 6 cm from the anal verge. Direct visualization of the tract with cystoscopy and colonoscopy will help establish the location and size of the fistula and the quality of the surrounding tissues and allows for biopsy of any areas suspicious for recurrent malignancy. Voiding cystourethrography or gastrograffin enema may yield additional information. Axial imaging and computed tomography or magnetic resonance imaging are useful adjuncts, especially when other modalities are equivocal [4]. If possible, the functional status of the urinary system should be assessed with a urodynamic evaluation. Those with severe underlying incontinence or voiding dysfunction are unlikely to see significant improvement after RUF repair and may be better served by permanent urinary diversion [17].

Classification

Rivera et al. have proposed this classification system for RUF, based on location, size, and patient history, to help guide treatment decisions and standardize reporting [18]. Not all authors have adopted this schema.

- Stage 1 – <4 cm from the anal verge, nonirradiated
- Stage 2 – >4 cm from the anal verge, nonirradiated
- Stage 3 – <2-cm-diameter fistula regardless of distance in a patient with prior radiation
- Stage 4 – >2-cm-diameter fistula regardless of distance in a patient with prior radiation
- Stage 5 – ischial decubitus fistula

Most other authors separate RUF into simple and complex fistulas. Simple RUFs are small (<1 cm), nonirradiated, with minimal symptoms, no associated sepsis, and no previous repair attempt. Complex RUFs are larger (>1 cm), with other complicating factors that may include previous radiation or cryotherapy, urethral stricture, sepsis, or previous failed repair.

Management of Rectourethral Fistula

Management of rectourethral fistula (RUF) depends on the fistula size and etiology, as well as the familiarity of the managing team with a particular approach. If a neoplasm is the cause of the RUF, management of the neoplasm must take precedence. Similarly, in the setting of Crohn's disease, medical management must be optimized before any attempt is made to intervene on the fistula. Readers are directed to the chapters on these entities for further information.

RUF is best managed with a multidisciplinary team including a colorectal surgeon, a urologist, and often a reconstructive/plastic surgeon. When the initial assessment has been completed, patients fall into one of two groups: simple or complex RUF. It is important to remember that a significant number of patients with RUF may heal without surgical intervention. A spontaneous closure rate of 14–46% was reported after fecal diversion alone [19], and some patients with a small RUF will heal with urethral catheter drainage alone [2]. Figure 14.1 shows an algorithm for assessment and management of RUF [19].

Many RUFs identified following laparoscopic or robotic prostatectomy are classified as simple [2]. Initial manage-

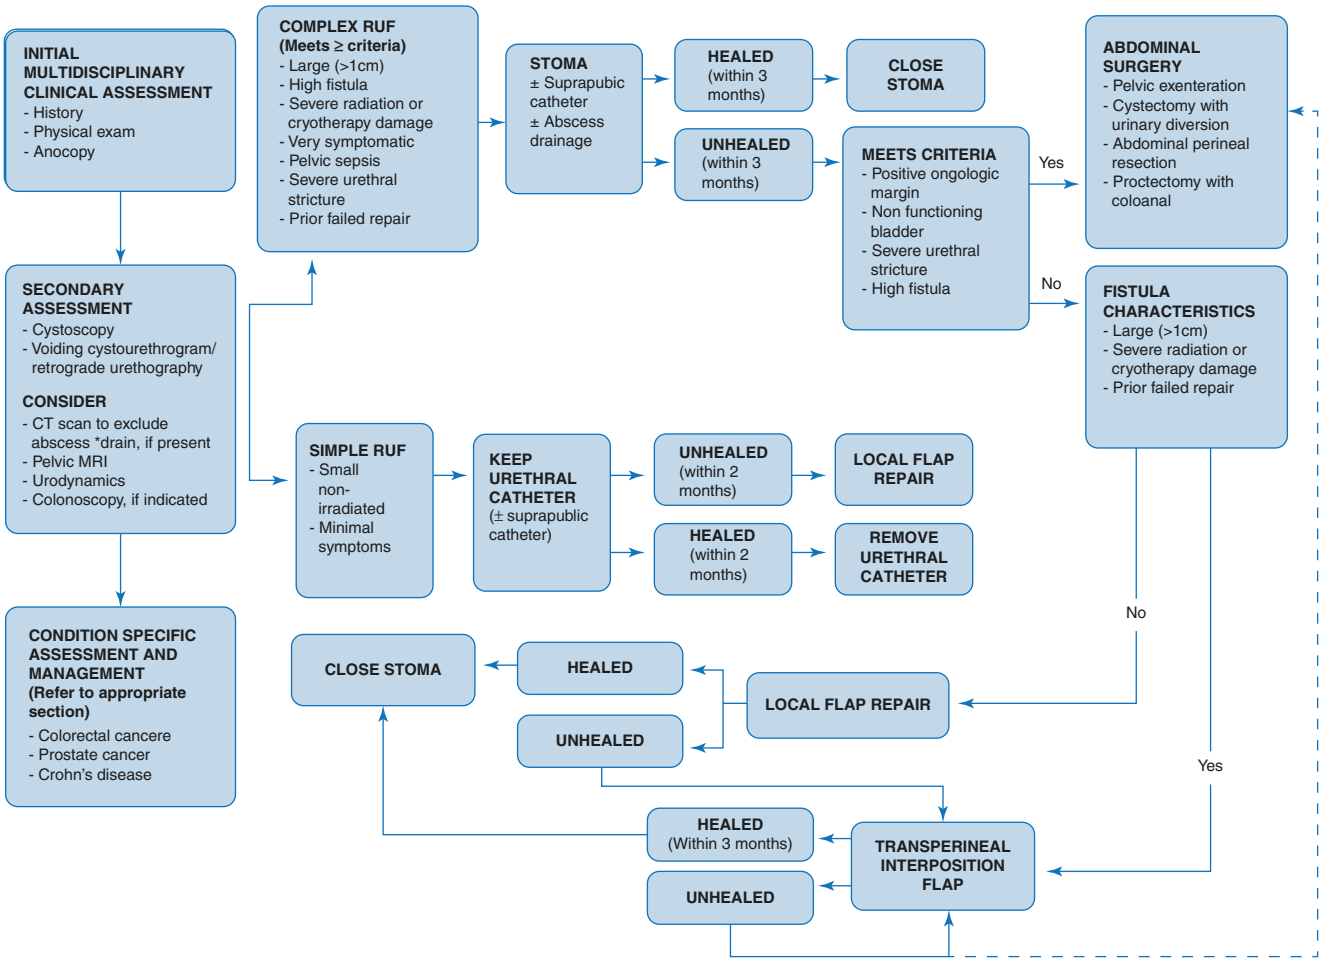

Fig. 14.1 RUF management algorithm. (Reproduced with permission from ASCRS Textbook of Colon and Rectal Surgery, third edition)

ment consists of urinary catheter drainage for 2–3 months. If the fistula heals, the catheter is simply removed. If the fistula has not healed, a local flap repair is indicated. A transanal flap is a good option in this situation, and fecal diversion is not required. If the local flap repair fails to heal, fecal diversion should be done. If the fistula remains unhealed after 2–3 months of fecal diversion, repair should be accomplished by either repeat local flap repair or transperineal repair approach with an interposition flap of gracilis or dartos muscle.

RUFs following external traumatic injury are most often complex [1]. These situations are managed initially with fecal diversion and often suprapubic bladder drainage to minimize fistula symptoms. Abdominopelvic imaging should be obtained to assess for pelvic abscess; if present, drainage is indicated. Most algorithms call for reassessment of the fistula after 3 months of fecal diversion/bladder drainage. Both endoscopic and imaging assessment is recommended, with evaluation of healing from both the rectal and urinary sides. If healing has occurred, the stoma is closed.

If the RUF remains unhealed after fecal diversion, and the patient is a poor operative candidate or refuses further surgery, permanent diversion is an option to manage symptoms. For those patients desiring definitive management, several options exist. For patients with positive oncologic margins after prostatectomy, a nonfunctioning bladder, or other intrapelvic complications, an abdominal approach should be considered. Rectal salvage may be possible in some cases. Otherwise, a transperineal or transanal approach is most commonly employed. A posterior (parasacral or transsphincteric) approach may also be utilized, though this is used less commonly now for reasons that will be discussed. Other techniques, such as puborectalis flap or large endoscopic clip closure, have been described in the literature with small numbers of patients and short follow-up.

Transanal Approach

Transanal repair with an endorectal advancement flap is a good option for a simple RUF. Absence of anal or rectal

stricture is a prerequisite; fecal diversion is not required. The technical details of the flap itself have been aptly described in the chapter on anal fistula (see Chap. 15); TEM platform can also be used to perform the procedure. The flap is outlined and mobilized as usual. The fistula is identified and divided, and the rectal wall is dissected away from the urethra sufficiently to provide exposure. The opening into the urethra is debrided of any granulation tissue. Small fistulas rarely require augmentation of the urethra. Pliable normal tissue such as pararectal fat, if available, can be approximated over the urethral opening of the fistula with interrupted 3–0 absorbable suture; polyglactin (Vicryl) is ideal. Some authors advocate introduction of a biologic mesh into the space between the rectal wall and the urethra; if used, this is parachuted in and secured with further 3–0 absorbable sutures (Fig. 14.2). The endorectal advancement flap is then brought into place and secured with interrupted 3–0 polyglactin sutures. The urethral catheter is maintained for 4–6 weeks before assessing fistula healing.

Transperineal Approach

Transperineal is the preferred approach for RUFs that require interposition of healthy, well-vascularized tissue. Successful closure rates are approximately 90% regardless of radiation or ablative therapy history. This technique allows good exposure for low and mid-rectal RUFs. For low, small RUFs, a

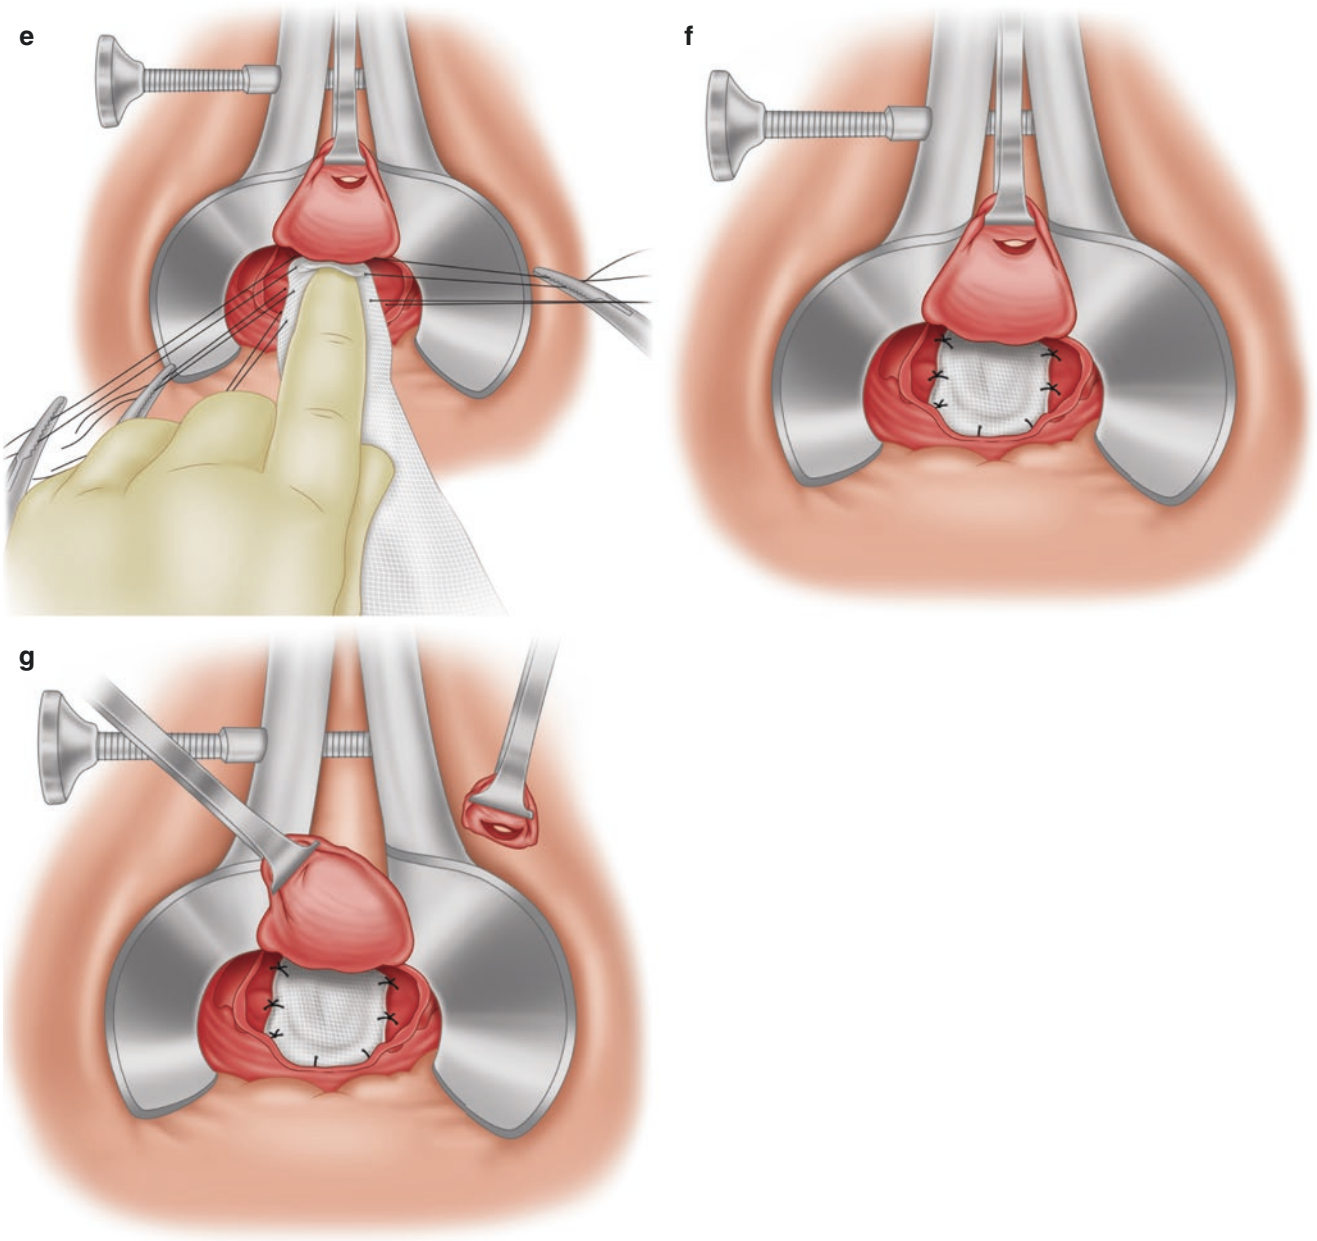

Fig. 14.2 (continued)

dartos muscle flap provides adequate tissue bulk with good reach. The entire operation is performed with the patient in prone jackknife position with excellent exposure. A U-shaped incision is made starting laterally on the perineum, extending onto the posterior scrotum and back up to the opposite side of the perineum (Fig. 14.3). The incision is carried down through the dermis and dartos muscle. This flap is dissected off the testicular tissue, progressively freeing the flap posteriorly to the transperineal edges of the skin incision. Dissection now proceeds into the rectoprostatic plane, anterior to the anal sphincters. The fistula is identified and separated; dissection proceeds another 3–4 cm cephalad. Adequacy of the urethral tissue is assessed; the urethra may be augmented with buccal mucosa [20] or biologic mesh at this point if indicated. Urethral closure is accomplished with 3–0 absorbable suture. Bladder may be imbricated over the closure if possible. Closure of the rectal defect is then performed with 3–0 absorbable suture; horizontal closure is preferred to minimize possible narrowing of the rectal lumen.

The skin is removed from the Dartos flap up to the transperineal incision. The flap is rotated upward into the dissected space. Sutures are placed into the flap edges, and the flap is parachuted into the dissected space with guidance to cover the entire dissection bed. Additional sutures are used to secure the

(**c**) View of completed repair of fistula openings in rectum and urethra. Solid black arrow points to rectal mucosa. Solid white arrow points to urethral repair. (**d**) Dartos flap denuded of skin in preparation for placement between the fistula repair sites. (**e**) Tacking sutures are placed adjacent to the rectal and urethral repairs; these will be used to parachute the flap deep into the space between the rectum and urethra and secure the flap. (**f**) Completed dartos repair with soft tissue of perineum coapted. (Reproduced with permission from Varma et al. [21]. Copyright © 2007 Wolters Kluwer)

flap as needed. The wound is then closed in layers over a small drain. Varma et al. reported on eight patients managed with a dartos flap. Half had undergone a previous repair attempt; all had fecal diversion and either urethral or suprapubic urinary diversion as well. Six healed without complication. Of the two failed repairs, one had previous radiation for prostate cancer, and the other had a history of HIV [21].

A gracilis flap is preferable for larger, higher, or radiated RUFs. The harvest of the gracilis flap may be performed in lithotomy or prone position, depending on surgeon preference. The gracilis muscle is traced externally about 4 cm posterior to the adductor muscle (Fig. 14.4a). Three small longitudinal incisions are made over the muscle's course; Penrose drains are placed around the muscle at each of these

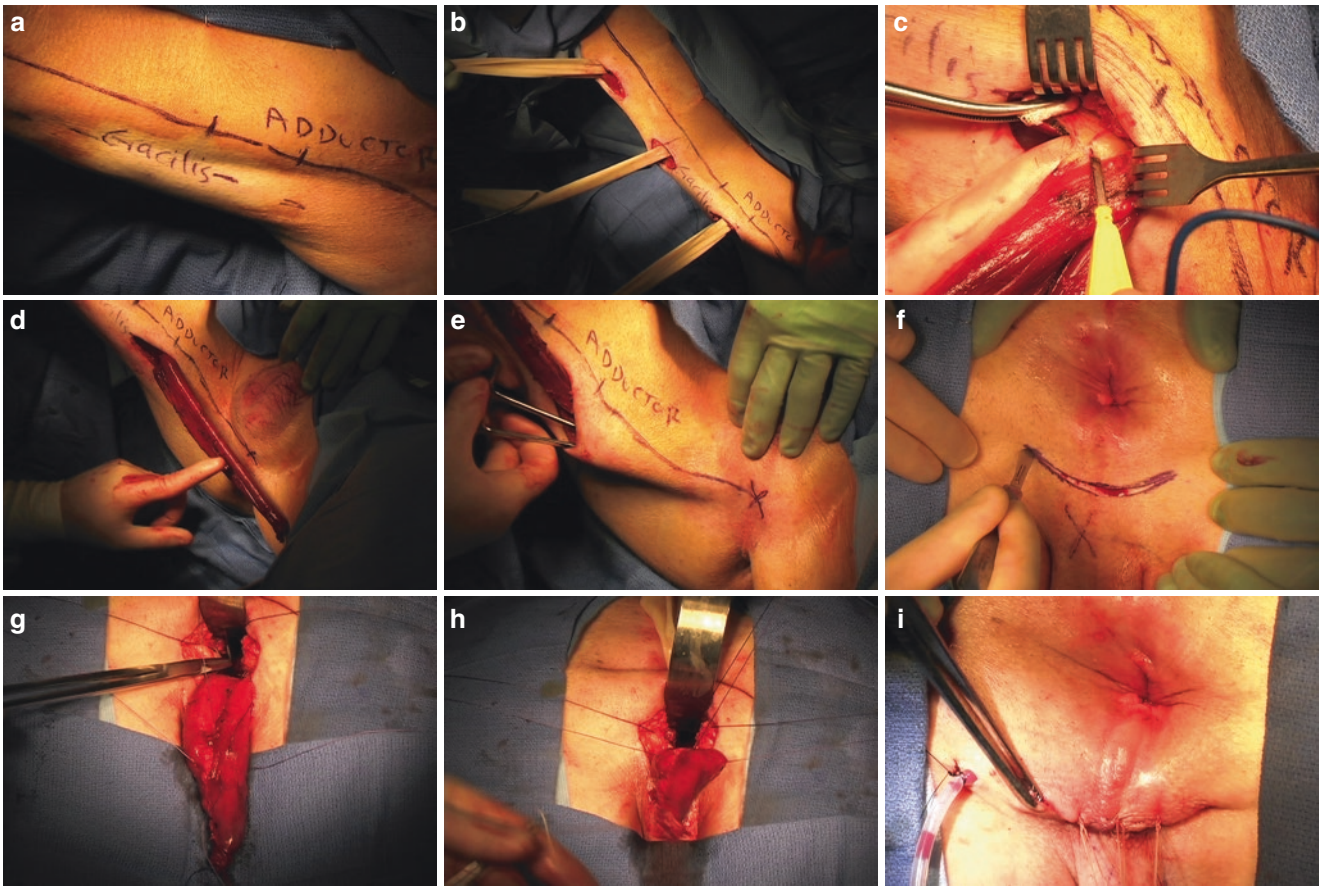

Fig. 14.4 Intraoperative pictures of gracilis muscle interposition flap for transperineal repair of rectourethral fistula. (Special thanks to G.A. Santoro and M.A. Abbas)

sites (Fig. 14.4b). The distal insertion at the medial aspect of the knee is disconnected, and the gracilis muscle is dissected off of surrounding tissue from distal to proximal. Small perforators from the superficial femoral vessels are clipped and divided. Care is taken to preserve the major neurovascular bundle which is typically located within 10 cm of the pubic symphysis (Fig. 14.4c). The freed portion of the muscle is exteriorized through the most proximal skin incision and rotated to ensure adequate length for perineal coverage (Fig. 14.4d). A large clamp is used to create a subcutaneous passage to tunnel the flap from the medial thigh into the *perineum* (Fig. 14.4e). The thigh incisions are closed over a small drain. If performed in lithotomy, the patient is then turned to prone jackknife position. The perineal dissection proceeds as outlined above (Fig. 14.4f). The gracilis flap is parachuted into the dissected perineal space as described above (Fig, 14.4g, h). If the muscle bulk is excessive, it may be carefully tailored. Additional sutures are placed to secure the flap as needed; the incision is closed in layers over a drain (Fig. 14.4i).

Posterior Approach

Posterior approaches have been used for years to manage RUFs. The overall success rate, about 88%, is similar to that of the transperineal approach, but most of the data on posterior approaches has come from nonirradiated patients. The use of these approach has decreased significantly over that last 15 years, in part because fistulas are now generally more complex and due to other issues such as limited exposure, inability to manage urethral stricture or bladder neck issues concurrently, and limited use of interposition flap. The York-Mason technique proceeds by posterior sagittal division of the anal sphincters, levators, and posterior rectal wall, exposing the anterior rectal wall and the fistula. The fistula is divided; urethral and then rectal walls are repaired. The incision is then closed in layers, reapproximating the rectal wall and each muscle layer meticulously. Major complications include rectocutaneous fistula and sphincter compromise. The Kraske technique uses a parasacral incision, coccygeal resection, and division of the anococcygeal ligament to

expose the posterior rectal wall. The posterior rectal wall is opened to provide exposure of the anterior rectal wall and the fistula. Fistula repair proceeds as outlined above. The proctotomy is closed, and the remainder of the incision is closed in layers over a drain.

Posterior approaches are used much less frequently today. Currently, transperineal approach with tissue interposition is favored for most complex RUFs. Patients with RUFs considered too high to approach transperineally, or with other intrapelvic issues, are best managed with a transabdominal or combined approach.

Transabdominal Approach

This approach is best suited for RUF patients with concomitant complex intrapelvic problems which cannot be adequately addressed with a perineal or posterior approach. Patients with positive oncologic margins after prostatectomy require a transabdominal approach for definitive management. Other complex situations such as nonfunctional bladder, strictured urethra, and previous failed repair attempt may also fall into this category. The approach and planned operation are tailored to patient and disease factors. Options include cystectomy and urinary diversion with rectal repair, proctectomy with coloanal anastomosis, abdominoperineal resection, and pelvic exenteration.

Rectal preservation vs. need for proctectomy must be carefully considered; a second attempt at low pelvic dissection and repair carries a much higher risk for failure than the initial attempt. If the rectal tissue is healthy, the fistula is not overly large, and healthy tissue can be obtained for interposition, then repair with omentum or rectus interposition may be a good choice. The urinary procedure should be accomplished first. Primary repair of the rectal wall follows. Omentum is mobilized, preserving the left gastroepiploic artery as a main blood supply. Sutures are placed to parachute the flap into position anterior to the rectal repair. Additional sutures are placed as needed to secure the flap into place. Rectus abdominis flap may also be used, with reconstructive surgery colleagues as co-surgeons.

If the rectal defect is too large for primary closure and tissue quality is poor, proctectomy with or without coloanal anastomosis is indicated. Dissection is carried down to the levator muscles to reach below the fistula. The rectum can be divided with a stapler, and a stapled coloanal anastomosis can be performed. For a very low fistula, mucosectomy or intersphincteric dissection from below may be needed to complete the dissection, with a handsewn anastomosis performed for intestinal continuity. If sphincter preservation is not indicated, the stump of rectum or anal canal can be left in place and an end colostomy performed, avoiding the morbidity of a perineal incision. If, however, there is an indication for a formal abdominoperineal resection, that can be performed.

Other Approaches

Reports of other approaches with small patient numbers appear with some regularity in the surgical literature. Solomon et al. reported on four RUF patients (one with history of radiation, one with Crohn's) in whom a bilateral puborectalis interposition was used via a transperineal repair approach. The puborectalis muscle is exposed bilaterally, mobilized as a 1-cm-wide strip, and released posteriorly at the level of the anorectal junction. The muscle strips are rotated medially and superiorly and overlapped to cover the closed fistula openings. Each muscle flap is stitched into place with absorbable suture; the wound is closed over a drain. All fistulas were healed at median 8 months' follow-up [22]. The smaller size of the available muscle limits this approach somewhat. Anecdotal reports of fibrin glue abound, usually as a low-risk attempt in a poor surgical candidate. Similarly, case reports of fistula cauterization and large over-the-scope-clips also appear; reported follow-up is short. These approaches have not entered the mainstream of RUF management.

Outcomes of RUF Repair

The outcome of RUF repair is variable. There is wide variation in patient populations and techniques, and patient selection clearly plays a role. Nearly all reports are series, with no randomized controlled trials due to the rarity of this problem. The reported overall fistula closure rate after repair is 68–100%. However, closure of intestinal or urinary diversion is significantly less likely in radiated patients.

The transanal approach is safe and effective in small, low (by definition nonradiated) RUFs. Garofalo et al. reported on 12 patients with RUF who underwent rectal advancement flap closure. Primary healing was accomplished in 67% (8/12 patients). Two of the four recurrences underwent a second successful repair for a final success rate of 83% [23].

The transperineal approach with muscle interposition is currently the procedure of choice for complex RUFs which do not have concomitant intrapelvic complications. While good results have been reported using a dartos flap with 75% healing [21], the flap used most commonly is the gracilis muscle. A large systematic review reported postoperative RUF healing in nonradiated and radiated patients at essentially the same rate (89% vs. 90%). However, permanent fecal diversion in radiated patients was 25% compared to 4% in nonradiated patients. Similarly, permanent urinary diversion was 42% in radiated vs. 4% in nonradiated patients. The

initial closure rate with a transperineal approach was 90%; the flap most commonly used was the gracilis [24].

Kaufman et al. reported on a series of 98 patients with RUF who underwent transperineal repair with interposition muscle flap; 49 were nonradiation induced and 49 were radiation or ablation induced. At median follow-up of 14.5 months (range 3–144), 98% of nonradiated RUF were healed after one procedure, compared to 86% of radiated RUF. Gastrointestinal continuity was restored in 94% of nonradiated RUF and 65% of radiated RUF [25].

Tran reported on seven patients, six with radiation history, treated with transperineal fistula repair and gracilis flap interposition (three patients had been previously excluded due to large fistula size). All seven had fecal diversion while five had urinary diversion as well. At 11 months' mean follow-up, all had healed; three had fecal continuity restored, one was awaiting stoma closure, and three had permanent fecal diversion. Five had stress urinary incontinence and two were awaiting artificial urinary sphincter insertion. There was no morbidity related to the gracilis harvest [26]. Hampson et al. reported on 21 patients with RUF; all underwent transperineal repair and all but 1 had a muscle interposition (19 gracilis, 1 of which was bilateral; and 1 rectus flap). Initial success was 95% with mean follow-up of 2.6 years. Thirty-day morbidity was 19%. Fifteen patients were evaluable for long-term telephone follow-up; 53% reported perineal pain, and 43% reported residual problems related to the gracilis harvest [16].

A series from Cleveland Clinic of gracilis flaps employed in a variety of complex fistula repairs included 36 men with RUF, mainly secondary to treatment of prostate cancer. Thirteen of these had undergone previous failed repair attempts. Initial fistula closure rate was 78%, but postoperative complication rate was 47%. Eight patients who failed underwent a subsequent repair attempt which raised the overall healing rate to 97% in this series [27].

It is clear that patient selection leads to improved outcomes. In a series of nine patients with nonradiated RUF, all with a previous failed repair attempt, all were successfully managed with transperineal fistula division and gracilis interposition graft [28]. All but one had fecal continuity restored; none reported fecal dysfunction or difficulty walking related to the gracilis harvest. A small series from India reported outcomes of six patients with RUF resulting from trauma (2), prostatectomy for benign hypertrophy (2), and open radical prostatectomy (2), none with history of radiation. All were managed with transperineal fistula division, buccal augmentation of urethra, rectal repair, and gracilis interposition flap with 100% healing after mean 27 months' follow-up [29].

Outcomes after York-Mason approach for RUF reflect much the same: Adding a muscle interposition improves healing and radiation is associated with poorer outcome [30]. An Italian series of 14 nonradiated patients with RUF managed over 20 years with York-Mason approach reported that all healed successfully with the exception of the single patient with Crohn's who suffered RUF recurrence after 11 years. Eleven (79%) had diverting stomas closed [15].

Dafnis reported on 20 consecutive patients with RUF managed by York-Mason approach between 2002 and 2016. Initial repair was successful in 90% (18 patients), 1 with a dartos interposition; diabetes, smoking, and irradiation history were associated with failure [31]. Van der Doelen et al. reported results of 28 patients who underwent York-Mason repair for RUF between 2008 and 2018. Initial overall success rate was 64%; ultimate overall success rate was 75%. The ultimate success rate in nonirradiated patients was 89%, vs. 50% in radiated. Outcomes after radiation were much improved by use of a gracilis interposition: 100% healing (3/3 patients) with graciloplasty vs. 29% (2/7) without [32].

Conclusion

Adult-acquired RUF is a complex and relatively rare condition. The most common etiology is multimodality management of prostate cancer, though management of rectal cancer and traumatic injury can also result in complex RUF. Population data studies will be required to assess whether the use of multimodality treatment for prostate cancer is related to an increase in the incidence of RUF. Simple RUFs have good outcomes with diversion alone or local flap management without fecal diversion. More complex RUFs require a multidisciplinary approach. Repair of the fistula is most often managed with a transperineal approach utilizing a muscle interposition flap for best outcome. Other complex and recurrent fistulas may also be managed with an algorithm similar to the one proposed here: fistula definition, fecal and urinary diversion as deemed necessary, and repair with interposition of normal, well-vascularized tissue. There are no data to support higher closure rate with fecal diversion; performance is based on surgeon preference and clinical reasoning. Fecal diversion should be considered in large complex RUF with persistent symptoms affecting quality of life and individuals with medical comorbidities that increase risk of infectious complications and the sequelae thereof. Some authors have suggested performance of a diverting loop ileostomy at the time of RUF closure due to its relative ease of performance and closure. Ileostomy also leaves the colon fallow should a more extensive procedure such as proctectomy with low anastomosis be required. Patients who have had radiation continue to experience higher risk of repair failure, as well as higher risk that fecal and urinary diversion will be permanent. It is also important to note that complications related to gracilis harvest, the most common flap used, are not inconsequential.

Rectovaginal Fistula

15

Brooke H. Gurland and Jon D. Vogel

Key Concepts

- Rectovaginal fistula (RVF) may result from benign or malignant disease or iatrogenic causes.
- Diagnostic evaluation of RVF is based on history and examination and may be enhanced by radiological studies.
- Anal sphincter function is a key component in the evaluation and treatment of RVF.
- When infection complicates RVF, it must be resolved prior to definitive treatment of the fistula.
- Asymptomatic or minimally symptomatic RVF may not require intervention.
- RVF due to Crohn's disease may, in some cases, be effectively managed with medical therapy alone.
- Surgical treatment of RVF is influenced by the etiology of the fistula, its location, the integrity of the anal sphincter, and if it is a primary or recurrent fistula.
- In some cases, the use of a well-vascularized soft-tissue flap and/or fecal diversion may be required to effectively manage the RVF.

Rectovaginal fistula is an abnormal connection between the anal canal or rectum and the vagina and most often results from obstetrical injuries or Crohn's disease but may also be due to a variety of other conditions including infection, surgical complications, radiation, or malignancy [1–8].

Rectovaginal fistulas may be classified as "low," with a tract between the distal anal canal (dentate line or below) and the inside of the vaginal fourchette, "high" with a tract connecting the upper vagina (at the level of the cervix) with the rectum, or "middle" for those that lie somewhere between [9]. The terms "anovaginal fistula" and "low rectovaginal fistula" may be used interchangeably. Rectovaginal fistulas may also be classified as "simple" or "complex." Simple rectovaginal fistulas have a low, small-diameter (<2.5 cm) communication between the anal canal and vagina and result from obstetrical injury or infection [10]. "Complex" fistulas involve a higher communication between the rectum and vagina, or a larger opening, or result from radiation, cancer, or complications of pelvic surgical procedures [8, 10, 11].

Flatus and/or stool per vagina, pain, dyspareunia, and local skin and mucosal irritation are the typical symptoms of RVF and range in severity from minimal to severely debilitating. Evaluation of RVF is centered on the history of present illness, past medical and surgical history, and physical examination. Bowel movement frequency, consistency, and the patients' ability to defer defecation and flatus should be assessed. The amount of fistula drainage should also be estimated. In some cases, the use of diagnostic imaging, manometric studies, endoscopy, or examination under anesthesia may be required to adequately define the anatomy of the fistula and the integrity of the anal sphincter complex. When infection complicates a RVF, it should be addressed urgently and prior to attempts to repair the fistula. The definitive treatments of RVF cover a range of interventions from as simple as diet modification to as complex as rectal resection with staged coloanal anastomosis. Between these extremes are other surgical treatments that include endorectal and vaginal advancement flap, anterior overlapping sphincteroplasty, vascularized soft-tissue flaps, low anterior resection of the rectum with colorectal or coloanal anastomosis, and episioproctotomy with reconstruction of the anal sphincter. When choosing the type of surgery to repair a RVF, a variety of factors should be considered and include the severity of symptoms, the general health of the patient, fistula etiology, the integrity of the anal sphincter, the condition of the rectum (e.g., proctitis, stricture), the pliability of the vaginal epithe-

lium and vaginal length, and if there were previous unsuccessful attempts to repair the fistula [12]. The success of surgical repair is also dependent on these factors, and in many cases, multiple attempts at repair are required [7, 13]. For example, in a retrospective analysis of 125 patients with RVF, who underwent 184 various surgical procedures, only 57% were healed after the initial repair but this increased to 87% after multiple operations [7]. In a more recent review of 79 patients who had surgical treatment(s) of their RVF, 72% were eventually ultimately healed, but this required a mean of 3.6 ± 2.4 (range 1–10) surgical procedures [6]. Aside from surgery, in patients with Crohn's disease-related RVF, Infliximab alone may be sufficient for fistula healing [14].

Etiology of Rectovaginal Fistula

Rectovaginal fistulas may be the result of obstetric injury, Crohn's disease, cryptoglandular infection, a complication of colorectal anastomosis or anorectal surgery, malignancy, or radiation therapy (Table 15.1).

Obstetrical

Obstetrical RVF results from pressure necrosis of the rectovaginal septum that occurs during labor, laceration of the sphincter complex during delivery, or episiotomy [15, 16]. Injuries can be identified at the time of delivery at which point immediate repair should be performed under optimal conditions by a dedicated experienced surgical team [17]. While obstetrical causes have been reported as the most common cause of RVF, the actual contribution of this etiology may be hard to determine [12, 18–20]. For example, in single-center recent studies from the Mayo Clinic [21] and the Cleveland Clinic Florida [7], only 23% and 24% of RVF were caused by obstetrical injury. In a Norwegian population-based study, that included 182 females with enterogenital fistula, 42 (23%) were due to obstetrical injury, and of these, only 24 (13%) were classified as RVF [16].

Crohn's Disease

A 2019 systematic literature review and population-based data analysis indicated a 1% prevalence of rectovaginal fistula among females with Crohn's disease [22]. Similarly, in a longitudinal study of population-based cohort from the Netherlands, including 728 females with CD, the overall cumulative probability of being diagnosed with an RVF at 10 years was 3% [23]. Recent studies indicate that the incidence of RVF has decreased in the biologic era. In the IBD-South Limburg cohort, the cumulative 5-year rectovaginal rate declined from 5.7% in the period 1991–2005 to 1.7% in

Table 15.1 Etiologies and repair options for rectal vaginal fistula

Broad category	Detailed category	Specific etiology	Location	Anal sphincter injury	Procedure options
Childbirth	Prolonged labor	Pressure necrosis of RV septum	Lower third of rectum	No	Transvaginal repair ERAF Transperineal repair
	Obstetric injury	3rd/4th perineal tears Episiotomy		No	Transvaginal repair ERAF
				Yes	Episioproctotomy Transverse perineal repair
Infection	Abscess	Cryptoglandular or Bartholin's cyst abscess	Distal	No	Transvaginal repair ERAF Perineal repair
	Diverticular	Penetrating inflammation	Proximal	No	Sigmoid resection, vaginal repair
Malignancy	Locall advanced Rectal, cervical, or vaginal cancer or radiation induced	Direct extension of tumor into vagina or rectum or chronic tissue damage from radiation		No	Fecal Diversion
					en-bloc resection
					Repair with tissue flap (for radiation-relate fistula only)
Iatrogenic RVF	Low anterior resection Ileoanal pouch anal anastomosis Hysterectomy	Anastomotic complication	Distal	No	Fecal Diversion Redo of anastomosis Flap
			Proximal	No	Redo of anastomosis with tissue interposition
Crohn's disease	Fistulizing perianal Crohn's Disease	Penetrating inflammation	Distal	No	Transvaginal Transperineal
				Yes	Seton Drainage, ERAF, Episioproctotomy, fecal diversion, proctectomy

Key: *ERAF* endorectal advancement flap

the years 2006–2011 [23]. Anal fistula may be the initial manifestation of Crohn's disease or may occur years before or after the diagnosis of proximal luminal disease [24]. The incidence of anal fistula increases with both disease duration and as the luminal disease distribution extends more distally in the GI tract, with the highest incidence in patients with Crohn's proctitis [25, 26]. As with other etiologies of RVF, a first step in their management is to control associated infection ("sepsis") if it is present. In general, this involves some combination of antibiotics, abscess drainage, draining seton(s), and patient-directed self-care with frequent irrigation of the healing wounds. The extent of disease should be assessed via examination of the anus and rectum, with anoproctoscopy, and often requires sedation or general anesthesia to achieve the dual goals of thorough assessment and minimal patient discomfort. The presence of proctitis, anal or rectal stricture, and associated ano-perineal fistula will influence both the course of treatment and prognosis of rectovaginal fistula in this setting. In terms of diagnostic imaging, MRI may be the most useful modality and should be used selectively in cases in which the clinical examination is insufficient [27]. Once any associated infection has been controlled, the next step is to consider if medical and/or surgical treatments are needed. Not all patients with Crohn's RVF require treatment [28]. Like other manifestations of Crohn's disease, the goal of RVF treatment is to control the symptoms of the disease. If the patient is asymptomatic or minimally symptomatic, it may be best to avoid medical and surgical interventions. Alternatively, patients with symptomatic RVF must be offered treatment to alleviate their symptoms.

Infliximab is an anti-TNF antibody that has been proven effective in the treatment of fistulizing perianal Crohn's disease [14]. In a subset analysis of the ACCENT-2, a randomized prospective trial of infliximab versus placebo for the treatment of fistulizing perianal Crohn's disease, among 25 women with RVF who were induced with infliximab, 16 (64%) responded to treatment with at least 50% closure of their RVF tracts. These responders were then randomized to maintenance infliximab or placebo and were assessed every 8 weeks until week 52, at which point 45% and 43% of RVF were closed in the infliximab and placebo groups, respectively [14]. While this study did not show a long-term benefit of infliximab in terms of fistula healing, there was a short-term benefit as the mean duration of RVF closure was longer in the infliximab-treated patients (45 weeks vs. 25 weeks). In a 2016, a systematic review of 16 studies and 137 Crohn's RVF demonstrated that 63% of patients had some response to infliximab and that 38% had a complete response, but did not include data on the long-term results of infliximab treatment in these patients [29]. Thus, with the data available, it may be fair to conclude that infliximab is "worth a try" in patients with Crohn's RVF and that it helps some patients, but it is far from a panacea.

In the not so distant future, fistula healing may be augmented by stem cell injections. There are reports of early promising results with injections of stem cells into rectal vaginal fistula in ten patients with Crohn's disease demonstrating a 60% healing rate [30].

The surgical treatments for Crohn's RVF are the same as those that are used for other causes of RVF and cover a spectrum of complexity that ranges from draining seton insertion to proctectomy with permanent ostomy. Between these extremes lay procedures including endorectal advancement flap, gracilis or bulbocavernosus (Martius) flap, rectal resection with coloanal anastomosis, and others. In comparison with non-Crohn's RVF, the success of surgical treatment is often lower for patients with Crohn's and varies with the specific type of intervention [7, 31]. For example, in a study by Pinto and colleagues from Cleveland Clinic Florida, the overall per-procedure success of surgical interventions for RVF was 78% and 44% for patients with non-Crohn's and Crohn's RVF, respectively [7]. As with non-Crohn's RVF, while the initial attempt at repair is not always successful, the majority will be healed after multiple attempts [7, 13]. A special consideration in the surgical treatment of Crohn's RVF is whether the use of Crohn's medical therapy positively or negatively impacts the success of surgical interventions. This question was evaluated by Narang and colleagues at the Cleveland Clinics, who concluded that recent use of anti-TNF, steroids, or immunomodulatory drugs did not negatively impact RVF healing after surgical repair [32]. Another consideration in patients with Crohn's RVF is the value of a temporary diverting ostomy. As stated by Pinto and colleagues, "The influence of a protective stoma on RVF repair remains controversial" [7]. There is no randomized trial of fecal diversion in RVF repair, and while retrospective studies have had variable results in terms of the benefit of diversion, these studies are limited by selection bias [6, 7, 31]. Therefore, the Cleveland Clinic approach to temporary fecal diversion in RVF repair, with its use in "redo repairs, technically challenging repairs, and suboptimal tissue conditions," seems reasonable [28]. In patients with Crohn's RVF in whom all else fails, the construction of a permanent ostomy may be required for symptom and disease control. Risk factors for permanent fecal diversion in patients with perianal Crohn's disease include complex fistula, anal stenosis, history of rectal resection, fecal incontinence, and the use of a temporary fecal diversion [33–35].

Cryptoglandular

In retrospective studies of the surgical treatment of RVF, anywhere from 2% to 40% of cases are classified as cryptoglandular in origin [8, 10, 21, 36]. Initial treatment in these cases is focused on eradication of sepsis. The use of subse-

quent surgical procedures is determined on an individualized basis with consideration of symptoms, anal sphincter integrity, and the condition of the surrounding soft tissues.

Anastomotic and Other Surgical Complications

Fistulization of a colorectal anastomosis to the vagina has been reported to occur in as many as 10% of women who undergo low anterior resection [3, 37, 38]. When this occurs, fecal diversion is generally recommended as the initial step to facilitate resolution of the acute inflammation and associated infection. In some cases, diversion alone may result in healing. In 2005, Kosugi reported that 6 of 16 (37%) colorectal anastomotic-vaginal fistulas treated with diversion alone healed within a period of 6 months [37]. Persistent fistulas were treated with neo-colorectal anastomosis, endorectal advancement flap, or gluteal-fold flap interposition. Other iatrogenic causes of RVF include rare occurrences after stapled hemorrhoidopexy or stapled transanal rectal resection (STARR) [4].

Radiation Injury

Radiation-related RVF occur after the use of radiation to treat cervical cancer and other pelvic malignancies. In a recent review by Zelga and colleagues, RVF developed anywhere from 5 months to 20 years after radiation treatment with a median interval of 20 months [39]. While in their series, the majority of patients with long-term follow-up were maintained with fecal diversion; other studies have demonstrated high rates of fistula resolution with the use of a bulbocavernosus flap [40, 41] or rectal resection with coloanal anastomosis [42].

Evaluation of Patient with RVF

RVF clinical evaluation begins with a thorough history of the illness: information about the duration of symptoms, the nature and volume of vaginal discharge, number and consistency of day and night bowel movements, the patient's ability to defer defecation and flatus, and if they have experience fecal incontinence. The use of pads to control drainage and the number of pad changes per day may be helpful in quantifying the amount of drainage from the fistula. Inquiries about the presence of urinary symptoms such as pneumaturia or fecaluria are also important and may help uncover the presence of an associated enterovaginal fistula. The patient's past medical, surgical, and childbirth history should be assessed to find clues of the etiology of the fistula and if prior attempts were made to repair the fistula. Awake examination in the surgery clinic is an important step in evaluation of the fistula. Inspection of the anoperineum includes an evaluation of the integrity of the perineal body and if there are scars in this area that resulted from an episiotomy or sphincter laceration repair. Inspection and digital examination of the anorectum and vagina are useful to assess the internal and external anal sphincter and the location and size of the RVF. Vaginoscopy and anoproctoscopy may also be useful to obtain information about the location and size of the fistula and if there is a stricture, proctitis, or other mucosal abnormalities of concern. If sufficient information about the anatomy of the fistula cannot be obtained during awake examination, an exam under sedation or general anesthesia should be considered. The "tampon test," in which the patient inserts a tampon or gauze pad into her vagina, leaves it in place for several hours, and then removes and inspects it for fecal staining, is an occasionally useful test to confirm the presence or absence of a RVF [18]. This test may also be modified and used during awake or sedated examination for the same purpose. This is done by carefully inserting a clean gauze or lap pad into the vagina and then by instilling a dilute Betadine solution into the rectum with a 60 cc syringe or similar instrument. The pad in the vagina is then removed and inspected to see if there is Betadine staining.

Diagnostic imaging is used selectively in the evaluation of RVF to define the trajectory and number of tracts and to determine if there are undrained fluid collections or local pathology. To obtain this information, magnetic resonance imaging (MRI) is the preferred imaging modality [43, 44]. CT imaging may also be used, but limitations in its ability to provide sharp contrasts between pelvic soft tissues make this modality relatively inferior to MRI. Fluoroscopic studies, including rectal contrast enema, are useful to evaluate a colorectal anastomosis for patency or fistula, while vaginography has been shown to have high sensitivity for detection of RVF [45]. Endoluminal ultrasound may also have a role in the evaluation of RVF, particularly for examination of the anal sphincter, but has limits in terms of its readability and limited view of the surrounding anatomy [44, 46]. Endoscopic evaluation of the rectum and colon may be considered in cases in which Crohn's disease or radiation injury is the suspected etiology of the fistula. Consultation with urologist and/or gynecologist may be needed in patients with suspected coexistent rectourethral or enterovesical fistula or in cases in which gynecological interventions are needed. In patients in whom surgery is planned and an ostomy is considered, preoperative site marking and education is advised [47].

Surgical Techniques

There are excellent review articles which describe the surgical techniques for RVF [18, 48]. A distal anovaginal or rectovaginal fistula can be surgically approached through the perineum, vagina, or rectum. For patient with anal sphincter injuries, deficient perineal tissue, or gaping introitus, a perineal approach is preferred (Figs. 15.1 and 15.2). However, if the perineum and sphincters are intact, the fistula can be repaired through the rectum or vagina avoiding the trauma associated with a perineal incision. Traditionally, colorectal surgeons prefer a transanal approach both based on their experience and comfort level with operating in the rectum and the philosophy that focusing the repair on the high-pressure zone of the rectum would lead to better fistula healing. However, no one specific surgical technique has been found to be superior, and fistula healing rates range from 50% to 85% depending on the case series and patient characteristics [1, 49, 50]. There are situations where avoiding anal sphincter stretching with retractors is advantageous, and we recommend that the colorectal surgeon consider transvaginal approaches in appropriate cases.

Fig. 15.1 This woman suffered from an obstetric injury several years prior. A probe is placed from the vagina through the perineum and from the perineum to the anus. This woman will benefit from a perineal approach to reconstruct her perineum. Her underlying sphincter injury will be addressed with an overlapping sphincter repair

Fig. 15.2 A fistula probe is in place through the vagina and rectum in this very distal fistula. Endoanal ultrasound confirms an anterior anal sphincter defect. A perineal approach with episioproctotomy is performed to repair the fistula and sphincter defect

Preoperative considerations include smoking cessation, weight loss, diabetes control, and improving bowel consistency and frequency. We recommend mechanical bowel preparation, but many authors prefer only an enema clean out and a single dose of perioperative antibiotics. It is important to discuss the possibility of postoperative dyspareunia and changes in bowel function associated with the repair. Postoperative complications may include infection, bleeding, and perineal sepsis. Breakdown of the perineal skin is common, and some surgeons leave the perineal skin loose to heal by secondary intention. The use of drains is surgeon dependent. Vaginal packing at the end of the procedure is selectively inserted as a pressure dressing to help with hemostasis. A short course of oral postoperative antibiotic is used by some surgeons but is not in our practice. Women undergoing local repairs are usually discharged the following morning with no dietary restrictions and on a stool softener or mineral oil to lubricate the stool. Perineal wound care involves a peri-bottle and handheld shower but tub soaking is avoided. Patients are restricted from sexual activity, tampon use, excessive leg stretches, and strenuous activities until their 6-week postsurgical visit.

Perineal Approach

Episioproctotomy

Episioproctotomy is our preferred approach for women with sphincter or perineal injuries (Fig. 15.3) [51]. This technique involves opening the fistula tract and creating a defect similar to a fourth degree perineal laceration. The

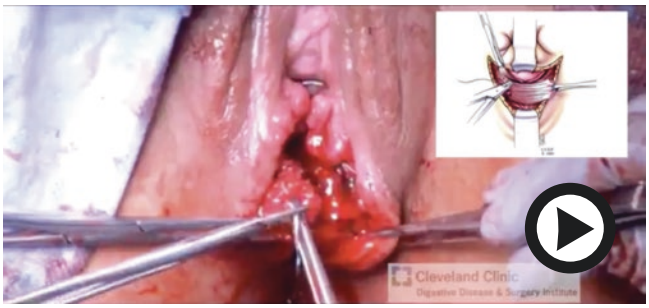

Fig. 15.3 Episioproctotomy. (https://doi.org/10.1007/000-339)

Fig. 15.4 The patient is in lithotomy position and the fistula tract was opened over the probe. Allis clamps hold the edges of the perineal skin. Anterior sphincter scar is visualized in the midline, and the sphincter complex will be mobilized laterally to perform overlapping sphincter repair

patient is positioned in either lithotomy or prone position. A longitudinal incision is made over the probe to create a cloacal defect (Fig. 15.4). Skin flaps are created on either side to mobilize the external sphincter laterally. The fistula tract edges are excised, and complete debridement of the fistula tract or granulation tissue is performed. The plane between the rectum and vagina is mobilized in the rectal vaginal septum until healthy pliable tissue is appreciated. Meticulous hemostasis is obtained throughout the procedure. The rectal mucosa is approximated with running 3-0 absorbable sutures. The levators and rectovaginal septum are approximated, but deep suture bites and unnecessary tension are avoided which can lead to levator spasm and dyspareunia. The sphincter muscles are overlapped and secured with mattress sutures. The vaginal mucosa is approximate with a running locking 3-0 absorbable suture. The hymenal edges are identified and aligned. The transverse perineal muscles are repaired and the perineal skin is loosely approximated. Success rates are reported from 64% to 100% [50].

Transverse Perineal Repair

An incision is made transversely through the perineal body, and dissection is carried out proximal to the fistula tract. The vaginal and rectal wall are mobilized and the fistula tract edges are excised. Closure of the rectal wall is performed in two layers. The rectovaginal septum and levators are approximated in the midline, and the vaginal epithelium is closed (Fig. 15.5).

Transrectal Approaches

Endorectal advancement flap (ERAF) technique has been well described in the literature, and this is by far the most common approach in the colorectal literature. A curvilinear incision is made nearly 180 degrees just distal to the fistula opening in the anal canal. The flap of mucosa, submucosa, and rectal wall is dissected off the rectovaginal septum. Mobilization of the rectal wall is performed proximal to the fistula to avoid tension on the repair. The fistula tract is excised and the opening is closed with absorbable suture. The flap is trimmed and approximated to the distal cut end (Fig. 15.6). The vaginal or perineal openings are left open to heal by secondary intention. Overall success rates are reported at 43–93% [1, 31, 50, 52, 53].

Rectal Sleeve Advancement

Rectal sleeve advancement can be used in select situations when the distal rectum is diseased but the proximal rectum is normal such as with Crohn's disease, radiation, or prior surgical procedure. Starting at the dentate line, a mucosectomy of the mucosa and submucosa is performed, and dissection is taken cephalad proximal until healthy tissue is encountered. Mobilization of the rectum is 90–100%. The healthy proximal rectum is brought down without tension and sutured to the neodentate line. This repair is typically considered in patients where the only other option is total proctocolectomy or permanent fecal diversion [54].

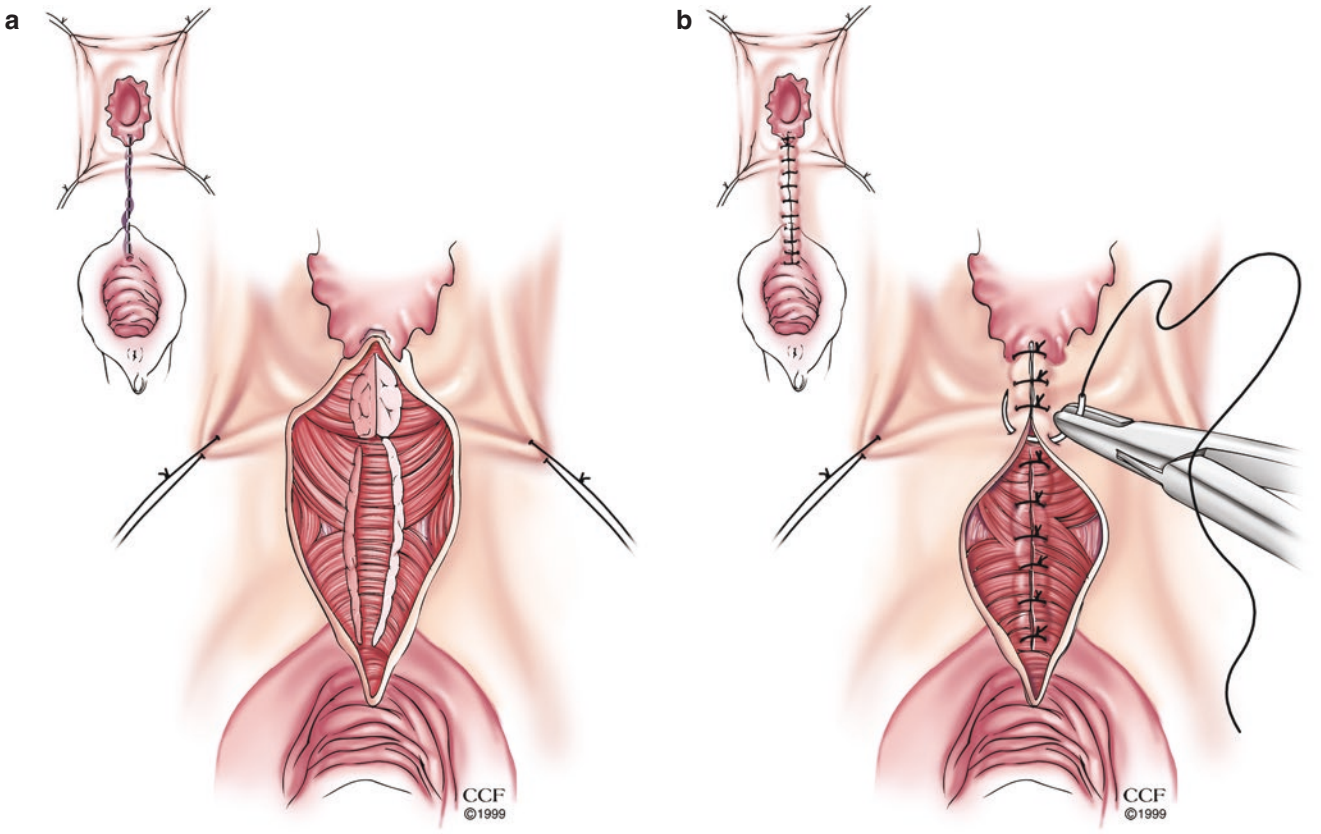

Fig. 15.5 Episioproctotomy. (**a**) flap of mucosa and submucosa is raised. A longitudinal incision is made along the perineum opening the skin, transverse perineal muscles, sphincter complex or midline scar, and rectovaginal septum and vaginal epithelium so that the fistula is completely opened. (**b**) The fistula tract and granulation tissue have been excised and the muscle layers identified and mobilized. A layered repair is performed. Vaginal Approach

Transvaginal repair is least commonly reported in the colorectal literature (Fig. 15.7). Advantages of vaginal approach are avoiding extensive mobilization of diseased rectum and avoiding sphincter stretch associated with anal retractors and tissue trauma associated with rectal flaps. Transvaginal approach is favored in patients with active Crohn's disease in the rectum, and studies have shown that endovaginal flaps produce similar outcomes to endorectal flaps [55]. The vaginal advancement flap consists of raising a posterior flap of vagina over the fistula. The rectal and vaginal orifices of the fistula are identified and repaired with absorbable sutures. The levator ani muscles are approximated in the midline. The vaginal flap is advanced over the repair. Alternative techniques are described in the literature involving coring out the fistula tract, freshening up the edges, and creating a flapless transvaginal RVF repair with healing rates of 67% in 15 patients [56].

Tissue Transposition Repairs

For more complicated repairs (such as prior failed attempts, Crohn's, and radiation-induced fistula), tissue transposition with muscle or pedicled adipose has been shown to be effective. The interposition of healthy well-vascularized tissue between the fistula layers increases bulk and obliterates dead space.

The Martius flap is harvested from the labia and includes fat and bulbocavernosus muscle. The posterolateral vascular pedicle which originates from a branch off the internal pudendal artery is preserved, and the flap is rotated and interposed between the cut and closed edges of the RVF (Fig. 15.8). Success rates for this procedure range from 60% to 100% [57, 58].

The gracilis muscle interposition offers a greater bulk of healthy vascularized tissue. The muscle is harvested from the thigh and then passed through a tunnel from the proximal aspects of the thigh toward the perineum and then positioned between the rectum and vagina. Overall success rates are reported from 53% to 92% [59, 60].

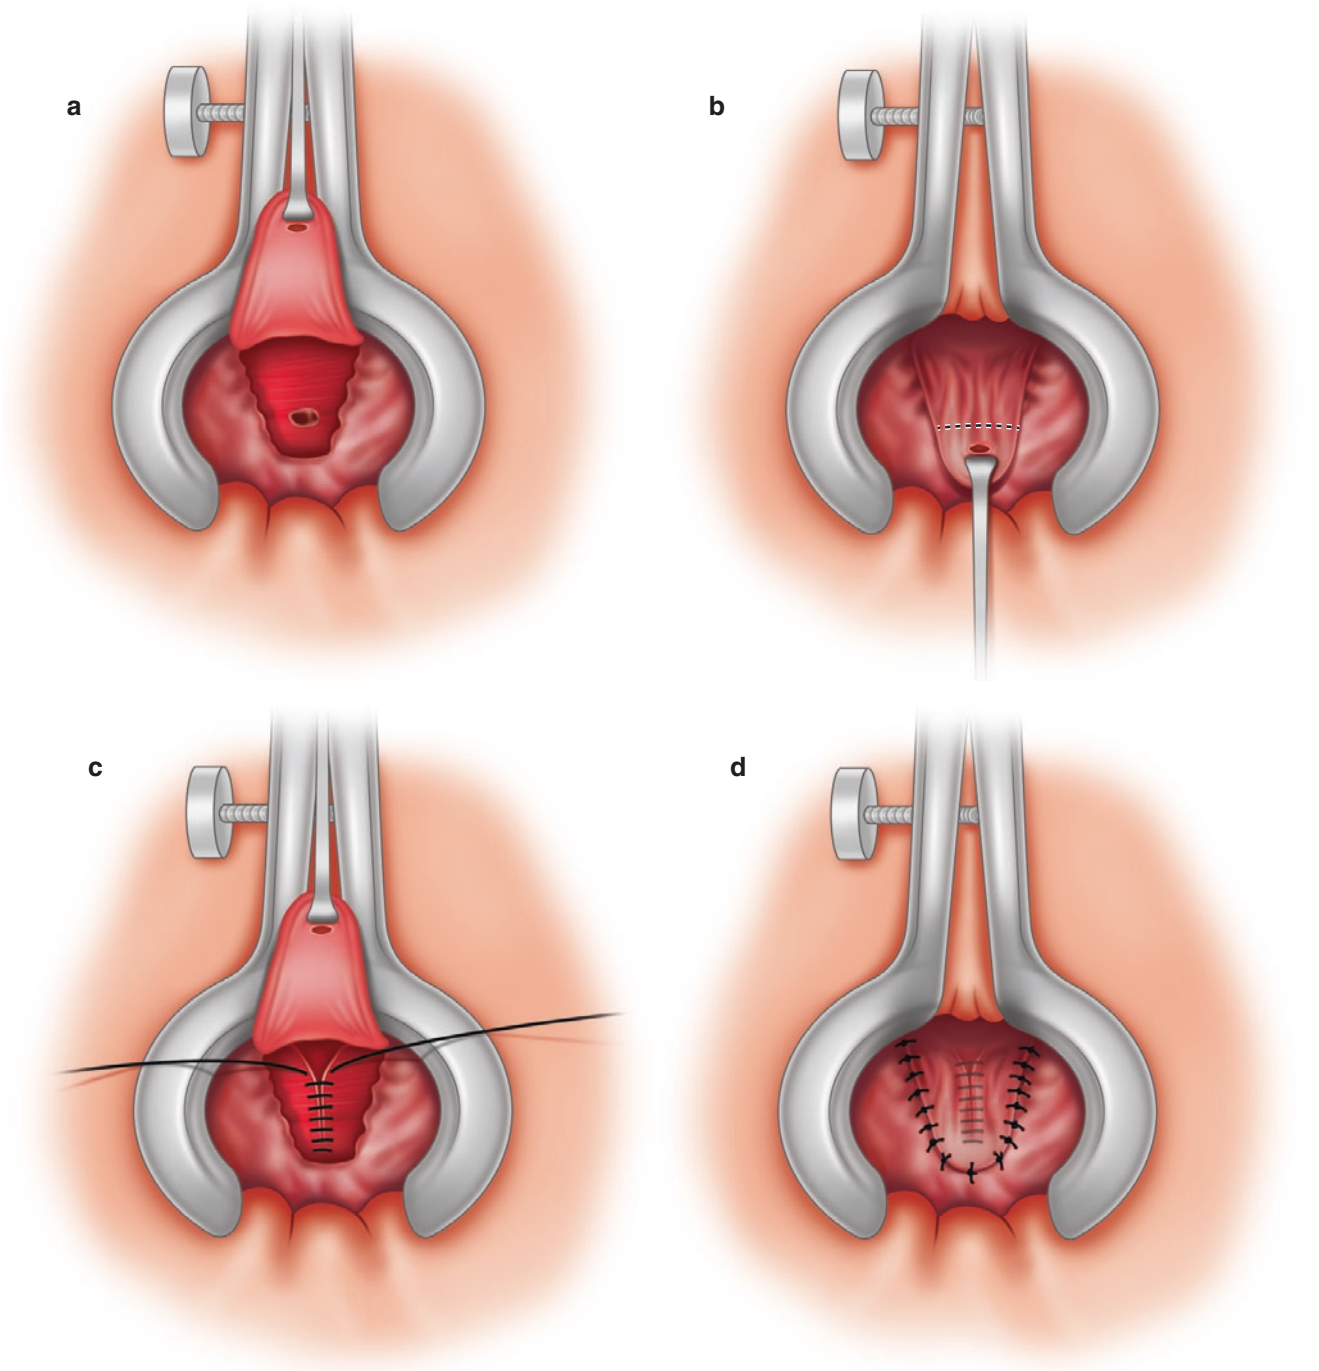

Fig. 15.6 Endorectal advancement flap. (**a**) flap of mucosa and submucosa is raised. (**b**) Adequate mobilization of the flap is performed to avoid tension. (**c**) Approximation of the lateral edges of the muscular layer over the fistula as an additional layer for reinforcement. (**d**) The flap is sutured in place

Bioprosthetic Products

There have been several biosynthetic products developed for fistula tract closure. The biological matrix is thought to promote inflammatory response and scar formation while minimizing dissection and trauma. Success rates are low ranging from 20% to 35%, and the initial enthusiasm for bioprosthetic material has diminished [6].

Abdominal Approaches

For RVF originating in the middle third of the rectum or upper portion of the vaginal or in patients with severely damaged tissue following surgery or radiation, an abdominal approach is warranted. When the patient has a high fistula with healthy tissue anterior dissection between the rectum and vagina, excision of the fistula tract and interposition of omentum have been reported with satisfactory success rates [61]. In most cases, resection of the diseased rectum with anastomosis at a lower level is necessary [62, 63]. This can be performed with two main techniques: an immediate anastomosis or delayed coloanal anastomosis (Turnbull-Cutait). When the distal rectal tissue is normal, an immediate anastomosis is performed. However, the Turnbull-Cutait is reserved for situations when there are other fistulous connections or an internal opening close to the suture line [64]. Circumferential sutures are placed at the neodentate line. The proximal bowel is prolapsed out of the anus and wrapped in gauze for 5–7 days at which point the patient returns to the operating room for amputation of the prolapsed rectum and suture fixation to the neodentate line [65, 66]. Temporary fecal diversion is highly recommended in the setting of abdominal procedures and radiation. Permanent colostomy should be considered in patients with severe radiation injury.

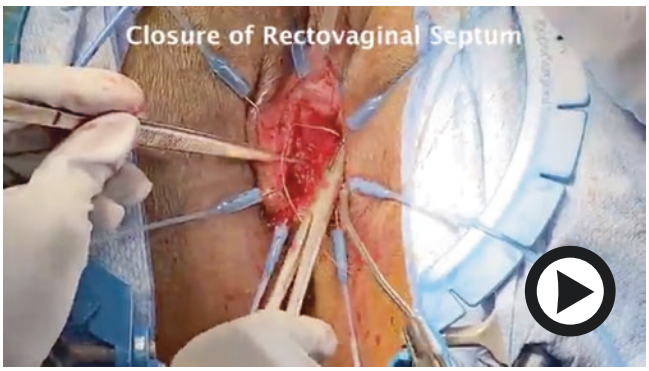

Fig. 15.7 Vaginal approach. (https://doi.org/10.1007/000-338)

Conclusion

RVF are uncommon but can pose a very challenging problem. The colorectal surgeon is likely to encounter the most complicated cases. A thorough understanding of the disease process and surgical options are imperative to provide the patient with the best opportunities for fistula healing.

Pilonidal Disease and Hidradenitis Suppurativa

16

Anuradha R. Bhama and Bradley R. Davis

Key Concepts

- Pilonidal disease is an acquired chronic, infectious disease typically of the natal cleft with an unknown etiology, thought to be due to a combination of environmental and patient-specific factors.
- The treatment for pilonidal disease should not result in worsening of quality of life than the disease itself. Incision and drainage for acute infections is mandatory, but further surgical treatment should be individualized.
- Several operative strategies exist for the treatment of pilonidal disease; surgeons should be familiar with the various options available, though no single option has proven superior.
- Wound care following pilonidal excision can have a major impact on quality of life and several nonoperative treatment strategies exist.
- Hidradenitis suppurativa (HS) is a chronic, relapsing, inflammatory skin condition that typically occurs after puberty. The primary clinical presentation is painful inflamed nodules in the apocrine gland-bearing regions that progress to abscesses, sinus tracts, and scarring.
- The overall disease burden is disproportionate to the estimated prevalence, and patients with HS not seen and evaluated by dermatologists and surgeons may not get timely and appropriate treatment.
- Therapy is initially medical and consists of antibiotics both orally and topically as well as immune modulators to manage the chronic inflammation.
- Surgery is an important treatment for both acute abscess formation and painful scarring and deformity. Excision with primary closure and skin grafting can result in cure for patients with recalcitrant disease.

Pilonidal Disease

Introduction

Pilonidal disease is a chronic, suppurative condition, typically of the sacrococcygeal natal cleft, that can present from quiescent and asymptomatic disease to an active and purulent infection. Clinical descriptions date as far back as the 1850s, yet this disease process continues to challenge clinicians today. The ideal treatment for this condition remains a dilemma, and classic techniques are still frequently utilized for treatment while newer techniques are explored. Pilonidal disease can result in significant quality of life impairment for the patient, but treatments for the disease can be equally frustrating, not infrequently resulting in chronic open wounds requiring extensive wound care with prolonged healing periods. When caring for patients with pilonidal disease, it is important to remember that the treatment of the disease should not be more debilitating than the disease itself.

The terms "pilonidal cyst," "abscess," "sinus," and "disease" are often used interchangeably. In the setting of an infection of the pilonidal sinus or cyst, the term "abscess" is most appropriate. In general, this spectrum of pilonidal conditions can be referred to as "pilonidal disease." There is a multitude of nonsurgical and surgical treatment options available for pilonidal disease that can be employed at various stages of disease severity. The plethora of literature compares procedures, with variable success and recurrence rates where no single procedure outshines the others. As such, it is important to have an understanding of the assorted options available to patients during any stage of their disease process, from the initial stage of diagnosis to recurrent disease several years after definitive surgical treatment.

Epidemiology and Etiology

The true incidence of pilonidal disease is unknown, as it relies on patient-reported symptoms and patients may not always seek treatment, especially in the case of relatively quiescent disease. Pilonidal disease can also occur in other anatomic locations besides the natal cleft, such as the interdigital web spaces of hair dressers or dog groomers and even the umbilicus [1–7]. It is estimated that approximately 70,000 cases of natal cleft pilonidal disease occur per year [8]. Traditionally, male sex was associated with higher risk of pilonidal disease; however, data suggests that this disease affects females equally, with up to 55% of female patients in some studies [9–11]. Pilonidal disease was once termed "jeep disease" due to the high incidence during World War II in jeep drivers, with an underlying theory that prolonged sitting in vehicles was the cause in those patients [12]. Other causative risk factors include obesity, hirsutism, poor hygiene, long periods of sitting/driving, excessive sweating, deep natal cleft anatomy, and family history [9, 11, 13–15].

The underlying etiology of pilonidal disease remains unknown, though there are several working theories. While the true underlying etiology may never be elucidated, the main controversy is whether pilonidal disease is inherited or acquired. Previously, pilonidal disease was thought to be due to an inherited, congenital malunion of the dorsal midline and treatment centered around removal of all embryologic remnants [16, 17]. Now, the leading hypothesis is that it is an acquired condition occurring in the natural environment of the natal cleft, which is one of warmth, repeated friction, and moisture. The underlying theory is that this environment, combined with an inciting trauma to the skin and surrounding hair follicles, results in a granulomatous foreign body reaction, leading to the formation of inactive pilonidal sinuses or active infections.

Diagnosis

Patients presenting with pilonidal disease can have a range of symptoms. Those with asymptomatic pilonidal disease may be completely oblivious to the presence of the sinuses. Patients typically become aware of the presence of the disease upon the development of an active infection, typically reporting pain and drainage. Frequently they may mistakenly report rectal bleeding and assume a diagnosis of hemorrhoids; however, these episodes of bleeding do not relate to bowel movements and occur spontaneously. Patients may also be referred with a suspected diagnosis of anal fistula, which rarely track to the natal cleft and can be typically ruled out on physical exam. Making the diagnosis of pilonidal disease is fairly straightforward, and the true diagnosis is evident upon physical exam of the natal cleft.

Fig. 16.1 Example of pilonidal disease. Note there are several pits present in the midline of the natal cleft

Physical exam will reveal one or several pits located in the midline of the natal cleft almost always contaminated by debris and hair (Fig. 16.1). The entire natal cleft must be examined after removing the debris and excess free hair. This may demonstrate tufts of hair coming from the pilonidal pits with associated drainage. The hair can be removed from the pits using a hemostat, which may cause some minor bleeding. In the setting of an acute abscess, there will be a raised area of erythema, fluctuance, induration, and tenderness, which is typically located just lateral to the midline. They can also be located quite some distance from the nearest pilonidal pit, but the underlying abscess cavity will communicate with a nearby pit (Fig. 16.2). The pits typically travel in the midline along the natal cleft. In some situations, the pits may be located quite inferiorly in the natal cleft close to the anal verge and may be mistaken for an external opening of an anal fistula.

Despite the prevalence of pilonidal disease and its variants, there is no formal classification system in place. There are no clear guidelines to inform procedure of choice, and typically surgeons perform procedures with which they are most comfortable. The lack of consensus results in an inability to generalize the available data, most of which are small, single-center studies. Generalizability of these single-institution studies is difficult, as procedure of choice is guided by surgeon preference as opposed to validated guidelines. Additionally, there is no true gold standard for comparison, and there is no study comparing all available treatments side by side. There is also heterogeneity in reported outcome measures, including postoperative infec-

Fig. 16.2 Pilonidal disease with midline pits and two abscesses – one located lateral to the right and one located cephalad in the midline

tion, recurrence rates, postoperative pain, time off work, wound healing time, and quality of life. Despite these challenges, it is important for clinicians to understand the variety of treatments available to treat the disease.

Treatment

Managing Patient Expectations

When caring for patients with pilonidal disease, it is important to establish a baseline set of expectations for their treatment course. Upon initial presentation, a majority of patients may be managed nonoperatively, and it is important for patients to understand the potential for recurrent symptoms that may require future intervention. Additionally, postoperative complication rates are relatively high regardless of which operative strategy is chosen. It is important that the patient has a clear understanding of the potential for these postoperative complications, which largely consist of wound infections and chronic wound complications requiring dressing changes and delayed healing. Additionally, while there are a variety of operative options, the best course of treatment remains controversial.

Nonsurgical Treatment

In patients who have quiescent disease, no invasive treatment is necessary. Risk factor modification may be employed including improved hygiene, weight loss, hair removal, and avoiding prolonged sitting. Cleansing the area with a washcloth or scrub brush may help prevent hairs from becoming trapped within the pits. Hair removal can be very effective as a step towards healing. Hair removal options include shaving, waxing, depilatory creams, or laser hair removal. Patients with light-colored hair may not be candidates for laser hair removal, as it typically works best in those with light-colored skin and dark hair. The available data to support laser hair removal is limited and heterogeneous [18]. Recurrence rates of 0–28% have been reported, which were less than those seen in the non-laser hair removal groups. Additionally, depilatory creams and laser hair removal are not recommended in the setting of an active infection or ulceration. In these cases, patients should be instructed how to shave the area and may even require weekly visits to have the area shaved in the clinic. Even when operative treatment is chosen, postoperative hair removal has been shown to decrease recurrence [19].

Antibiotics

Antibiotics are typically not indicated but should be prescribed in certain circumstances. Antibiotics alone will not treat pilonidal disease but can be used as an adjunct in cases with extensive surrounding erythema/cellulitis and systemic signs of sepsis (fevers, rigors, malaise) or in certain patient populations (diabetes, immunosuppressed, artificial heart valves, or other implanted prostheses). If antibiotics are indicated, a third-generation cephalosporin and metronidazole should be prescribed [20]. If there is an acute abscess, antibiotics should not be used as the sole treatment, and incision and drainage is indicated. Typically, incision and drainage is sufficient treatment.

Phenol

A nonsurgical outpatient option to ablate pilonidal disease is phenol application. This procedure is performed under local anesthesia with overall success rates of 62–95% and low complication rates of 0–2% [21–23]. Phenol causes a caustic burn without causing pain given the anesthetic and analgesic effects of phenol solution. The phenol solution also denatures the hairs thought to cause pilonidal disease. The procedure involves debriding the tract, enlarging the cavity slightly, and then instilling 1–3 mL of crystallized phenol solution into the pilonidal cavity while protecting the surrounding skin with ointment. Typically, one to four sessions are required to achieve good results [24]. Success rates are higher when combined with laser hair removal or depilatory creams [25–27]. The procedure can also be utilized successfully in those with recurrent pilonidal disease [24].

Fibrin Glue

Similar to phenol treatment, fibrin glue (or thrombin gelatin matrix) may be utilized with recurrence rates ranging from 0% to 17%, in the absence of infection [28]. This procedure is performed by first shaving the surrounding hair and preparing the operative field in a sterile fashion. After hair and debris are removed from the sinus using a curette, fibrin glue is instilled into the sinus. The fibrin glue acts as a sealant that allows a clot to form. Efficacy for this procedure demonstrates success rates of 96% with high patient satisfaction (79%) [29, 30]. Those that reported they were dissatisfied required further treatment due to procedure failure [30]. A similar study found a 27% recurrence rate after a median of 4 months, and after second fibrin glue application, the success rates were 96.6% [31]. Fibrin glue may also be used as an adjunct with other more advanced surgical flaps, though the durability of this is unknown [32, 33]. A meta-analysis was performed that comprised four randomized control trials of fibrin glue to treat pilonidal disease which included a total of 253 patients [34]. This study revealed low-quality evidence for the use of fibrin glue as monotherapy or in conjunction with advanced flap-based procedures. Given the lack of high-quality evidence and long-term results, the true utility of fibrin glue remains unclear at this time [35].

Surgical Treatments

Incision and Drainage

Acute pilonidal disease is defined as the presence of an abscess with or without associated cellulitis [36]. Regardless of the chronicity of the disease, if a patient presents with an acute abscess, incision and drainage should be performed. The main overarching concept of performing an incision and drainage in this setting is to place the incision off of the midline over the area of maximum fluctuance. Frequently, incision and drainage with unroofing of the cavity can successfully treat the disease without the need for additional procedures. Incision and drainage is nearly always successful for resolving the immediate infection. Recurrent infections are typically due to failure to address underlying hair, debris, granulation tissue, and epithelization that are present within the cavity [37]. Abscesses that are inadequately drained may also recur if the incision site heals prematurely without true healing by secondary intent. When performing an incision and drainage, it is important to ensure that the abscess is unroofed and the skin edges are no longer opposed to avoid premature healing.

Lay Open Technique Versus Excision with Primary Closure

The lay open technique is one in which an incision is made overlying the sinus tract of the pilonidal cyst and allowed to granulate by secondary intention (Fig. 16.3). A fistula probe can be used to identify the extent of the tract. An incision can be made on top of the probe using electrocautery, unroofing the track. The overlying skin can be excised in order to create a shallow wound and prevent the wound from prematurely healing at the skin surface level. The exposed tract can then be debrided using curettes or cautery. The skin edges can also be marsupialized using absorbable polyglycolic acid or Vicryl suture in a running fashion, making the defect smaller and shallower. The wound may be too shallow for traditional

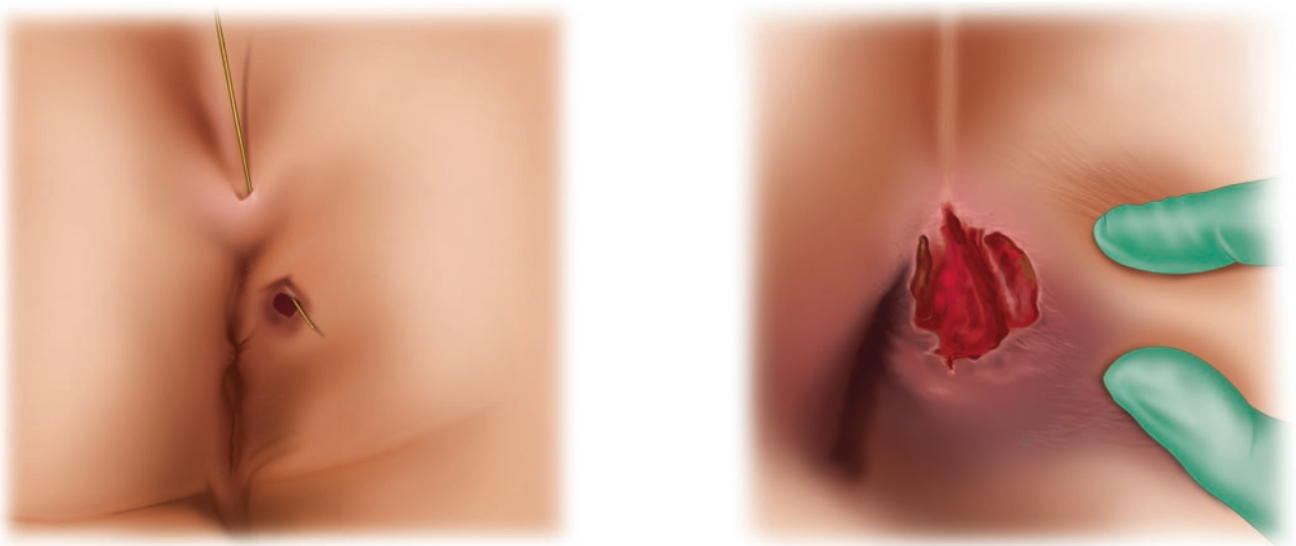

Fig. 16.3 Lay open technique: A fistula probe is used to identify the tract. An incision is made overlying the probe using electrocautery to unroof the tract. The chronic granulation tissue can be debrided and the wound edges marsupialized if desired

packing, but a dressing of gauze can be placed and changed regularly to protect the patient's clothing from drainage.

Success rates for initial operation are reported to be as high as 97% [38]. Patients who undergo the lay open technique have recurrence rates varying between 8.8% if the abscess is incised and left open to 20.8% if they are excised and left open [39]. Postoperative infection rates are similar between lay open and primary closure techniques, but recurrence is significantly less likely with the lay open technique [40]. The lay open technique requires more intense wound care, such as dressing changes done twice daily, often requiring assistance from a family member. Sometimes, wounds can heal with hypertrophic granulation tissue, which can result in drainage and require further cauterization in the office setting to achieve complete healing.

Another option is excision with primary closure. Typically, the entire pilonidal cavity is excised down to the sacral fascia. The wound is then irrigated and closed in layers. The deep tissues are closed using absorbable polyglycolic acid suture. The final skin layer can be closed using a nylon or polypropylene suture in a vertical mattress fashion. The final dressing applied may include buttressing sutures to create a pressure dressing that remains in place for several days postoperatively to prevent the development of a seroma. Primary closure has been shown to result in faster healing and decreased time off from work [41–44]. Avoiding inconvenient and prolonged wound care is one of the attractive benefits of primary closure, but patients should be counselled as to the potential risk of postoperative infection requiring opening of the incision. A Cochrane review comparing 26 trials with 2530 patients identified faster healing times with primary closure but no difference in surgical site infection rates [45]. When comparing midline versus off-midline closure, there were decreased surgical site infection rates with faster healing times with off-midline closure [45]. There are no obvious benefits for open versus closed excision; but if the decisions is made to perform primary closure, then the preferred technique is to keep the closure off of the midline.

Complex Surgical Treatment

There are no formalized guidelines as to when complex surgical treatment is indicated following acute incision and drainage of an abscess. The goal of flap-based surgical treatment is to excise the diseased tissue, cover the defect with healthy tissue, and raise the natal cleft anatomy. In general, surgical excision should be considered for patients with chronic sinuses that harbor extensive, chronic, epithelialized granulation tissue, which will not heal with hygiene and hair removal alone. Surgical excision should also be considered for patients who have undergone multiple abscess drainage procedures. Timing of surgery can be typically arranged in an elective fashion. There are several types of flaps, described below.

Karydakis Flap

A Karydakis flap involves excising the effected tissue in an elliptical fashion, with the inferior and superior corners of the ellipse about 2 cm from the midline (Fig. 16.4). The skin and soft tissue, including all the pilonidal pits, are excised

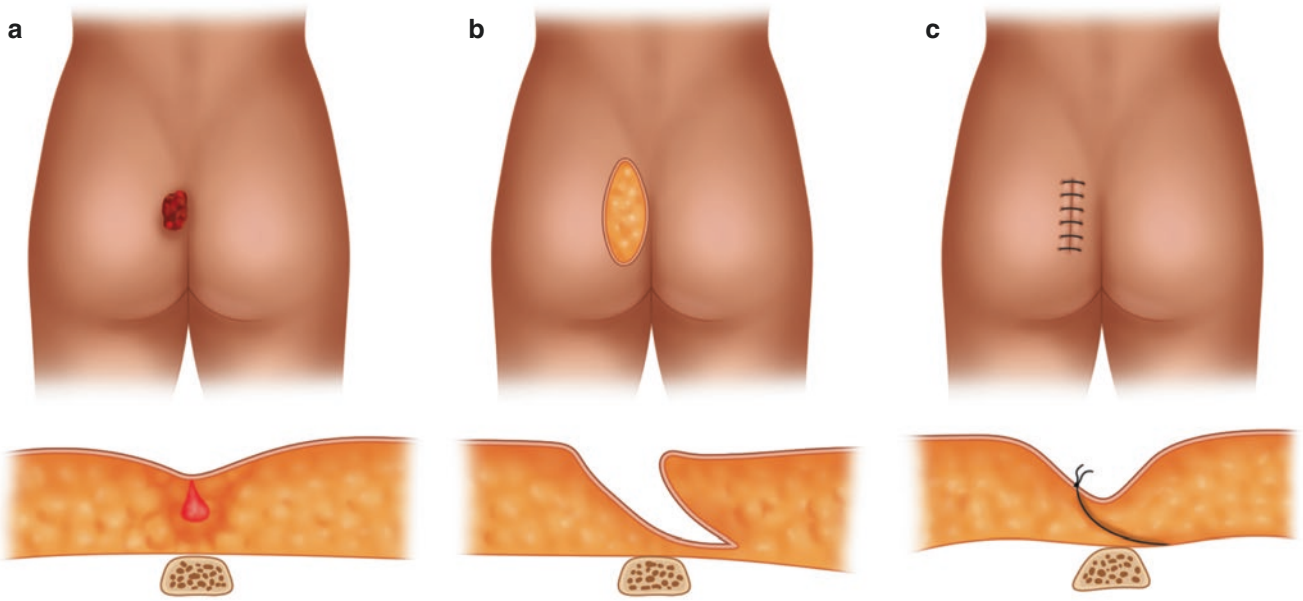

Fig. 16.4 Karydakis flap: (**a**) The affected tissue is excised down to the sacral fascia in an elliptical fashion off of the midline. (**b**) A flap of skin and subcutaneous tissue is raised and advanced over the excision defect. (**c**) This is secured in place by suturing in layers

down to the sacral fascia. After this tissue is excised, a flap of the skin and subcutaneous tissue is raised on the opposite side of the midline. This is then advanced over the resection bed. The wound is closed in layers with the deepest layer of absorbable polyglycolic sutures including the sacral fascia. Additional layers of absorbable polyglycolic sutures are placed to approximate the flap. The skin is finally closed with nonabsorbable suture (either polypropylene or nylon) in a vertical mattress fashion. A pressure dressing is applied and can be secured in place with tie-over sutures [46]. These sutures are typically left in place for 10–12 days [47].

The Karydakis flap generally has good results. Kardyakis reported his results in 6545 subsequent cases with a wound complication rate of 8% and recurrence rate of under 2% [48]. In more recent trials, the Karydakis flap has morbidity rates as high as 21% [49]. A trial comparing Kardyakis flap to excision with healing by secondary intent showed recurrence rates of 1.2% and an 18.7% rate of wound complications [50]. Another study demonstrated a 1-year recurrence rate of 3% and a 10% wound dehiscence rate when performed for recurrent disease [50]. Another trial demonstrated a wound complication rate of 8.1% and recurrence rate of 2.7% [51].

Rhomboid Flap (aka Limberg Flap)

A rhomboid flap, also known as a Limberg flap, is a rotational flap (Fig. 16.5). This involves first mapping the site of excision. This is done by identifying the extent of the pits and marking the shape of a diamond with the superior and inferior apices of the diamond just to the left of the midline. This results in a wound that does not come to a point just above the anus, which is the site with the highest risk of wound failure. The purposed excision site should include any former incision and drainage scars. This excision site will be in the shape of a diamond. The marking of the flap starts from the lateral apex of the diamond, typically on the right side. A horizontal line is drawn from the lateral apex that is approximately 5–6 cm in length. This horizontal mark represents the contralateral lower edge of the flap after rotation, and so it is important to ensure the lengths are congruent. Another line is marked from the lateral end of the horizontal line inferiomedially at an acute angle. Incisions are first made to resect the diamond-shaped tissue down to the sacral fascia. Next, the lipocutaneous flap is raised. Care should be taken to ensure that the flap is undermined appropriately to allow for a tension-free closure without creating ischemia. The flap can be secured into place with absorbable sutures. The final layer of the skin can be closed with vertical mattress sutures, and some may choose to also apply surgical glue. The use of a drain is per surgeon preference.

Results of the Limberg flap are conflicting. Wound infection rates are reported to range from 1.5% to 4% [52, 53]. Recurrence rates have been reported between 0% and 4.9% [51, 52, 54]. Conversely, complications have been reported to be as high as 49%, including a wound dehiscence rate of 45%, infection rate of 4%, and recurrence rate of 13% [53].

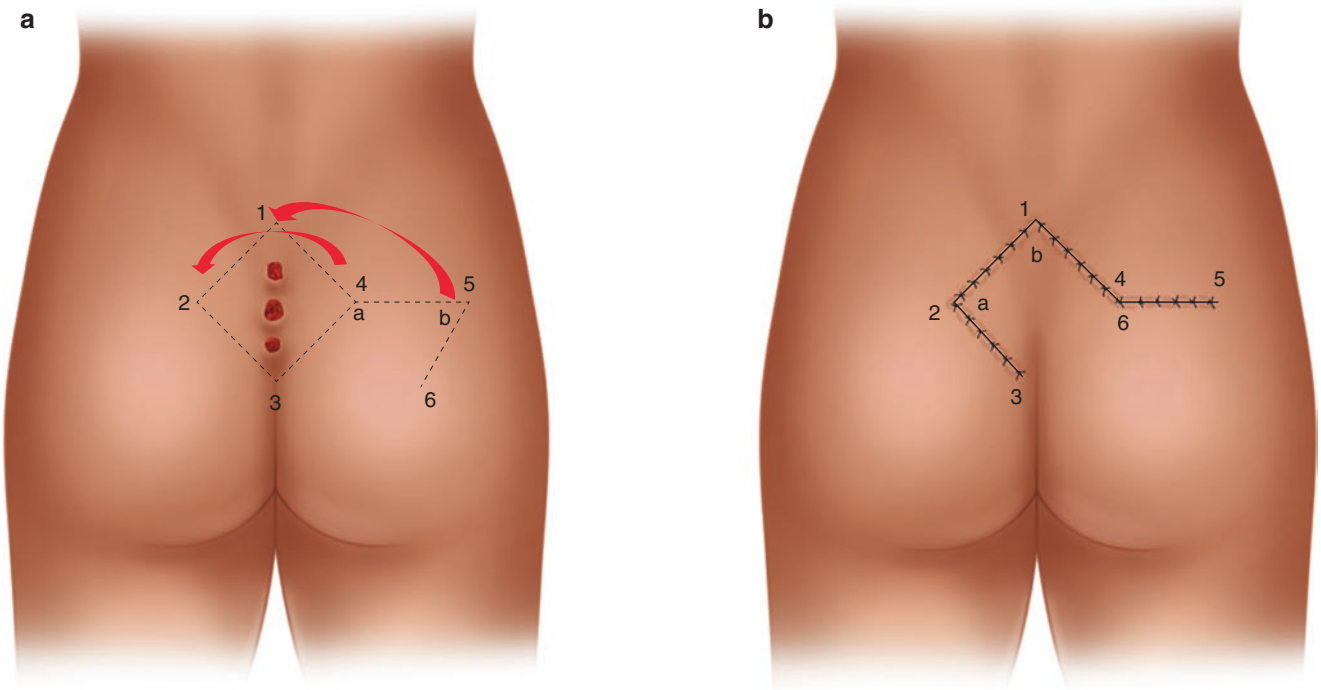

Fig. 16.5 Limberg flap (rhomboid flap). (**a**) The excision site is marked in a rhomboid shape, and the edges of the flap are drawn out. The rhomboid affected area is excised in a rhomboid shape down to the sacral fascia. (**b**) The flaps are raised as marked and then rotated as indicated by the arrows. The flap is secured in place with several layers of absorbable suture over a drain

Another study demonstrated an overall morbidity rate of 19.7% and recurrence rate of 1.6% [55]. One downside of the Limberg flap is the postoperative scarring, as it is not as cosmetically appealing as other flaps.

Cleft Lift Flap (Bascom Procedure)

The cleft lift flap, also known as the Bascom procedure, is designed to "lift" the concavity of the natal cleft and create an incision that is closed off midline (Fig. 16.6). This procedure is performed by first marking the "safety zone" of the gluteal cleft. The patient is placed in a prone position, and the safety zone is defined by the tissues that are able to touch when the gluteal cleft is pulled together – this is marked and represents the most lateral extent of the dissection. The tissue to be excised is also marked out. The area of excision comes across the central pits in the midline and extends in a scimitar shape at the inferior aspect of the excision site. This procedure, unlike the other flaps, does not require excising the entirety of the diseased tissue. After the excision area is marked, create an incision vertically across the midline through the central pits and ensure that the inferior aspect follows the scimitar-shaped marking. Creation of the flap occurs before excision of the diseased tissues. The flap is raised towards the opposite side from the tissue to be excised, which can be performed sharply or with electrocautery. The thickness of the flap should be similar to that of a mastectomy, and care should be taken to preserve subcutaneous tissues towards the anal side. Next, the excision of the skin overlying the area of disease is performed, with a majority of the subcutaneous tissue left in place. Any central scarring

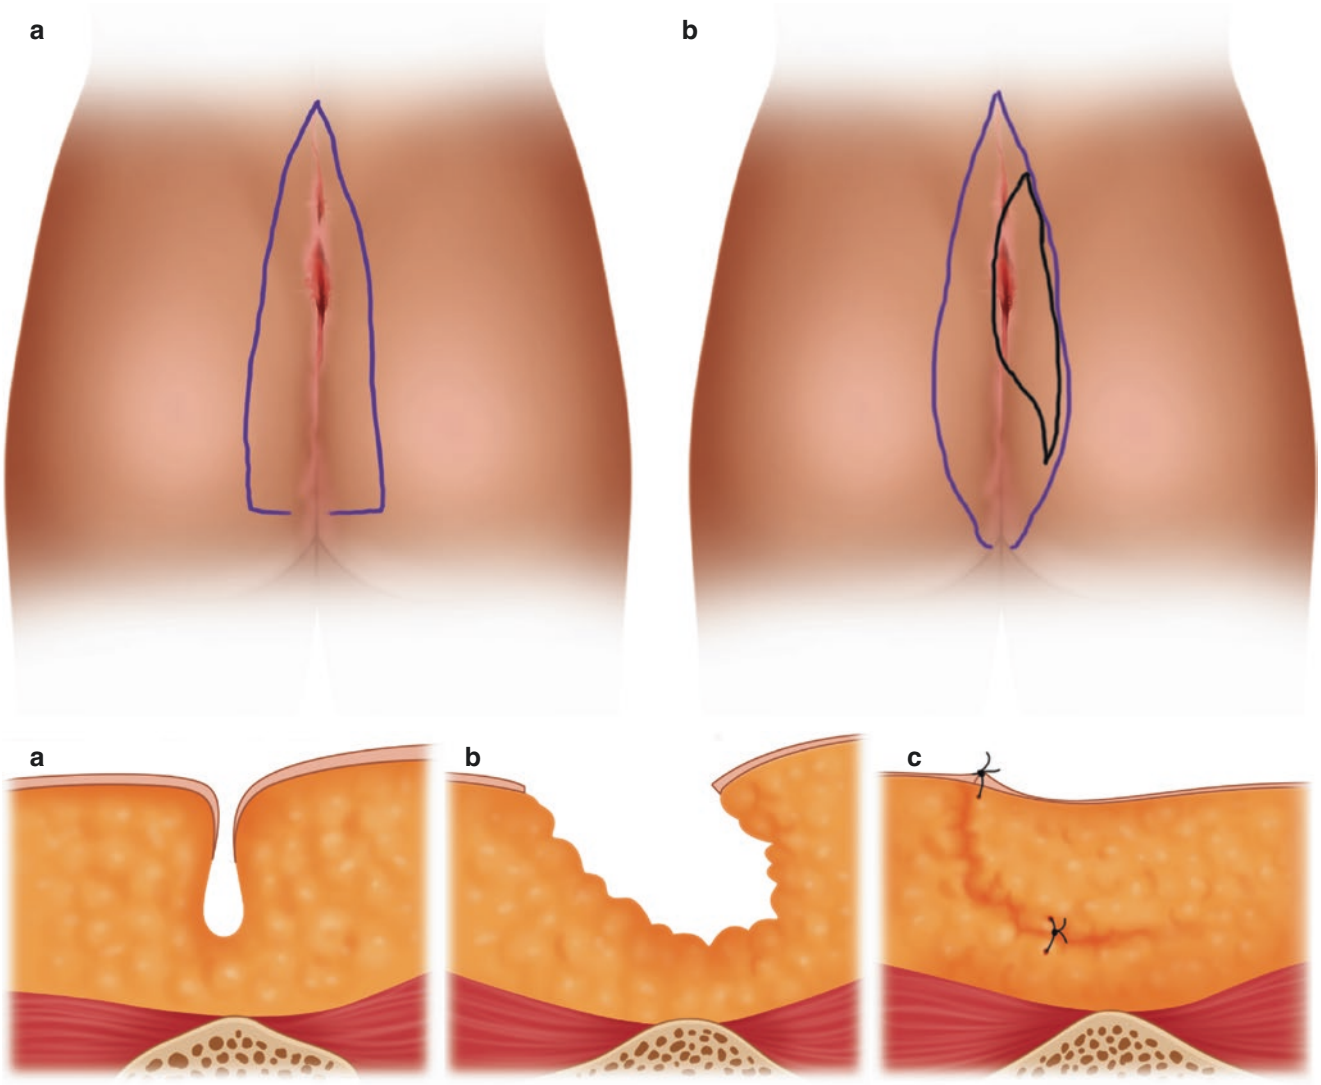

Fig. 16.6 Bascom flap (cleft lift). (**a**) First, a safety zone and a scimitar shaped incision are marked. (**b**) An incision is carried in the vertical midline and a flap is raised towards the opposite side from the tissue to be excised. After the buttock tapes are removed, the flap is checked to see the extent of reach contralaterally. Then the diseased tissue is excised, ensuring the flap will cover this tissue. (**c**) The flap is then secured in layers over a drain

can be lanced to free the contracture. The excision site is then closed with absorbable polyglycolic acid suture to close the deep space. A 7 mm closed suction drain is placed. The skin is then closed over a drain in a subcuticular running fashion using absorbable monofilament suture. This raises the natal cleft and keeps the incision off the midline.

Initially described by Bascom and Bascom, this procedure had initial success rates of 90% with a 100% success rates after the remainder of the patients underwent additional procedures [56]. A follow-up study by the same authors demonstrated healing rates of 96% [57]. Further studies have replicated these good results with healing rates as high as 97% [20, 58]. Patient satisfaction is high with cleft lift procedure, given a decrease in postoperative pain and low recurrence rate, though postoperative morbidity is as high as 20% [55].

Minimally Invasive Treatments

Minimally invasive treatments for pilonidal disease are desirable given the major morbidity that can occur with other operative options. These include endoscopic/video-assisted ablation, laser ablation, and trephination.

Endoscopic/Video-Assisted Ablation of Pilonidal Sinus (VAAPS)

In this procedure, a 4 mm hysteroscope is inserted into the opening of the pilonidal cavity after the opening is saucerized with electrocautery. The sinus and its lateral tracks are identified with the scope, under a continuous infusion of saline, and a mechanical adhesiolysis is performed. Any hair that is visualized is removed with grasping forceps. The cavity is ablated using a 5F bipolar electrode in one centimeter increments. The main sinus tract and any accessory tracts are identified. Finally, the residual cavity is debrided, and an iodine solution is injected into the cavity [59]. This procedure has demonstrated high healing rates and patient satisfaction scores. A prospective study with a median follow-up of 52 weeks demonstrated a success rate of 67% with a delayed healing rate of 77% [60]. Recurrence rates have been reported to be lower than standard excisional operations [61]. Modifications include the injection of phenol in the tract [62, 63]. When compared to the traditional Limberg flap, endoscopic treatment of pilonidal disease may have higher recurrence rates but is associated with fewer postoperative complications [64].

Laser Ablation of Pilonidal Sinus

The diode laser has been used in several other disease processes such as anal fistula and can be applied to pilonidal disease as well. This outpatient procedure depends upon ablation of the epithelium of the pilonidal sinus and promotion of new granulation tissue. The area is injected with local anesthetic, and the subcutaneous tract is located. The tract is debrided to remove hair and debris and then curetted to remove the tissues lining the tract. The tract is irrigated with saline, and a diode laser is introduced into the tract. Laser energy is delivered to the tract to create a homogenous ablation and destruction of the tissues in the tract. Every pit must be treated with the laser. Results of this operation have been promising [65]. Patients are able to return to daily activities and return to work immediately in as many as 92.8% of patients. Patients with less severe disease have better outcomes. Success rates are around 85–90%, and recurrence rates of as low as 2.9% have been reported [66, 67]. Complications include pain, hematoma, abscess, and drainage.

Trephination

Trephination is a procedure that involves the use of skin trephines to excise pilonidal pits and debride the underlying tracts and cavities (Fig. 16.7) [68]. Each pit is individually probed to evaluate the anatomy including the depth of the pit and presence of any associated tracts. Skin trephines sized 2.0–9.0 mm in diameter are used to core out the pits. When a subcutaneous tract is identified, excision is carried down to the cavity with 4.0–5.0 mm trephines. Any acutely infected areas are excised using 6.0–9.50 mm trephines and left open to heal by secondary intent. This technique has been reported to have a healing rate of 89.7% at 4 weeks with a recurrence rate of 16.2%. Postoperative complications occur in <5% of patients with wound infection rate <1% [69]. Postoperative wound care is minimal and includes light packing to allow the wounds to heal by secondary intent. Performing trephination does not exclude future excisional flap procedures in the case of recurrence.

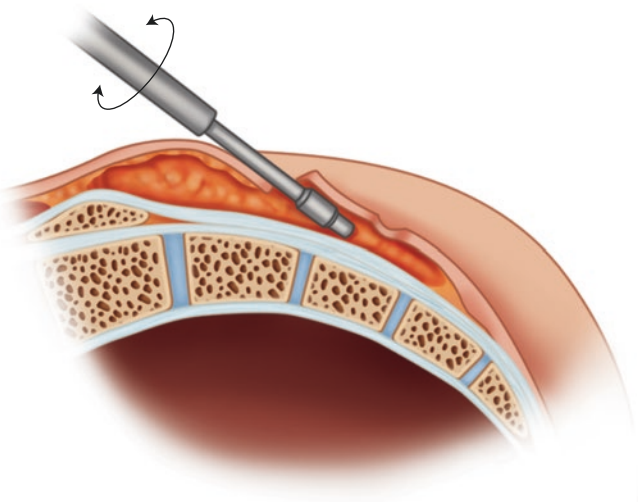

Fig. 16.7 Trephination. A skin biopsy punch is used to core out each symptomatic pit, which are left open to heal by secondary intent

Management of Recurrent Disease

Despite the variety of surgical options available to treat pilonidal disease, recurrent disease remains prevalent with rates as high as 34% after 1 year and 66% after 5 years [70]. There are no formal guidelines for the management of recurrent pilonidal disease with limited data to drive practice guidelines [36]. As described, no single procedure is without recurrence risk, so it is important to recognize the need to manage recurrent disease as well as primary disease. In the setting of an acute abscess, eliminating the immediate infection is necessary with incision and drainage. After resolution of the immediate infectious situation, the wound must be evaluated to assess the extent of the recurrence. Recurrence tends to be higher following treatment with antibiotics and need for incision and drainage, and up to 45% of patients with recurrence are obese [71]. When recurrence occurs, local excision, flap-based procedures, or minimally invasive procedures may be considered.

Wound Healing Adjuncts

Regardless of which type of surgical treatment is chosen, small or large wounds may form and require chronic management. This is most likely the result of the repeated friction that occurs in the natal cleft area with movement. After ruling out recurrent sepsis and prior to embarking on extensive surgical re-excision, local wound care efforts should be utilized to promote healing. Silver nitrate can be applied to any hypertrophic granulation tissue. Warm water soaks and soap cleansing can also encourage the wound to heal by secondary intention. In the case that this does not result in complete wound healing, several products are available that may encourage definitive wound healing. These include silver-impregnated gauze strips, hydrophilic wound dressing cream, and creams with methylene blue and gentian violet. Application of these twice a day, covered with a regular gauze dressing to protect the clothing, can result in successful healing without the need for further surgical intervention (Fig. 16.8).

Hidradenitis Suppurativa

Introduction

Hidradenitis suppurativa (HS) or acne inversa is a chronic, recurrent, inflammatory skin disease, initially presenting as

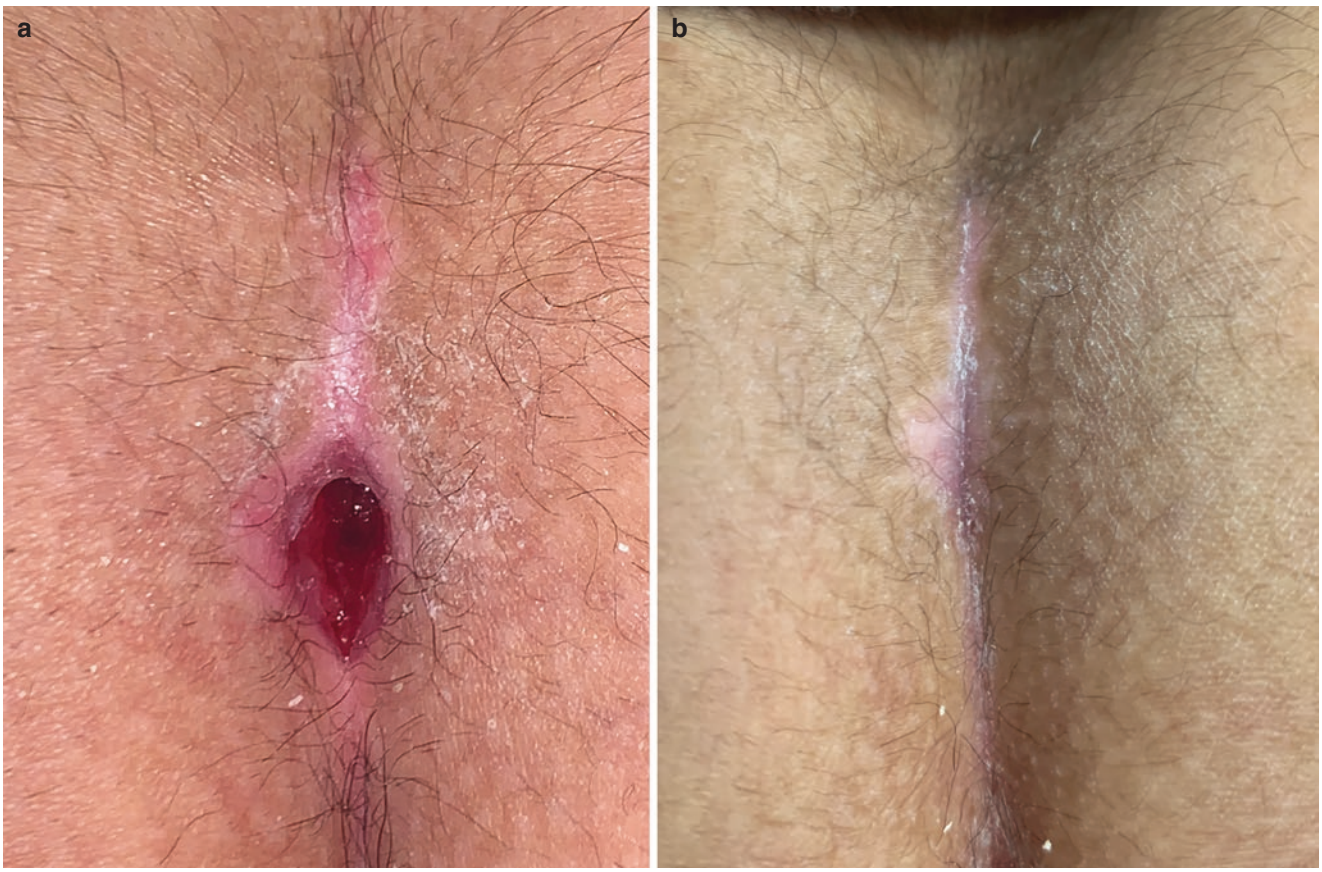

Fig. 16.8 (**a**) This is a nonhealing pilonidal wound after excision with primary closure. Several attempts at sitz baths, dressing changes, and silver nitrate had failed. (**b**) This is the same wound after 2 weeks of twice daily use of hydrophilic wound dressing cream

painful subcutaneous nodules as the characteristic suppurating lesion. These nodules can spontaneously rupture and coalesce which create deep dermal, exquisitely painful abscesses. The inflammatory abscesses can ultimately heal, producing fibrosis, dermal contractures, and induration of the skin as well as chronic sinuses. The severity of the disease is variable as is the clinical presentation with periods of quiescence and active flares. The disease occurs in the apocrine gland-bearing skin folds, typically the perineum, inguinal, inframammary, and axillary regions. The most commonly affected region is the axilla (70%) followed by the perineum and groin [72]. Patients may experience symptoms in more than one location. HS is associated with a marked reduction in quality of life and high incidence of comorbid mental illness [73]. Once believed to be the result of apocrine gland infection, it is now considered a disease of follicular occlusion. Factors implicated in the development of HS include (1) host defenses, (2) genetics, (3) endocrine abnormalities, (4) obesity, (5) smoking, and (6) environmental.

Incidence and Etiology

The exact incidence of HS is not known due to sparse epidemiologic data. In a recent cohort analysis, the overall prevalence in the US population was estimated at 0.1%, or 98 per 100,000 persons [74]. Woman were more than twice as likely to be affected compared to men with the prevalence highest among patients aged 30–39 years compared with all other age groups. HS prevalence among African American patients was more than threefold greater than white patients. Only 2% of cases occur before the age of 11 years [75]. In a retrospective study of 855 patients, 7.7% reported an onset of HS before the age of 13 years [76]. Early onset HS was associated with stronger genetic susceptibility and more widespread disease.

Modifiable risk factors have been identified as smoking and obesity. In a recent cohort analysis of smokers in the United States, the overall adjusted odds of developing HS was 1.9 (95% confidence interval 1.84–1.96) among tobacco smokers, compared with nonsmokers [77]. Tobacco smokers diagnosed with HS were most commonly aged 18–39 years, women, and white and had a body mass index (BMI) ≥30. Although the precise pathophysiologic role of smoking in HS remains uncertain, nicotine has been found to promote colonization of *Staphylococcus aureus* in intertriginous areas, chemotaxis of inflammatory mediators, and hyperplasia of the infundibular epidermis which can lead to the disease process [78]. In a recent meta-analysis of 25 studies (101,977 HS patients and 17,194,921 non-HS controls), a significant association between current smoking status and HS was identified (OR = 4.26 [95% confidence interval 3.68–4.94]) [79]. Both the prevalence and severity of HS are increased in obese patients with one study demonstrating an increased odds ratio of 1.12 for every one unit increase in body mass index [80, 81]. Obesity may aggravate HS via increased skin-skin and skin-clothing friction. Mechanical stress is associated with worsening of HS by increasing follicular occlusion and rupture [72].

Increasingly HS is viewed as an auto-inflammatory skin disorder associated with alterations in the innate immune system although large gaps remain in the understanding of the pathogenesis of HS [82]. There is increasing evidence supporting the role of Th17 cells and enhanced expression of IL-17 and IL-1β, which represent potential targets for therapy. Bacteria and biofilms are likely contributory but secondary drivers of inflammation [83]. This is aggravated by obesity, metabolic syndrome, and smoking [84, 85]. The primary defect in HS pathophysiology rests with the hair follicle. Follicular occlusion, followed by follicular rupture, with discharge of contents including keratin and bacteria into the surrounding dermis resulting in a foreign body-type immune response are necessary conditions for the development of clinical HS [86].

Clinical Presentation and Diagnosis

Diagnostic delay in hidradenitis suppurativa is a significant problem. In one study the average patient delay in seeing a physician (time from onset of symptoms to the first visit with any physician) was 2.3 ± 5.0 years, and the diagnostic delay was 7.2 ± 8.7 years [87]. Patients present with a range of signs and symptoms from a single open comedone (clogged hair follicle) to multiple painful, swollen nodules, generally with little purulent discharge. The inflammatory process may resolve without treatment but often waxes and wanes over many weeks to years. Chronic skin changes and discharge may develop that is both painful and socially limiting including sinus tract formation, contractures, and fibrosis (Fig. 16.1). In a study of 100 patients, 21% reported missing work, and 60% reported loss of work productivity during the preceding week as a result of HS. Seventy-two percent of these patients reported daily activity impairment with moderate to strong correlations between reduction in quality of life and presenteeism, overall work impairment, and activity impairment. Activity impairment was higher among patients with Hurley stage III [88].

The diagnosis of HS is made by lesion morphology (nodules, abscesses, tunnels, and scars), location (axillae, inframammary folds, groin, perigenital, or perineal), and lesion progression (two recurrences within 6 months or chronic or persistent lesions for ≥3 months). The differential diagnosis in the perineal or genital area is primarily between HS and other subcutaneous tunneling diseases, and if uncertain, a biopsy should be considered. The absence of midline pits

over the sacrum helps distinguish HS from pilonidal disease; the absence of involvement of the anal canal helps distinguish HS from Crohn's disease and benign anal fistula.

Given the wide-ranging severity of both disease burden and symptoms, there have been a number of classification systems proposed in an effort to quantify and categorize patients with HS [81, 89–92]. The majority of these scoring systems has not been validated or may be better suited for research purposes than clinical care of patients impacted by the disease. Disease severity can be classified according to the Hurley classification, which defines stage I as transient nonscarring inflammatory lesions; stage II as separate lesions consisting of recurrent abscesses with tunnel formation and scarring and single or multiple lesions separated by normal looking skin; and stage III as coalescent lesions with tunnel formation, scarring, and inflammation [93]. This system has been criticized as its intent was to classify the disease severity in a single anatomic region, and many patients with HS have disease that is multifocal, and a revised system has been proposed. This new classification subdivides Hurley stage I and II into three substages, mild (A), moderate (B), and severe (C) based on the overall extent of the disease and degree of inflammation. Hurley stage III is not subcategorized and is always severe. The refined Hurley classification strongly correlates with HS severity assessed by both patients and clinicians using quality of life scoring tools [20]. Other critics have pointed out that the Hurley score is a static score and not sufficiently responsive to change, particularly relating to the inflammatory component of HS [94]. The Sartorius score is another classification system that is commonly used whereby involved anatomical predetermined regions are counted, classified, and weighted according to type. Additional points are given for the longest distance between two lesions within each affected anatomical region and for any regions containing Hurley III. The points are added for an overall severity score [81]. Another approach for physician assessment is the Hidradenitis Suppurativa Clinical Response (HiSCR) score developed and validated for use as the primary endpoint in randomized control trials studying the use of adalimumab [92]. The primary component of HiSCR evaluation is the objective and uncomplicated counting of HS lesions. The HiSCR is a valid and meaningful endpoint for assessing HS treatment effectiveness in the inflammatory component of HS and is also significantly correlated with improvements in all physician-related measures (Hurley stage, modified Sartorius scores, and HS Physicians Global Assessment) and patient-reported outcomes (visual analogue pain scale, dermatology life quality index, and work productivity and activity impairment questionnaire).

Several comorbid conditions have well-known association with HS given the systemic nature of the disease. The link between hidradenitis suppurativa and systemic associations may be attributed to common genetic or environmental factors or shared inflammatory pathways.

Metabolic disorders including obesity and metabolic syndrome are the most common associated conditions observed in patients with hidradenitis suppurativa [95]. Autoimmune diseases, like inflammatory bowel diseases, autoinflammatory diseases, spondyloarthritis, some genetic keratin disorders, and also the risk of skin tumor, seem to occur more frequently in these patients [82]. There is a well-established link between acne and HS as well as pilonidal disease. In one study evaluating the disease severity of HS, the presence of severe acne was associated with an increased Sartorius score, as was male sex, increasing BMI, atypical locations of HS lesions, and absence of a family history of HS [96]. In a review of 826 patients with HS, overall 45% of the patients had Hurley I, 41% had Hurley II, and 13% had Hurley III. Severity was associated with male sex (OR 2.11; $p < .001$), disease duration (OR 1.03; $p < .001$), body mass index (OR 1.03; $p = .01$), smoking pack-years (OR 1.02; $p = .001$), and axillary (OR 2.24; $p < .001$), perianal (OR 1.92; $p < .001$), and mammary lesions (OR 1.48; $p = .03$). Women had earlier onset, more inguinal and mammary lesions, and more frequent family history for hidradenitis suppurativa. Men more commonly had gluteal, perianal, and atypical lesions and a history of severe acne. Patients with a family history had earlier onset, longer disease duration, a history of severe acne, and more extensive disease and were more often smokers [97].

Treatment

Treatment of HS is multidisciplinary as there are a host of medical and surgical therapies from incision and drainage to infusions with biologic agents. The practicing colorectal surgeon may be the first medical provider to identify these patients especially when their disease is located in the perineal region. Surgery of HS lesions is typically reserved for intractability and acute abscess formation but is one of the most successful treatments available. The persistent and recurring nature of the disease requires an individualized treatment plan. It is imperative to educate the patient about the chronic relapsing nature of the disease and to elicit the goals of therapy prior to making any decisions about treatment options.

Medical Therapy

Topical Therapy

Clindamycin lotion (1%) is the only antibiotic that has been studied as a topical agent. In a placebo-controlled, double-blind, randomized trial in 30 patients with HS, the overall effect of clindamycin treatment based on patients'

assessments, number of abscesses, inflammatory nodules, and pustules was significantly better than placebo at each monthly evaluation over the 3-month study period [98]. It is primarily used in patients with Hurley stage I or mild stage II. The proposed dosing regimen is twice daily, for 3 months. If clinical response is not achieved after that treatment period, other treatment options must be considered.

Other topical agents include resorcinol, a phenol derivate with keratolytic and anti-inflammatory properties. It was evaluated in 32 HS patients, and by days 7 and 30, there was a significant reduction in the clinical size of the lesions and the mean pain score [99].

Systemic Antibiotics

Antibiotics are commonly used to treat HS flares because of secondary bacterial infections, and some, such as tetracycline and rifampicin, also may have immunomodulatory properties. For example, tetracycline suppresses neutrophil migration and chemotaxis and inhibits matrix metalloproteinase [100].

Tetracycline 500 mg b.i.d. has been evaluated and compared with topical clindamycin in a double-blind, randomized, controlled trial of 46 patients with Hurley stage I and II disease [101]. No significant difference was identified between the two treatment arms. Tetracycline can be used as a first-line treatment in patients with more widespread Hurley I and mild Hurley II stage, when topical therapy would not be practical, for up to 4 months. Clindamycin 300 mg b.i.d. in combination with rifampicin 600 mg once daily or 300 mg b.i.d. has been evaluated in several case series [102]. In a study of 116 patients with severe HS, combination therapy decreased the Sartorius scores, while quality of life scores improved significantly. In another prospective study, 26 patients were given combination therapy for 12 weeks with 1-year follow-up with a reported initial clinical response in 19 of 26 patients (73%) immediately following the treatment and then decreasing to 7 of 17 patients (41%) at 1 year. The remaining relapsed a mean of 4.2 months following treatment cessation [103]. This treatment combination can be used as a first-line treatment option in patients with moderate and severe HS for up to 10 weeks.

Biologics

Adalimumab, given subcutaneously at a dose of 40 mg weekly, has been studied in a prospective, randomized, double-blind, placebo controlled trial [104]. One hundred and fifty four patients with moderate to severe HS who had failed antibiotic therapy were treated. There was a significant reduction in the HiSCR, as well as pain scores, while quality of life and work productivity increased. These results have been reproduced in three additional randomized trials [105, 106]. Adalimumab is recommended as a first-line treatment option in patients with moderate to severe HS who were unresponsive or intolerant to oral antibiotics. Infliximab (IFX) 5 mg/kg has been evaluated in a randomized, placebo-controlled, crossover trial. No significant difference was noted in the HiSCR score although more patients receiving IFX achieved a 50% reduction in HS lesions compared to placebo. There was a significant improvement in patients' quality of life scores and VAS pain scores. Infliximab is recommended in patients with moderate to severe HS as a second-line treatment option, only after failure of adalimumab. If clinical response is not achieved after 12 weeks of treatment, other treatment modalities must be considered. Both anakinra (recombinant IL-1 receptor antagonist) and ustekinumab (human IgG1κ monoclonal antibody) have been recently studied in the treatment of moderate to severe HS and have shown to be efficacious as an alternate therapy [107, 108].

There is some evidence to support the use of biologics as an adjunct to surgery as a means to decrease recurrence when compared with surgery alone [109]. In one study, 68 patients with moderate to severe HS were treated with biologics. The mean disease duration was 10 years, and Hurley stage III was seen in 63% of patients. Patients who received biologics had a larger drop in their Sartorius scores and active nodule count than those who never received biologics. The effect of biologics was greater in patients who also underwent surgery. Timing of biologics relative to surgery did not impact efficacy. Patients who received HS surgery with biologic therapy were most likely to achieve a 75% reduction in active nodule count [110]. In another study, 11 patients underwent combined surgical and biologic therapy, whereas radical resection alone was performed in 10 patients. Biologic agents including infliximab ($n = 8$) and ustekinumab ($n = 3$) were initiated 2–3 weeks after closure and were continued for an average of 10.5 months. Recurrence was noted in 19% and 38% of previously treated sites for combined and surgery-only patients, respectively ($p < 0.01$). For the combined cohort, the disease-free interval was approximately 1 year longer on average ($p < 0.001$). New disease developed in 18% and 50% of combined and surgery-only patients, respectively ($p < 001$). No adverse events were noted among patients who received biologic therapy [111].

Other Medical Therapies

Androgens influence HS, as evidenced by the effects of pregnancy and menstrual cycles for many patients, but the recommendations on hormonal therapies are based on limited evidence. The only RCT of hormonal therapy compared ethinyl estradiol/noregestrol with ethinyl estradiol and cyproterone acetate; it was a double-blind, controlled, crossover trial of 24 women. Both therapies resulted in similar improvement, with 12 patients improving or clearing completely [112].

Metformin is a biguanide involved in several processes: it reduces gluconeogenesis of the liver, and it improves the insulin-mediated glucose uptake by skeletal muscles. It also reduces the androgens produced by ovaries and has been shown to have anti-inflammatory properties [113, 114]. Patients with mild to moderate HS have seen improvement in both the clinical course of their disease and quality of life scores when taking metformin over a 24-week period. Most of the patients in the trial were females with features of polycystic ovarian syndrome.

Historically, retinoids were frequently used for HS, because the pathogenesis was considered more similar to that of acne vulgaris. However, results have been disappointing consistent with the current understanding of HS as a follicular disorder. In all, 4 retrospective and 3 prospective uncontrolled cohort studies have been reported for isotretinoin monotherapy, for a total of 207 patients. Therapy ranged from 4 to 10 months, and outcome measures varied markedly, but a total of 85 of 207 (41%) improved, with better responses in milder disease. Isotretinoin should be considered most strongly in patients with concomitant nodulocystic acne [115].

Laser Therapies

Laser and light-based therapies have been used in the management of HS and work to reduce the occurrence of HS flare-ups by decreasing the number of hair follicles, sebaceous glands, and bacteria in affected areas. The best results are seen when treatment is individualized, taking disease severity into consideration when selecting specific energy-based approaches [116]. In a study by Tierney et al., Nd:YAG laser was shown to be an effective treatment for patients with stage II or III HS. The authors completed a prospective randomized controlled study of 22 patients in which 3 monthly laser sessions were performed on half of the body and results were compared with the other control half. Using a modified Sartorius scoring system, percentage decreases in HS severity after 3 months of treatment were 65% for all anatomic sites, 73% for inguinal sites, 62% for axillary sites, and 53% for inframammary sites. This reflected a statistically significant change in HS severity from baseline to month 3 in the treated areas but not at the control sites [117]. Carbon dioxide laser excision may help patients with more extensive involvement and has high patient satisfaction; however, it has been studied only in patients with Hurley stage II disease and has higher recurrence rates compared with wide excision [118]. In a study evaluating the carbon dioxide laser in 24 patients with a mean follow-up of 27 months, 22 patients reported resolution with no recurrence of their HS. Postsurgical results were reported to be cosmetically satisfactory [119]. Vaporization was usually able to reach the deep subcutaneous fat or fascia, and healing occurred over a median of 4 weeks.

Surgery

Patients who fail medical therapy and who are experiencing debility and pain from their HS lesions may opt for surgery which can lead to some excellent outcomes. While the evidence for surgical therapies in HS is limited and mostly based on cohort studies and case series with differing definitions and outcome measures, the main goal is always to excise the pilosebaceous or hair-bearing region of the involved area (axilla, inframammary fold, groins, and perineum). The extent of the excision will depend on the extent of the disease and the goals of the patient, with a range of options from simple incision and drainage to wide local excision and skin grafting. Excision should involve the entire skin down to the subcutaneous fat and even fascia as appropriate to ensure elimination of the pilosebaceous unit. For tense and painful abscesses, no medical therapy should be offered, and surgical drainage is required with the understanding that this is a temporizing measure and recurrence of disease is inevitable [120].

In an effort to avoid the morbidity of a large wound, studies have explored the efficacy of a deroofing technique in which the roof of a lesion is surgically removed and the floor of the lesion is left exposed. Forty-four patients with recurrent Hurley stage I or II HS lesions underwent 73 deroofing techniques with 83% showing no recurrence during a median follow-up period of 34 months. The other 17% of patients showed recurrence after a median follow-up period of 4.6 months. Ninety percent of patients responded that they would recommend the procedure to other individuals with HS [121]. A variation using an electrosurgical loop to excise the overlying skin has been developed and coined the STEEP procedure (skin tissue sparing excision with electrosurgical peeling), with a 4% recurrence rate [122]. The goal is to reduce the collateral injury to surrounding normal tissue and maintaining as much of the subcutaneous fat as possible. This is achieved by performing successive tangential excisions of the affected tissue until the epithelialized bottom of the sinus tracts has been reached. From here, healing occurs by secondary intention. Fibrotic tissue can also be completely removed as this can serve as a source of recurrence. This tissue-sparing technique results in low recurrence rates, high patient satisfaction with relatively short healing times, and favorable cosmetic outcomes without contractures [123]. No controlled, prospective studies exist, but deroofing appears to be effective for acute and chronic lesions, with utility in a variety of outpatient settings [124, 125].

For patients with more extensive disease, wide local excision has been the mainstay of traditional surgery and can result in a disease-free state where the excision is performed. Once the area has been excised, the resulting wound may be approached in different ways. If the wound is small, it can be closed primarily without tension. For larger wounds, the defect may be left open to close by secondary intention.

Perineal and perianal wounds so treated rarely require a colostomy. Large wounds may also be treated by immediate or delayed split-thickness skin graft.

Because surgery alone does not alter disease biology, understanding the trade-offs between extent of excision, surgical morbidity, and reducing the risk of future lesions is an important consideration. In a series of 590 patients treated with excision, deroofing, or drainage, drainage was associated with the highest recurrence, whereas deroofing and wide excision were about equal in effectiveness. Most patients in this series were white (91%), men (57%), and smokers (58%) with Hurley stage III disease (81%). Postoperative complications occurred in 15 patients (2.5%), and 24% suffered postoperative recurrence, which necessitated reoperation in 12% of those patients. Recurrence risk was increased by younger age (hazard ratio [HR], 0.8), multiple surgical sites (HR, 1.6), and drainage-type procedures (HR, 3.5). Operative location, disease severity, gender, and operative extent did not influence the recurrence rate [120]. In a retrospective review of 79 patients who had 220 operative sites evaluated over a 4-year period, a 25% recurrence rate was identified. The median disease-free interval between surgery and recurrence was 8 months. Almost two thirds of recurrences necessitated repeated excisional surgery ($n = 35$, 63%). Patients who achieved remission had a significantly lower number of affected regions than those who experienced a recurrence (2.3 vs 3.6, $p = .0023$). Additionally, recurrence rate differed significantly between body locations ($p = .0440$). Operative sites in the axilla had the lowest rate of recurrence, while operative sites at the groin held the highest recurrence rate. There was no significant difference between the rates of wound complication for each location. Smoking, BMI, Hurley grade, closure method, and excision size did not influence local cure rate. There was no difference in the recurrence or complication rates between operative sites closed with direct sutures, skin grafts, or rotation advancement flaps [126]. In a meta-analysis of 22 articles on surgical treatment of HS, the estimated average recurrences were wide excision, 13.0%; local incision, 22.0%; and deroofing, 27.0%. In the wide excision group, recurrence rates were as follows: 15% for primary closure, 8% for flaps, and 6.0% for grafting. The secondary intention healing option was most commonly chosen after local excision and deroofing [127].

Overall, patients report good outcomes following surgery with one study evaluating patient-reported outcomes included movement, pain, satisfaction with treatment, willingness to undergo surgery again, and appearance. Patients graded each outcome on a 4-point scale. The median score regarding function, aesthetics, and satisfaction after all interventions was 17 out of 20, but the score was lower after fasciocutaneous flaps than primary closure, healing by secondary intent, and split-thickness skin grafting [128]. In a survey of 111 patients with Hurley stage III disease following excision or unroofing, patients were satisfied or very satisfied with their surgical results (85%), were glad they underwent surgery (96%), and would recommend surgery to a friend or relative (83%). Most patients were satisfied or very satisfied with the appearance of their healed wound (62%). Retrospective mean quality of life increased significantly from 5 preoperatively to 8.4 postoperatively ($p < .001$) [125]. Negative pressure wound therapy has been shown to shorten the duration between excision and delayed closure or grafting. It has been suggested that this system improves wound healing by increasing blood flow and granulation tissue formation, reducing bacterial load, and thereby reducing the size and complexity of the wound. Comparisons of various approaches using negative-pressure wound therapy alone versus silver dressings or dermal regeneration templates (Integra, Integra LifeSciences, Plainsboro, NJ) are limited [129–131].

Conclusions

HS is a chronic disease that can result in significant debility and suffering. Most patients present in their prime working years and report a loss of productivity secondary to the waxing and waning nature of the disease. Treatment should be multidisciplinary with a focus on managing the patient's goals and expectations. For smaller areas of mild disease, topical or oral antibiotic therapy can be effective. For more widespread or severe disease, biologic agents have shown to be efficacious with newer treatment options emerging with evolving understanding of the inflammatory targets. Surgery remains an important treatment option and includes controlling infection with incision and drainage to wide local excision of the affected area to remove the hair-bearing skin followed by split-thickness skin grafting or healing by secondary intention.

Dermatology and Pruritus Ani

17

Konstantin Umanskiy and Evangelos Messaris

Key Concepts

- Pruritus ani often results in considerable emotional and physical distress and significantly affects the patient's quality of life.
- A detailed and complete history and physical examination can help to identify a specific etiology in 75% of cases.
- Culture swabs and skin biopsy are important adjuncts to physical examination.
- In most cases, initial therapeutic approach is aimed at improvement of anal hygiene, dietary modification, and toileting habits.
- The patient's expectations should be set to anticipate slow improvement of their symptoms.
- Various topical and systemic therapeutic modalities can be offered sequentially with emphasis on incremental improvement rather than complete resolution of symptoms.

Introduction

Pruritus ani is a condition characterized by severe, intense itching around the perianal area. Pruritus ani is the Latin term for "itchy anus" and describes all conditions that result in itching and irritation in the perianal skin. The disease has been first reported in ancient Egypt [1]. Since, it has continued to be a serious disorder usually arising from benign conditions. It may be transient or chronic and difficult to treat. In the 1600s, pruritus (itch) was officially defined by the German physician Samuel Hafenreffer as the "unpleasant sensation that elicits the desire or reflex to scratch" [2]. Anal pruritus is estimated to affect 2–5% of the general population, but most patients will not seek medical attention, unless the symptoms intensify or become chronic [3]. Anal pruritus is more common in the fourth to sixth decades of life and has a higher prevalence in males (4:1 ratio compared to females) [4]. Treating patients with anal pruritus can be frustrating for both the patient and the physician. Having the patient understand the possible cause of the disease, the pathophysiology, and the steps in the treatment of it is critical. This common understanding will help the patient manipulate through a complex treatment plan without losing trust for the treating physician.

The purpose of this chapter is to summarize the presentation and diagnostic approach to pruritus ani, as well as the available treatment strategies and their supporting evidence.

Pathophysiology

The urge to itch in pruritus ani is mediated by the extensive, unmyelinated C fibers that are predominant in the anoderm and perianal skin. Stimulation of these fibers leads to scratching and frequent wiping in order to relieve the urge. This often contributes to excoriation and cutaneous injury, which causes additional stimulation of the C fibers, inciting more itching and scratching (Fig. 17.1). Itch-transmitting polymodal, unmyelinated C fibers enter the dorsal horn of the grey matter of the spinal cord and synapse there with secondary neurons, which cross over to the contralateral spinothalamic tract and ascend to the thalamus [5]. Then tertiary neurons relay itch to the level of conscious perception in the cerebral cortex, anterior cingulate, and insular cortex, while the premotor cortical areas participate in intention to scratch. The most important cytokine mediators of itch sensation include histamine, acetyl choline, substance P, calcitonin gene-related peptide (CGRP), opioid peptides, proteases, bradykinin, serotonin, platelet-activating factor, neurotrophins, prostaglandin E, and other cytokines. Histamine is the most potent pruritogen.

There are two major biochemical pathways for the sensation of itch, one is histamine dependent and one is not. Histamine receptors are coupled with Gq proteins, which upon

binding on histamine activates phospholipase Cβ3 (PLCβ3), which in turn cleaves phosphotidylinositol-4-5-biphosphonate (PIP2) into the second messengers diacylglycerol (DAG) and inositol triphosphate (IP3). DAG activates protein kinase Cε (PKCε) which phosphorylates and thereby opens the TRPV1. Activation of TRPV1 leads to channel opening which allows passage of the positively charged ions sodium, potassium, and calcium resulting in depolarization. Thereby voltage-dependent sodium channels are activated generating action potentials along the nerve fiber which lead to the sensation of itch. Histamine-induced itch is mediated by activation of TRPV1 and requires phosphoinositide-interacting regulator of transient receptor potential channels (PIRT), a membrane protein modulating TRPV1 function [6–11].

In the non-histaminergic pathway of itch, PAR-2 has been shown to play a crucial role [12]. PAR-2 activation has been shown to increase the release of IL-6 and granulocyte-macrophage colony-stimulating factor from keratinocytes in atopic eczema patients. 5-HT is, like histamine, mainly secreted from skin mast cells in the periphery and is able to activate sensory neurons directly. The action of 5-HT may be partly mediated by cutaneous 5-HT2 receptor. It activates PLC 3 elicits, an itching sensation associated with pruritic diseases, such as polycythemia vera and cholestasis.

Etiology

Approximately 75 percent of cases of anal pruritus are secondary to inflammatory, infectious, systemic, neoplastic, and anorectal disorders that contribute to the development of pruritus (Table 17.1). Despite extensive workup, no clear etiology of pruritus ani can be identified in up to 25% of patients.

Table 17.1 Common causes of anal pruritus

Category	Specific inciting factors
Diet	Tomatoes, chocolate, citric fruits, spices, coffee (including both caffeinated and decaffeinated), tea, cola, beer, milk and other dairy products
	Popcorn, figs, prunes, grapes, spicy foods, peanuts
Diarrheal state	Inflammatory bowel diseases, irritable bowel syndrome
Fecal soiling	Encopresis
	Incontinence
	Chronic diarrhea
	Poor hygiene
	Transient relaxation of internal sphincter
	Prolapsed, hemorrhoids, etc.
Local irritation	Soaps and detergents
	Topical creams and medications
	Obesity, excessive hair
	Tight-fit clothing
	Poor hygiene or excessive hygiene
Dermatologic disorders	Psoriasis
	Contact dermatitis
	Atopic dermatitis
	Bowen's disease, Paget's disease
	Hidradenitis
Anorectal disorders	Fissures
	Hemorrhoids
	Proctitis
	Abscess
	Fistula
	Rectal cancer
	Anal cancer (squamous cell carcinoma)
	Adenomatous
Infections	*Candida albicans*
	Dermatophytes (*Malassezia furfur*)
	Staphylococcus aureus
	Beta-hemolytic streptococcus
	Corynebacterium minutissimum (erythrasma)
	Human papilloma virus
	Herpes simplex
	Sarcoptes scabiei (scabies)
	Enterobius vermicularis (pinworms)
Systemic disease	Diabetes mellitus
	Leukemia
	Thyroid disorders
	Liver disease
	Renal failure
Gynecologic	Menopause, vaginitis
Psychological	Depression, anxiety, psychosis

These cases are classified as idiopathic, or primary, pruritus ani and are considered as a diagnosis of exclusion. Cases with no identifiable cause are the most difficult to treat.

Fecal Soilage

It is very common for patients to have perianal fecal contamination that leads to increased wiping that consequently

is associated with trauma and continuous scratching. Fecal soilage can be present because of diarrhea, anal incontinence, pelvic floor dysfunction, or just lack of adequate dietary fiber [13]. In a case-control study that included 23 men with anal pruritus and 16 controls who underwent anorectal electromyography and manometry, patients with anal pruritus had a greater rise in rectal pressure during internal sphincter relaxation (29 versus 18 mmHg) and prolonged internal sphincter relaxation (29 versus 8 seconds) as compared with controls [13]. Others have shown that after doing a saline infusion test, patients with anal pruritus develop early leakage (after 600 mL) as compared to control subjects (after 1300 mL). There is an inverse relationship to the severity of symptoms and the volume of first leakage. Again, leaking and soiling seem to be major factors. Although rare, anal manometry should be considered in cases with negative initial workup and no improvement after intensive therapy. Furthermore, in patients with anal itching and pelvic floor dysfunction, the role of pelvic floor physical therapy is important and should be encouraged in such cases. In patients with chronic diarrhea such as ulcerative colitis, Crohn's disease, or irritable bowel syndrome, the treatment of the primary disease will usually resolve the anal pruritus.

Dietary Factors and Medications

Specific foods such as coffee, tomatoes, beer, cola, tea, peanuts, milk produce, citrus, chocolate, and grapes have been implicated in causing or exacerbating pruritus ani. Some studies have reported that pruritus ani was reduced within 2 weeks after avoiding specific foods, such as chocolate, citric fruits, spices, coffee (including both caffeinated and decaffeinated), tea, cola, beer, milk and other dairy products, and tomatoes and tomato-based products like ketchup [14]. It is not clear whether food-induced pruritus ani is a variation of an allergic reaction to the food or a consequence of direct exposure of the skin to specific ingredients [15]. Several medications such as tetracycline, colchicine, quinidine, peppermint oil, local anesthetics, and neomycin have been associated with anal pruritus. It is unclear if these medications and foods act as direct irritants or indirectly cause irritation by causing diarrhea or fecal seepage. These food and medication can alter the pH of the stool or lower sphincter tone. Relaxed anal sphincter pressure combined with exaggerated anal reflexes lead to liquid stools, quicker transit time, and increased frequency of bowel movements. Ultimately, soiling progresses as does perianal trauma from repetitive cleaning. If a food, beverage, or medication is found to exacerbate symptoms, it should be avoided.

Dermatologic Diseases

Several dermatologic diseases can present with perianal skin lesions or no findings on exam and cause severe anal pruritus [16].

Contact dermatitis is the most common perianal dermatologic condition and is characterized by macular erythema, hyperkeratosis, or radial fissuring. Irritant contact dermatitis results from exposure to substances that cause physical, mechanical, or chemical irritation of the skin [16]. Contact dermatitis can be just from mechanical irritation or from an immune-mediated reaction, which is a result of a mechanical or chemical irritant that may act as an allergen [17]. Irritant contact dermatitis can be caused by common exposures used repeatedly on a daily basis (soaps, cleansers, rubbing alcohol, feces) and, in some cases, with one exposure (bleach, formalin). Treatment involves removing the offending agent, keeping the area dry (cotton ball or folded cotton gauze), and avoiding further trauma to the skin. For cases that first line of treatment is not successful, patch testing by an allergist or dermatologist can be useful to determine if there is an inciting allergen, especially in severe or refractory contact dermatitis.

Atopic dermatitis presents with thickened skin and leathery patches. This commonly hereditary condition presents at a young age (early childhood) and is associated with other lesions in the neck, antecubital, and popliteal fossas. The diagnosis is most of the times clinical based on the type of skin lesions (thickened skin, increased skin markings, lichenification, and excoriated and fibrotic papules), early onset in life (younger than 10 years old), significant family history of severe allergic disease, and the associated skin lesions in flexor areas of the body. Treatment is with a topical barrier like petroleum-based creams, zinc oxide creams, anti-inflammatory drugs, and antihistamines. The concomitant use of topical anesthetics and steroids, while leading to temporary relief, can frustrate attempts at identification of the inciting compound.

Psoriasis presents with erythema and sharply defined boundaries with or without the typical scaling. In most cases of perianal psoriasis, the characteristic scaling is not visible. The psoriasis plaques may look different due to the persistent scratching thereby making the diagnosis difficult. These lesions are sometimes referred to as inverse psoriasis because they are without scales and tend to be paler. Inverse psoriasis, also known as intertriginous or skin-fold psoriasis, is a form of psoriasis that presents itself as erythematous plaques with poor or non-desquamation in skin flexion folds. Patients with anal psoriasis present a cyclical quality to the symptoms, with the majority of pruritus occurring at night. The presence of associated lesions in the groin, genitalia, intergluteal cleft, axilla,

and umbilicus will hint the physician to place the appropriate diagnosis. Furthermore, there are forms of paradoxical psoriasis in the perianal area that can be caused by biologic therapy (anti TNFa agents) for the treatment of patients with inflammatory bowel disease [18]. For perianal psoriasis, the treatment is usually a low- to mid-potency topical steroid. Tacrolimus and dapsone can also be used for more severe cases [19].

Lichen simplex chronicus is a condition that can result from chronic diarrhea. Inflammation in the perianal area results in thickened (lichenified) and cracked, excoriated skin. Treatment is focused on controlling the frequency of bowel movements. Psyllium husk, loperamide, and silver sulfadiazine can be used with addition of low-dose hydrocortisone for more severe cases.

In a similar way, *lichen sclerosus* (*atrophicus*) presents mainly in women with a thinning and wrinkling of the perianal skin, also known as a "cigarette-paper" appearance with associated skin discoloration. This also classically affects the labial skin and perineum. Lichen sclerosis may be associated with squamous cell carcinoma. Thus, the affected area should be examined at least annually, and a biopsy should be considered for any suspicious lesions. Treatment is a topical glucocorticoid like clobetasol propionate 0.05% for 6–8 weeks [20]. Tacrolimus has also been used for this condition.

Seborrheic dermatitis is a rare cause of anal itching. It is caused by a fungus called *Malassezia furfur*, and it is treated with an antidandruff shampoo or any other topical antifungal agent.

Hidradenitis suppurativa is a chronic, suppurative process involving the skin and subcutaneous tissue. The usual initial presentation is of recurrent, painful, and inflamed nodules. The nodules may rupture, discharging purulent, sometimes malodorous material. Persistent disease leads to the formation of sinus tracts, end-stage "tombstone" comedones, and scarring [21]. There are three stages of the disease: stage 1 is abscess formation, single or multiple, without scarring or sinus tracts; stage 2 is recurrent abscesses with tract formation and scarring, single or multiple, and widely separated lesions (Fig. 17.2); and stage 3 is multiple interconnected tracts and abscesses throughout an entire body area. Treatment strategies can be categorized broadly into medical and surgical. Antibiotics, retinoids, hormones, and immunosuppressive agents have been used. All have shown success in reducing symptoms temporarily but none long term. Antibiotics must be chosen to cover both aerobic and anaerobic bacteria. Topical clindamycin and oral clindamycin with rifampin, in addition to tetracycline, erythromycin, and doxycycline, have shown efficacy at reducing symptoms. Long-term treatment up to 12 weeks is required to achieve remission. Evidence is lacking that antibiotics change the natural course of this disease. Isotretinoin, finasteride, prednisone, and cyclosporine have resulted in temporary remission. Infliximab and etanercept (TNF-α inhibitors) are biologics that have shown promise in improving symptoms. Radiation, cryosurgery, and laser therapy have been effective in a small series of patients with early stages. Upon diagnosis of HS, the extent and stage of disease should guide surgical approach. For stages 2–3, surgery is regarded as the most effective treatment.

Fig. 17.2 Mild form of hidradenitis suppurativa with several abscesses and sinus tracts

Cutaneous *squamous cell carcinoma* in situ (Bowen's disease) appears as a well-demarcated plaque with crusting and scaling. Perianal *intraepithelial adenocarcinoma* (Paget disease, Fig. 17.3) usually occurs in the seventh decade of life and appears as a slowly expanding, sharply demarcated erythematous plaque that can be eczematous, crusting, scaling, or ulcerated. If discovered, endoscopic evaluation of the colon is needed to rule out an underlying carcinoma. Wide local excision with frozen sections is performed in noninvasive Paget's disease, while more radical surgery may be required for invasive disease [22]. Cloacogenic carcinoma and squamous cell carcinoma of the anal margin can present with refractory pruritus ani (Fig. 17.4) [23]. Thus, for any lesions that do not respond to the first line of treatment, biopsy is mandatory in order to rule out neoplastic disease.

Other skin disorders that may be associated with anal pruritus include scleroderma, erythema multiforme, dermatitis herpetiformis, lichen planus, radiation dermatitis, and Darier disease.

Anorectal diseases associated with anal pruritus include prolapsed internal hemorrhoids, abscesses, fissures, and fistulas. Details about the diagnosis and treatment of these diseases are given in a different chapter.

Fig. 17.4 Anal carcinoma presenting as an ulcer. (Courtesy of Dr. Dana Fugelso)

Pruritus ani can have an *infectious* inciting factor. Risk factors for developing an infection that can cause anal symptomatology include diabetes, immunocompromised state, obesity, hyperhidrosis, and living in tropical climates. *Fungal infections* are the most common perianal infections [16]. These include *Candida albicans* and dermatophytes. *Candida albicans*, a saprophytic yeast, is normally present in the gut. The yeast can cause a perianal fungal infection in patients with compromised immune defenses such as patients with uncontrolled diabetes mellitus, on chemotherapy, prolonged antibiotic use, prolonged use of steroids, or other immunosuppressive medications. The infected skin appears moist, red, and macerated. Under microscopic scrutiny, mycelium forms and spores can be identified from scrapings of the lesion, after preparing the scapings with 20% potassium hydroxide. Treatment consists of applying nystatin powder or ointment or imidazole compound several times daily, along with controlling or eliminating the precipitating cause. *Epidermophyton floccosum*, *Trichophyton mentagrophytes*, and *Trichophyton rubrum* are fungal infections that can occur in the perineum. The presence of dermatophytes is always associated with pruritus. Topical and systemic antifungal agents have been successfully used for the eradication of the fungal infections.

Bacterial infections such as *Streptococcus*, *Staphylococcus aureus*, and *Corynebacterium minutissimum* (erythrasma) have all been implicated [24]. *Corynebacterium minutissimum* causes erythrasma which affects the perianal area, axilla, thighs, and toe web spaces. A classic, large pink-reddish patch is seen initially which eventually turns brown. Under an ultraviolet lamp (Wood's lamp), the lesions appear with a coral to salmon fluorescence from the porphyrin production made from the bacteria. It is best diagnosed by a Wood's lamp, which reveals the coral-red fluorescence [25]. *Corynebacterium minutissimum* is susceptible to erythromycin 250 mg q6 hours or tetracycline.

Pruritus ani can also be caused by *parasitic infections*, especially in tropic climates and younger ages. Pinworms (*Enterobius vermicularis*) are often implicated in the pediatric population but can occur in adults. The worms emerge at night, and consequently pruritus worsens in the nighttime. Scratching tends to scatter the eggs in the bed and wherever the patient gets dressed. The diagnosis is made using a cellophane tape test. The adult worms and eggs can be identified on the tape. Lactophenol is used to enhance the slide. Mebendazole is the treatment of choice. Perianal topical application of albendazole as well as a single oral dose 100 mg has been demonstrated to provide immediate relief

[26]. *Pediculosis pubis* is a parasite, visible macroscopically, that can lay its eggs in the pubic and perianal hair. Treatment consists of malathion 0.5% lotion applied to the hair. All sexual partners must be treated, and clothing and bedding need to be sterilized by washing in very hot water. *Scabies* is a mite, *Sarcoptes scabiei*, that creates dark punctate lesions, which are readily identified on the trunk and particularly between the fingers and ventral surface of the wrists. Scabies can infect the perianal area. The diagnosis is established using potassium hydroxide preparation to stain the parasite. Treatment includes topical permethrin with cure rates in randomized trials approximating or exceeding 90%. Alternatively, oral ivermectin is advantageous because of ease of administration and lower cost. Detailed cleansing of all clothing and bedding by washing in hot water is necessary to avoid re-infestation. Individuals with classic scabies can return to work, child care, or school the day after the first treatment.

Sexually transmitted diseases like herpes simplex, gonorrhea, and *condyloma acuminata* can also present with itching. A detailed sexual history is usually the first clue that a sexually transmitted disease needs to be addressed. Patients who present with tenesmus, purulence, and proctitis, in addition to pruritus, should be tested for gonococcal infection. A swab should be done and placed on Thayer-Martin media. Anal gonorrhea is treated with ceftriaxone 250 mg IM plus azithromycin 1 g PO. Syphilis often presents as a painless chancre, starting as a papule that eventually ulcerates. In contrast to syphilis, painful ulcers in the perianal region are usually associated with herpes and chancroid. Syphilis is caused by the spiral-shaped bacterium *Treponema pallidum*. These spirochetes can be seen on dark-field microscopy from scrapings obtained at the base of the lesion. Alternatively, serologic screening can be done with a nontreponemal test. Treatment is a one-time dose of penicillin G 2.4 million units IM.

Viral etiologies of pruritus ani include herpes (HSV) and condyloma (human papilloma virus). HSV infection often presents as painful, scattered lesions including ulcers and vesicles. Perianal presentation of herpes simplex virus (HSV-2) is rare, compared to its frequent presentation as genital infection and even less frequently when compared to herpes simplex virus (HSV-1), which presents as the familiar "cold sore" and "fever blister." The mode of infection is usually sexual, but the virus may be spread by direct contact. A viral culture taken from the base of the ulcer or from vesicular fluid is usually diagnostic. The disease is usually self-limiting in 1–3 weeks if there is no secondary bacterial infection. Supportive treatment is recommended, and medication can limit the symptoms and duration of the attacks. The treatment of an acute episode is acyclovir 800 mg three times a day for 2 days or valacyclovir 500 mg PO three times a day. For patients with frequent recurrences, acyclovir 400 mg twice daily or valacyclovir 500 mg daily have been advocated. Large anal condylomata can cause pruritus and usually requires excision and/or fulguration in the operating room (Fig. 17.5).

Anal pruritus has been associated with *several systemic diseases* such as diabetes, cholestasis, lymphoma, leukemia, pellagra, renal failure, thyrotoxicosis, hypothyroidism, human immunodeficiency virus (HIV) disease, and deficiencies in vitamins A and D and iron. Frequently the patients with systemic diseases have generalized pruritus that indicates the diagnoses and the cause of the itching. Treatment of the systemic disease resolves the perianal symptoms.

Several *psychiatric disorders*, such as stress, anxiety, and depression, have been associated with pruritus ani. Despite these associations, scientific evidence is lacking. There is a study that attempted to link emotional disorders with pruritus ani, but it did not reach statistical significance. If any psychiatric condition is present, it should be treated concurrently

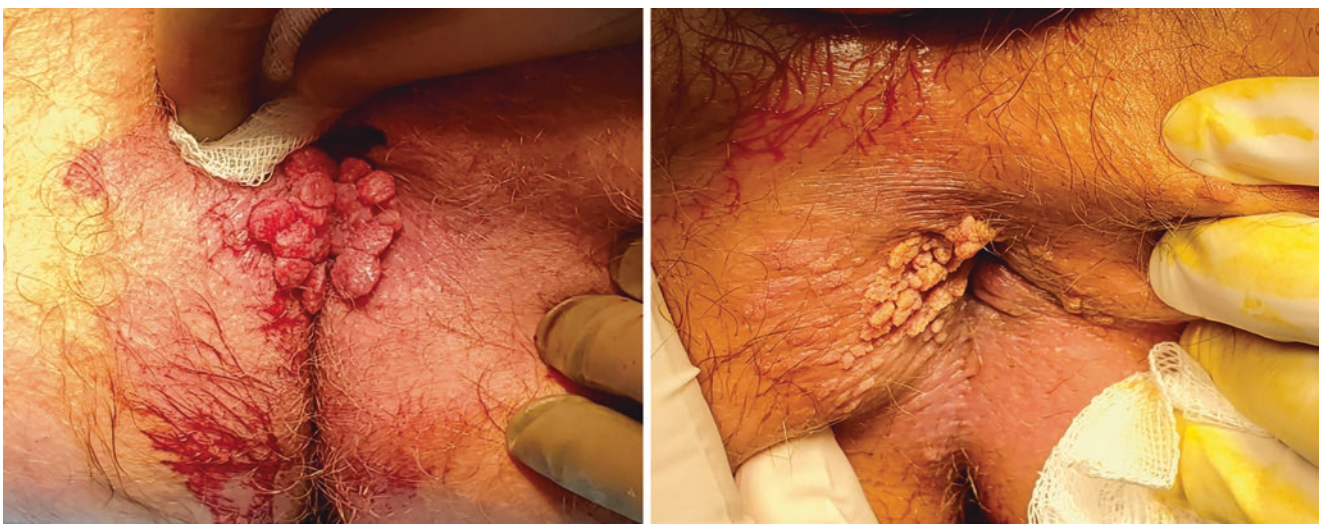

Fig. 17.5 Perianal condylomas either small or large can exacerbate skin irritation and moisture and cause anal pruritus

with the anal disease. Anxiolytic medications may benefit some patients especially at bedtime [14].

Diagnostic Approach

The clinical assessment of a patient with anal pruritus begins with a history, physical examination, and anoscopy. The decision to perform laboratory testing and endoscopic evaluation should be guided by the clinical assessment and/or response to initial therapy.

History History taking in patients with anal pruritus is critical because it can help identifying the causative factor and guide appropriate treatment. Symptoms, which usually start insidiously, are characterized by the occasional awareness of an uncomfortable perianal sensation. Some patients feel an itch, whereas others sense burning. With time, the condition may progress to an unrelenting, intolerably tormenting burning sensation in addition to the urge to scratch and otherwise irritate the area in a futile effort to obtain relief. These feelings will usually lead the patient to self-treatment with over-the-counter medications or with self-made remedies. The patient will usually overtreat the condition that will exacerbate the problem. The history of present illness should include questions related to all known risk factors for anal pruritus (Table 17.1). Thus, the physciscian should collect information on the duration of anal pruritus and the presence or not of associated symptos such as: generalized pruritus, fecal seepage, diarrhea, constipation, or a change in bowel habits, systemic symptoms including fever, night sweats, fatigue, change in appetite or weight, heat/cold intolerance, decrease in urine output, change in the color of stool or urine, and jaundice. A personal history of diabetes; dermatological, gastrointestinal, thyroid, renal, or sexually transmitted diseases; radiation; and food allergies is very important to assess. Changes in diet to include foods associated with anal pruritus or use of topical or systemic medications should be reported. Anal hygiene practices including the use of soaps, detergents, perfumes, and the frequency of cleansing or use of tight-fitting undergarments need to be described in detail. Coexisting skin and perianal conditions should be questioned. Atopy, urticaria, hay fever, allergies, and family history are key components as are the use of over-the-counter medication.

Physical Examination An examination of the whole body for any skin abnormalities or lesions should be performed before the focused exam. Dermatologic diseases are usually not limited to just one site of the body. Inguinal lymph nodes should be palpated before the patient is placed on prone jack knife position for focused examination. The presence of palpable inguinal lymph nodes is suggestive of a neoplasia or sexually transmitted diseases. The perianal exam should include a detailed inspection of the perianal area looking for skin color changes, nodules, fistula opening, skin lesions, hemorrhoids, fissures, skin rash, or ulcers. Perianal plaques with a distinct boundary are suggestive of psoriasis, erythrasma, or neoplasia. Perianal erythema may be seen in patients with chronic steroid use and candidiasis. Hyperpigmentation of the skin may result from chronic inflammation due to an infection or chronic discharge. The skin around the genitalia should also be thoroughly inspected. If sexually transmitted diseases are suspected, appropriate swabs should be obtained before the rectal examination is performed. Valsalva maneuver can exclude mucosal prolapse. A digital examination of the anorectum should be performed to identify anorectal lesions, sphincter, or pelvic floor issues. If any lesion is identified that is suspicious for malignancy, a biopsy of the lesion should be performed either in clinic under local anesthesia (punch/full-thickness biopsy) or in the operating room under general anesthetic. Every patient with pruritus ani needs to undergo an anoscopy to evaluate the anal canal and the distal rectum. Anoscopy is a quick, relatively painless, inexpensive procedure that can be performed in an unprepped patient to exclude distal anorectal disorders. Hemorrhoids, fissures, polyps, masses, and inflammatory changes can be clearly visualized with an anoscope.

Based on the physical exam, there is a clinical staging system for patients with pruritus ani. The stages represent the severity and the chronicity of the skin findings [27].

- Stage 1. No lesion is seen at inspection of anal verge, but patient finds palpation and anoscopy painful. Other anal lesions have been excluded.
- Stage 2. Red dry skin only, at times weeping skin with superficial round splits and longitudinal superficial fissures.
- Stage 3. Reddened weeping skin, with superficial ulcers and excoriations disrupted by pale, whitish areas with no more hairs.
- Stage 4. Pale, whitened, thickened, dry leathery, scaly, skin with no hairs and no superficial ulcers or excoriations (chronic condition) (Fig. 17.6).

The staging system is rarely used, but it can simplify the communication between physicians or provide structured results for research done on anal pruritus.

Fig. 17.6 Chronic perianal skin changes from fecal soilage and persistent anal pruritus

Laboratory Testing

Anal culture swabs for virology and microbiology are inexpensive and can be performed at the first evaluation of the patient that carries high risk for an infectious etiology. Viral cultures should be kept on ice. Fluid from vesicular lesions should be aspirated or taken with a swab from the base of an unroofed lesion and placed on a cell culture media or a microscopic slide for Tzanck smears if herpes zoster is suspected. Skin scrapings may be submitted for fungus culture or examined for hyphae with KOH prep. In patients with diarrhea, bacterial stool cultures as well as ova and parasites on three different stool samples can be useful. In patients with suspected streptococcal or staphylococcal perianal infections, nasal or throat swabs rarely detect the offending bacteria and therefore are unnecessary.

Blood testing is usually not needed during the first evaluation of the patient unless systemic symptoms are reported. Furthermore, if the patient has failed the first line of treatment, as part of the escalating diagnostic pathway, several blood tests are recommended. The physcician should obtain a complete blood count with differential to evaluate for evidence of hematologic malignancy, myeloproliferative disease, or iron deficiency anemia. Furthermore, obtaining levels of serum bilirubin, transaminases, and alkaline phosphatase to evaluate for evidence of liver disease, thyroid-stimulating hormone to evaluate for evidence of a thyroid disorder, blood urea nitrogen (BUN) and creatinine to evaluate for renal disease and human immunodeficiency virus (HIV) antibody test in patients with risk factors for HIV infection can assist in diagnosing the primary cause of the pruritus.

Endoscopic evaluation in the form of colonoscopy is indicated in patients with systemic or refractory symptoms or a change in bowel habits, diarrhea, abdominal pain, or hematochezia.

Tissue biopsies are usually not needed in the first evaluation, unless a clear lesion suspicious for malignancy is present. If the first line of treatment fails and the causative factor has not been identified, then at the second visit, tissue biopsy should be performed either in clinic under local anesthesia (punch/full-thickness biopsy) or in the operating room under general anesthetic. Tissue samples should be sent to both the microbiology and the pathology laboratories. Histopathology will demonstrate epithelial intercellular edema and vesiculation. In more chronic cases, hyperkeratosis and acanthosis will be present.

Rarely, patients with persistent or recurrent anal pruritus could benefit from anal manometry. Patients with pruritus ani have an abnormal transient internal sphincter relaxation, one that is greater and prolonged compared to controls. Thus, occult fecal leakage occurs and causes perianal itching [13].

Treatment

The care of patients with anal pruritus can be challenging. The patient should be informed about the chronic nature of the condition, not just to reduce the expectation of immediate cure but also to improve compliance with advice given. It is common for both patients and physicians to get frustrated and discouraged when initial therapy is not successful, and despite extensive testing, no definitive diagnosis can be made. The aims of treatment for any form of anal dermatitis are rapid relief of symptoms and prevention of recurrence. Successful management depends on accurate diagnosis and ruling out coexisting disorders. For patients that have an obvious factor causing the anal pruritus, the sole intervention needed is the treatment of the inciting factor, and the symptoms should resolve. Thus, all anorectal conditions should be sought and treated, as even small skin tags may hide fecal residue or trap moisture perpetuating the condition. Anal dermatophyte infections should be treated with a topical imidazole. Fungal infections should be treated with a topical imidazole if thought to be pathogenic. In rare cases per os, antifungals can be used such as fluconazole. β-Hemolytic streptococci, *S. aureus*, and *C. minutissimum* should be eliminated with topical antibiotics such as fusidic acid or mupiro-

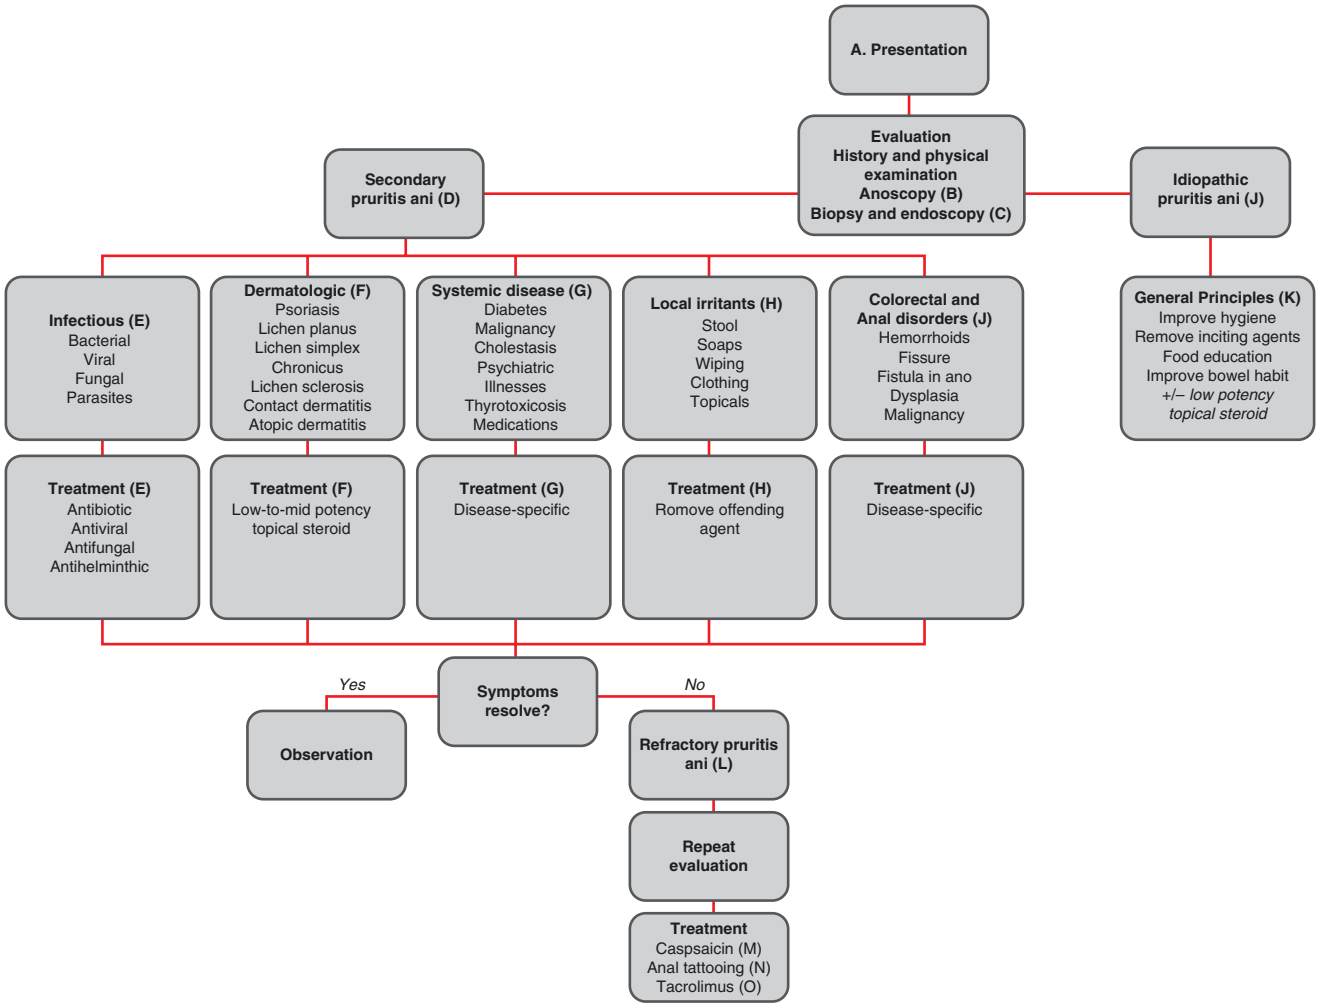

Fig. 17.7 Diagnostic and treatment algorithm for patients with anal pruritus

cin, and oral antibiotics may be necessary in more chronic and advanced cases.

For the patients that do not have an obvious risk factor causing the anal pruritus, a stepwise approach of escalating treatment and diagnostic tests is recommended. Reassurance and education are key for the success of the treatment. We have constructed an algorithm that delineates the diagnostic and therapeutic recommendations for patients with anal pruritus (Fig. 17.7).

First Encounter

The majority of patients with either secondary or primary pruritus ani will benefit from simple, general principles including improving anal hygiene, removing any potential inciting agents, food education, and improving bowel habit. These interventions can be effective in up to 90% of idiopathic cases. Key goals for treatment are the reestablishment of ideal anal hygiene and the reassurance that there is no underlying condition causing the symptoms. The ultimate goal is to restore clean, dry, and intact skin.

Inciting Agents Any inciting factors, mechanical or chemical irritants, trauma, and scratching should be avoided.

Hygiene Sitz baths without additives, taken after defecation, often help keep the perianal skin clean. Bidets are becoming more popular as an alternative. Patients should be counseled to avoid soaps, scrubbing, and aggressive wiping. Excessive moisture can cause hygiene problems. Blotting with damp toilet paper should be used instead of a moist wipe. Using a hair dryer on the lowest setting or dabbing with a towel is also beneficial. Apply corn starch powder or talc to ensure the intergluteal fold remains dry. Avoid corn-

starch powder if there is suspicion of a fungal infection as fungus is known to thrive very well in cornstarch. Soaps, perfumes, dyes in tissue or clothing, and baby wipes containing deodorants should be avoided because they can act as irritants. Handheld detachable shower heads and bidets are very effective in cleaning and washing away any remaining soap or stool residue. There are commercially available mineral oil-based preparations that can be used at home or taken along in a pocket or a purse for use in public facilities. A homemade solution for a cleaning agent is the use of diluted white vinegar. One tablespoon in an 8 ounce glass of water can be kept in the bathroom and applied with a cotton ball.

Light cotton as undergarments should be used instead of tight fitting, synthetic underwear. Clothes should be washed in non-perfumed detergent. A dry cotton ball or gauze placed at the anus can be used to limit moisture in the area. As a general rule, topical creams should be avoided initially as they may trap moisture. For cases with significant skin changes, a cream with zinc oxide or, alternatively, petroleum ointment can be applied after washing. Additional topical agents such as numbing medications, menthol, phenol, camphor, or a combination of them may be helpful. There are commercial or compound creams which are a combination of zinc oxide and menthol and can be very beneficial at relieving patients' symptoms. In specific cases, if there is any concern that there may be an infection, topical antibiotics (gentamicin, clindamycin, or bacitracin) or antifungals (clotrimazole, nystatin) may be added in conjunction with other therapies. Most creams can be applied at nighttime before bed and again in the morning after bathing.

In cases with severe skin irritation in the office, the surgeon can apply Berwick's solution (crystal violet 1%, brilliant green 1%, 95% ethanol 50%, distilled water 100%) followed by cool air drying or hair dryer. This is covered with tincture of benzoin and dried once more, and the sealant may remain on the skin for up to a week, which is enough time for skin to regenerate or re-epithelialize.

Acute itch is a marker of fecal seepage, and immediate cleansing is the most effective remedy, especially for nocturnal itch. Patients should be given advice on how to cleanse when outside their homes. If the barrier creams do not work, the patient can use ostomy powder in the perianal area three times a day. Ostomy powder is designed to protect the skin from irritation related to moisture. Although it was designed to be used around the stoma or under the ostomy barrier, it absorbs moisture in the perianal area and keeps the skin dry.

Food Education Patients should receive a list of foods (Table 17.1) that they should avoid: coffee, cola, beer, tomatoes, chocolate, tea, citrus, and lactose-containing foods. An elimination diet may be attempted. Encourage patients to keep a diary and then reintroduce the foods one at a time in an attempt to determine the offending foods.

Bowel Habits High-fiber diet and an addition of fiber supplements are highly encouraged. The fiber serves to absorb the moisture from the stool, adding bulk and allowing for complete evacuation of stool during bowel movements. High-fiber diet and bulking agents are helpful in absorbing water from stool, in turn decreasing fecal seepage. High dose of psyllium husk 2 tablespoons every am with 8–10 8 oz glasses of liquids over the day is highly recommended. If stools still remain loose, additional medications may be helpful. Antidiarrheals such as loperamide or atropine/diphenoxylate can enhance the action of the fiber and thicken or firm the stool and help decrease seepage.

Second Encounter (3–6 Weeks After First Encounter)

Clinicians should be prepared to manage refractory pruritus ani if there is no resolution of symptoms despite previous treatment. Repeating a thorough history may identify an inciting event that may have not been identified initially. Journals with foods and/or timing of symptoms should be reviewed since they can demonstrate a temporal relation to onset of symptoms. A biopsy and endoscopy should be performed if they were not done at the initial evaluation. Similar to initial evaluation, the focus should be on finding an underlying cause. These patients will need to be counseled that refractory pruritus ani may be a chronic condition requiring a long-term treatment plan and their expectations need to be set that treatments are aimed at improving symptoms rather than complete resolution. After the first line of treatment fails, a short-course trial of a low-potency topical steroid (1% hydrocortisone) can be tried twice a day for 2 weeks. This should be tapered off using a barrier cream containing zinc oxide to prevent skin atrophy [28]. In a randomized trial, patients with primary pruritus ani received 1% hydrocortisone or placebo for 2 weeks. Treatment with 1% hydrocortisone resulted in a 68% reduction of itch, and 75% of the patients had improvement in their quality of life [29]. Steroids can be used up to 8 weeks at most. Long-term use of topical steroids has been associated with atrophy of the skin. While it is unlikely that low-potency steroids (hydrocortisone 1%) have a curative effect over time, they can work as a "bridge" therapy that can alleviate symptoms long enough for the patient to stop the itch-scratch-itch cycle and allow for healing of excoriated skin. In more chronic or severe cases, the use of high-potency steroids (clobetasol propionate 0.05%) can increase the chances for symptom relief. While commonly prescribed by referring physicians, it may

be necessary to stop use of topical steroids while a causative agent is sought. Oral steroids are not indicated.

Systemic antihistamines may reduce nocturnal scratching; however, as this is probably a marker of anal seepage, the patient should be advised to wash the area immediately and apply a barrier cream. There have been no randomized trials exploring the usefulness of antihistamines in pruritus ani, but some series have reported some effect against peri-anal itch [30]. Sedative antihistamines like diphenhydramine (25–50 mg) or hydroxyzine (12.5–25 mg) are given to break the itch-scratch-itch cycle and to prevent the patient from night scratching. Sedating antihistamines may be effective by aiding sleep rather than local inhibition. Topical antihistamines are not potent enough and can sensitize or irritate the skin.

In patients who do not respond to these drugs, agents which have anti-depressive effects like doxepin (10–25 mg up to 75 mg) or amitriptyline (25 mg up to 100 mg) can be used. Doxepin, a tricyclic antidepressant, possesses both anti-H1 and anti-H2 activity. Amitriptyline is particularly useful in anogenital itch having neuropathic qualities such as stinging or burning. Gabapentin (a structural analogue of gamma-aminobutyric acid) and selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine, paroxetine, sertraline, fluvoxamine, mirtazapine, and citalopram may be useful for patients with intractable pruritus resistant to routine therapy [31–33].

Local anesthetics such as lidocaine gel 2–5% can provide temporary relief but have no treatment effect or long-term result. There is no place for the topical use of anesthetics as they do not alter the disease and sensitize and moisturize the skin.

Hypnosis has been used, but there is insufficient evidence available for its recommendation.

The use of capsaicin is indicated in refractory cases. Topical capsaicin produces a short burning sensation that in consequence provides an inhibitory feedback, which may eliminate the need to scratch. Furthermore, as a component of chili peppers, it has been reported that it has the ability to suppress histamine release, deplete substance P, and damage C fiber terminals, the fibers that mediate itch signaling. A randomized, crossover study showed topical 0.006% capsaicin cream applied three times a day to be superior to placebo (1% methanol) in those who had pruritus ani for greater than 3 months. Overall, 31 of 44 (70%) patients had a response to capsaicin, 8 had no response, 1 had response equally with capsaicin and methanol, and 4 withdrew because of side effects [34].

Tacrolimus is a non-corticosteroid, macrolide anti-inflammatory drug. There are some studies reporting that topical application of tacrolimus ointment for 4 weeks may decrease itch intensity and frequency in pruritus ani and improve the Dermatology Life Quality Index (DLQI), a quality of life questionnaire. The studies have small sample sizes and potential carryover effect. In general, local tacrolimus in a 0.1% concentration is well tolerated and appears to be most effective in patients with atopic dermatitis [35]. Two randomized controlled trials comparing topical tacrolimus 0.1% to placebo in a total of 53 patients with chronic idiopathic pruritus ani showed significant symptomatic improvement up to 6 weeks follow-up [35, 36]. This agent may be a good alternative to topical steroids or as a replacement when tapering off steroids to help avoid skin atrophy.

Anal tattooing with methylene blue is an intervention of last resort with good results. The exact mechanism of action is not clear, but it appears that methylene blue may be directly toxic to the nerves supplying the perianal skin, thus suppressing the desire to scratch and disrupting the vicious itch-scratch-itch cycle. The procedure is consisted of several intradermal and subcutaneous injections of 10 ml 1% methylene blue + 5 ml normal saline + 7.5 ml 0.25% bupivacaine with adrenaline (1/100,000) + 7.5 ml 0.5% lidocaine in prone jackknife under sedation or general anesthesia in the perianal region and the entrance of the anal canal. The tattoo disappears in about 3–4 weeks. The initial study [37] demonstrated a more than 80% complete or partial response, and then other reports have confirmed the initial trial [38–40]. The surgeon should be aware that there can be complications after the procedure such as decreased perianal sensation, transient fecal incontinence, and local inflammatory reactions in the injection area. A recent systematic review demonstrated that methylene blue injection can successfully treat anal pruritus; however, the evidence to support the findings was graded as weak, due to the limited number of patients participating in the studies [41].

Conclusions

Pruritus ani is a common condition that all primary care, general surgeons, and colorectal surgeons will encounter in their career. There are several etiologies for the disease, some of which are easy to diagnose and some are not. Once underlying dermatologic, food, infectious, neoplastic, and anorectal pathology has been treated, the therapy must be directed toward proper anal hygiene, avoidance of irritants, and minimizing skin trauma. If the first line of therapy is not successful, then more diagnostic and therapeutic interventions are needed to cure the disease. Managing patient expectations at the first visit is of paramount importance, as the resolution of symptoms often takes time.

Sexually Transmitted Infections of the Colon and Rectum

18

Michelle Cowan and Andrew T. Schlussel

Key Concepts

- Recognize at-risk populations who are susceptible to sexually transmitted infections and to understand the growing public health concern in transmission of these organisms.
- Develop a basic understanding of anorectal immunology and how it relates to the inoculation and systematic infection by viral and bacterial organisms.
- Recognize pathology in patients with sexually transmitted infections that require operative intervention.
- Provide an overview of diagnostic and treatment recommendations for sexually transmitted infections.
- Provide prevention strategies for sexually transmitted infections.

Introduction

The term sexually transmitted disease (STD) refers to a variety of clinical syndromes and infections as a result of pathogens acquired and transmitted through sexual activity, whether it be vaginal, anal, or oral sex. The term STD has recently been replaced with sexually transmitted infection (STI), a less stigmatizing and more accurate phrase as acquiring an infection does not necessarily correlate with symptoms or disease, such as in the case of human papillomavirus (HPV). In the United States, the incidence of STIs has been on a steady climb over the last several years with an estimated 2.4 million reported cases of chlamydia, gonorrhea, and syphilis alone in 2018 [1]. Specifically, anorectal STIs are also thought to be on the rise due to the increased practice of anal receptive intercourse; however, accurate numbers are hard to quantify. In addition to anal intercourse, additional risk factors for anorectal STIs include oral-anal sex and contiguous spread from genital infections with reports demonstrating that approximately 50–60% of cases of chlamydia and gonorrhea occur at non-urethral sites [2]. Anorectal STIs are often asymptomatic; however, when present, symptoms are often similar to other common anorectal conditions. Initially, anorectal STIs may be inappropriately attributed to hemorrhoids, and thus colorectal surgeons play a critical role in the diagnosis and treatment of these pathogens, and a high level of suspicion is required to ensure an accurate diagnosis is achieved in a timely fashion. This chapter reviews sexually transmitted infections of the anus and rectum and current approaches to their presentation, diagnosis, and management.

Anorectal Immunology

The mucosal integrity of the anorectum plays a critical role in the transmission of both viral and bacterial organisms. This physical barrier protects the host from pathogens and is composed of an immune system that functions autonomously from the rest of the body. Infection ensues when a virus or bacteria diffuses through this layer and gains access to the circulatory system. Appropriate maintenance of this mucosal defense mechanism is necessary for optimal protection from disease.

Viral entry into the systemic circulation may occur through direct penetration of damaged mucosa. In the setting of human immunodeficiency virus (HIV), this organism has the distinct ability to bind secretions, facilitating its transport across the epithelial barrier to infect target cells. The abundant quantity of T cells in the gastrointestinal (GI) tract makes it a preferential target for viral replication and final introduction into the blood stream [3–6]. The ability to resist and recover from a primary infection requires an intimate balance between the innate and antigen-specific immune

responses of the host. The pathway from inoculation to infection is a complicated process and not well understood. Cellular immunity at the level of the mucous membranes is controlled by the interaction of Langerhans (LC), or dendritic cells, and T cells which in concert become primed to identify pathogens. This process occurs rapidly in the GI tract where active T cells and dendritic cells are readily exposed to pathogens as they are located immediately beneath the epithelial surface.

Pathogens have variable effects on the immune system following infection. Human papilloma virus (HPV) has been demonstrated to increase the number of LC in the anal mucosa [7]. However, HIV is associated with a dramatic decrease in LC when coinfected with HPV, and this relationship results in a greater risk of recurrence. Furthermore, HIV is correlated with a more aggressive HPV infection due to a decrease in T lymphocytes and suppression of LC in the anorectal mucosa. This subsequently allows for HPV to persist and progress to anal dysplasia or carcinoma [8]. This viral interaction within the immune system demonstrates how HIV-positive patients are at greater risk of coinfection with secondary organisms due to the local immunosuppression of the anorectal mucosa.

Anal receptive intercourse is a mechanism for the direct delivery of pathogens into abraded and now vulnerable anal mucosa. Intercourse denudes both the protectant cell layers and the natural mucous coating of the anus and rectum. This provides a means of entry into the epithelial cell layer and subsequent release into the circulatory system [9]. Once the mucosa is damaged from a virus such as herpes simplex virus (HSV) and HPV, a separate population of lymphocytes is activated. This T-cell-mediated mechanism is considered a critical defense response against such organisms and further supports how a coinfection with HIV poses such a significant consequence in the infected host [10]. Parasitic infection such as *Entamoeba histolytica* or *Giardia lamblia* may occur through oroanal intercourse, where these trophozoites or cysts burrow into cells to gain access to the GI tract resulting in systemic illness [11]. Although the utilization of latex-based condoms is recommended to protect against the inoculation of pathogens, patients with a latex allergy may be at even greater risk of disease transmission due to the caustic immunologic response and further destruction of the immune-competent mucosal barrier.

Screening and Prevention

Sexual activity incurs the risk of receiving or transmitting a sexually transmitted disease. STDs may be asymptomatic, or symptoms are mild and unnoticed. It is critical that patients with high-risk behaviors are encouraged to undergo testing. Providers should maintain an open, non-judgmental conversation with the patient to allow them to feel comfortable in disclosing potential risk factors. The Centers for Disease Control and Prevention (CDC) has multiple recommendations regarding patient cohorts and testing [12]. All people between ages 13 and 64 should be tested at least once in their life for HIV (Table 18.1). Sexually active woman younger than 25, or those older with multiple sexual partners, should be tested yearly for chlamydia and gonorrhea. All men who have sex with men (MSM) should be tested for chlamydia and gonorrhea at least annually and should strongly consider every 3–6 months if they participate in high-risk behaviors. All contact sites including urethra, rectum, and pharynx should be tested regardless of condom use. Similar time frames are recommended for the screening of syphilis in both populations (Table 18.2). Type-specific serologic testing for HSV can be considered during initial STI screening for patients with multiple sexual partners (Table 18.3). HIV testing should be performed annually in MSM population if their status is negative or unknown or their sexual partners have had more than one partner since last being tested (Table 18.4) [12]. Anal dysplasia screening in the high-risk MSM cohorts or HIV-positive patients is also important.

Counseling and education of both the patient and their sexual partners are essential in the management of any sexually transmitted infection. Although patients should be offered

Retesting post-treatment to detect response or repeat infections
Partner services for treatment and counseling

The most reliable means of preventing STI transmission is to abstain from oral, vaginal, and anal sex or to be part of a monogamous relationship with an uninfected partner. Especially for those patients that are being treated for an active STI, abstinence until their treatment course is completed is critical. Male condoms, when used correctly, are effective in preventing the transmission of STDs. It is important that latex condoms are not used passed their expiration date, a new condom is used after each sexual encounter, and only water-based lubricants are used on latex condoms to maintain its integrity. Patients should be provided instructions on the correct use of condoms, so they are consistently placed correctly to maximize their effectiveness in preventing the spread of HIV and STIs (Table 18.5).

Primary prevention of STI transmission requires an accurate assessment of the patient's sexual behaviors, as well as their biological risk assessment such as HIV status. HIV is not only a risk factor for STI transmission, but diagnosis of an STI puts the patient at increased risk for HIV, and testing should be implemented. In efforts to mitigate the transmission of STDs, patients should be educated on exposure avoidance and be provided pre-exposure vaccinations when available. These products exist for HPV and hepatitis A and B. HPV vaccination is recommended for both boys and girls beginning at the age of 9 with the 9-valent vaccine recommended for male patients. This vaccine known as Gardasil®9 was initially rec-

ommended in MSM up to 26; however, the Food and Drug Administration recently approved implementation in male patients up to 45 years old (Table 18.5) [12, 13].

Due the high risk of HIV transmission throughout the world, significant efforts have been made to implement both a pre-exposure and post-exposure regimen to minimize spread. In 2012, the Food and Drug Administration (FDA) approved the use of pre-exposure prophylaxis or PrEP as a one-time dose of disoproxil fumarate 300 mg and emtricitabine 200 mg, for the use in those at high risk of HIV acquisition to include MSM, heterosexual men and woman with multiple sexual partners and variable condom use, and injection drug users who share needles [14, 15]. Dosing is one tablet a day while the patient remains at risk. It is critical that the patient's HIV status is known prior to treatment as an improper treatment regimen can lead to drug resistance. McCormack and colleagues in 2016 demonstrated an 86% reduction in HIV transmission in homosexual and MSM populations [16]. A similar reduction was found by Molina et al., when on-demand dosing of PrEP was utilized. This regimen included consuming two pills prior to sexual activity and one pill for 2 days following the last sexual encounter [17]. On-demand dosing may improve compliance as the average patient in this study only took 15 pills per month. Once therapy is initiated, patients should be screened every 3 months for HIV status, renal function, and STDs. After a good sexual history is obtained, patients should be counseled on the risks and benefits of once daily dosing of PrEP, and when taken consistently, there is a 99% reduction in the risk of HIV transmission [12, 18].

Post-exposure prophylaxis (PEP) may be considered within 72 hours of exposure to bodily fluids known to be positive for HIV, or the patient is at significant risk for transmission. Rapid HIV testing should be performed when available, but testing should not delay therapy. Treatment is with a three-drug regimen to include tenofovir disoproxil fumarate 300 mg with emtricitabine 200 mg once daily and raltegravir 400 mg twice daily or dolutegravir 50 mg daily for 28 days [12].

In addition to providing treatment and confidential partner notification, certain STIs require formal reporting to support public health efforts in tracking the incidence and prevalence of diseases. Requirements are based on state law; however syphilis, gonorrhea, chlamydia, chancroid, HIV, and AIDS are reportable in every state. The reporting process can be through the provider or laboratory, and providers should be familiar with their local public health STI program policies. All reports are strictly confidential, and the public health department may contact the clinician to determine treatment rendered. There are anonymous notification services in some states; however, the patient should be encouraged to discuss their diagnosis with their partner so they can seek appropriate counseling and treatment.

Diagnosis and Initial Evaluation and Treatment

Asymptomatic

Sexually transmitted infections of the anus and rectum are often asymptomatic making the diagnosis challenging. In fact, in men who have sex with men, approximately 85% of rectal sexually transmitted infections are asymptomatic [2]. In women, solely screening the urogenital epithelium resulted in overlooking 12–30% of chlamydia and gonorrheal infections, respectively, when compared to testing multiple mucosal sites [19]. As a result, anorectal STIs may go untreated which can lead to chronic pelvic and abdominal pain, difficulty or inability to conceive, prostatitis, and epididymitis. More importantly, failure to treat extragenital STIs results in an infectious reservoir placing patients at risk of acquiring or transmitting HIV [20]. Therefore, current guidelines recommend general screening for STIs from all surfaces in asymptomatic individuals in high-risk subgroups based on sexual behavior and biologic risk profile [12]. Individuals at a greater risk of contracting or transmitting an STI include but are not limited to adolescents and young adults aged 15–24, incarcerated persons, gay and bisexual men, pregnant women, those who fail to practice safe sex or have multiple partners (i.e., swingers and sex workers), and those with a limited access to health care (Table 18.2) [12].

Symptomatic

Symptoms associated with anorectal STIs commonly encountered by a colon and rectal surgeon include anal pain, tenesmus, urgency, bleeding, and mucopurulent drainage. Physical exam may demonstrate painless or painful lesions and ulcers with or without mucosal inflammation and/or discharge. These signs and symptoms are often mistaken for other processes such as fissures, hemorrhoids, hidradenitis, fistula-in-ano, or a malignancy for which an STI is not even considered until the patient presents with persistent symptoms despite various over-the-counter and prescribed therapies. In adolescents and young adults, these symptoms along with proctitis seen on exam can closely mimic inflammatory bowel disease (IBD), specifically lymphogranuloma venereum [21]. In patients initially diagnosed with IBD but not responding to appropriate therapy as expected, infectious proctitis should be considered.

Distinguishing an anorectal STI from other potential causes of proctitis mandates a thorough workup including a sexual history and previous STIs. A complete anal exam should be performed with anoscopy +/− endoscopy to evaluate for mucosal erythema, friability, exudate, and discharge.

Table 18.6 Treatment recommendations for genital herpes simplex virus

Initial clinical episode	Suppressive therapy	Episodic therapy
Treatment duration: 7–10 days	Acyclovir 400 mg; twice/day	Acyclovir 400 mg; three times/day Duration: 5 days
Acyclovir 400 mg: Three times/day	Valacyclovir 500 mg; once/day	Acyclovir 800 mg; twice/day Duration: 5 days
Acyclovir 200 mg: Five times/day	Valacyclovir 1 g; once/day	Acyclovir 800 mg; three times/day Duration: 3 days

However, it is imperative that if suspicious for an anorectal STI based on history and external exam, swabs to test for gonorrhea, chlamydia, and herpes need to be done prior to the introduction of lubricant during the anoscopy or endoscopy as many medical lubricants are bacteriostatic. Testing often requires two separate swabs, one viral (herpes) and one bacterial (gonorrhea and chlamydia); however, each institution is different, and thus each provider should familiarize themselves with their specific institutional protocols. In any patient with proctitis or proctocolitis, it is essential to rule out other infections such as enteric pathology and examine the stool for *Giardia lamblia* and *Entamoeba histolytica* which can also be inoculated by sexual contact. Lastly, endoscopic mucosal biopsies should be considered to rule out cytomegalovirus (CMV) in those with AIDS or immunocompromised state.

During their initial encounter, and in addition to swabs for gonorrhea, chlamydia, and HSV, all patients with a suspected STI should undergo serologic testing for syphilis and HIV. Once testing is complete, empiric therapy should be considered for both the patient and sexual partners. This decreases the risk of transmission and improves the rate of successful treatment outcomes. Treatment should be targeted towards gonorrhea, chlamydia, and herpes (Tables 18.2, 18.6, 18.7) (Fig. 18.1). Treatment should include dual therapy for gonococcal disease with ceftriaxone plus either doxycycline or azithromycin, both of which will also treat chlamydia. Azithromycin is currently recommended by the CDC due to a high rate of tetracycline resistance and is preferred in patients with a penicillin allergy as well as those who are noncompliant as it is a one-time dose in clinic. However, azithromycin may be inferior to doxycycline in the treatment of rectal-specific infections [22]. While awaiting final test results, patients should also be started on empiric valacyclovir to treat HSV. Patients should also be counseled and strongly encouraged to inform current and prior sexual partners in the last 3 months about their potential risk of STI so they can pursue

testing and/or start empiric therapy, both of which can reduce the risk of reinfection and diminish transmission of STIs. Providers can also refer patients to partner notification programs at several local health departments to facilitate this process and assist in counseling and testing.

Currently, the mandatory reportable STIs in all 50 states include gonorrhea, chlamydia, syphilis, HIV, and chancroid, with state-specific reporting for other infections. All reports are strictly confidential, and all states allow minors to consent for STI care without parental permissions and without requiring the provider to inform the parents; however, some states limit a minor's consent based on type of service. The accurate reporting of STIs is integral to the public health department's ability to track occurrences and also mobilize resources to underserved areas.

Bacterial Sexually Transmitted Infections

Chlamydia

Epidemiology and Presentation

Chlamydia trachomatis is the most common reportable STI in the United States with almost two million new cases in 2018; however, this number is likely an underestimation as many cases go unreported as they are often asymptomatic [1]. Infection is often seen in sexually active young adults, and it is estimated that approximately 1 in 20 women ages 14–24 has chlamydia [23]. Left untreated, chlamydial infection in women can lead to ectopic pregnancies and infertility as well as pelvic inflammatory disease (PID) in the case of chronic or repeated infections. As such, annual screening is recommended in sexually active women under the age of 25 as well as older women at high risk with data showing that screening and subsequent treatment for chlamydia lead to a lower risk of PID in women (Tables 18.1 and 18.2) [12, 24].

Chlamydia trachomatis is an obligate intracellular bacterium with at least 15 different types or serovars. Serovars D–K are typically responsible for the more common clinical spectrum of urethritis, cervicitis, and PID, as well as neonatal disease and proctitis. Serovars L1–L3 are more aggressive and most commonly responsible for lymphogranuloma venereum (LGV) and often present as a more severe form of proctitis that can include erythematous and friable rectal mucosa with ulcerations as well as potential for perianal abscesses, fistulas, and fissures and can often mimic IBD, specifically Crohn's disease [25]. The urethra is the most common site of infection in males resulting in urethritis with symptoms of pyuria, dysuria, and urinary frequency. A minority of men will present with epididymitis and symptoms of unilateral testicular pain, swelling, and tenderness. In women, the urethra and cervix are the most common site and can present with cervical discharge and bleeding. Rectal chlamydia occurs due to spread via anal receptive intercourse or contiguous spread from genital disease with some data to support that in some subpopulations, chlamydia infection is most prevalent in the rectum with over 50% of chlamydia infections in MSM being located in the rectum and also more likely to be symptomatic [2]. Symptoms of rectal involvement can include a milder form of proctitis with tenesmus, pain, and discharge. Regardless of site of infection, the incubation period for chlamydia can range from several days to up to 2–3 weeks due to its slow replication cycle [26].

Diagnosis

Testing for chlamydia is either done for patients who are otherwise asymptomatic and qualify based on screening guidelines or performed on patients based on symptoms and clinical suspicion after a thorough history and physical examination table 18.1. The recommended diagnostic test is the nucleic acid amplification test (NAAT) which has ~97% sensitivity and specificity, can be performed on easily obtainable specimens such as urine or vaginal swabs, and provides diagnosis in under 48 hours [12]. In men, the preferred specimen for diagnosis is a first-catch urine, while in women, the preferred testing site is a vaginal swab (either provider or patient collected) with a first-catch urine sample as an alternative. However, as mentioned previously, testing should be done at multiple sites, especially in high-risk populations such as MSM, and those with symptoms suggesting extragenital involvement [27]. Interestingly, while NAATs are the preferred method to detect chlamydia from urine and vaginal swabs, historically no commercial test has been approved by the FDA for use with extragenital (rectal or pharyngeal) specimens, despite the fact that more recent data demonstrates superior sensitivity and specificity of NAAT testing compared with traditional culture [28]. Therefore, culture has stayed the traditional route of testing for extragenital sites. However, in 2019, the FDA approved the first tests to detect chlamydia on extragenital samples, specifically the Aptima Combo 2 Assay and the Xpert CT/NG, which rely on transcription-mediated amplification and are both already cleared for genital and urine samples [29, 30].

Treatment

Treatment for chlamydial STI can be easily treated with antibiotics, and treatment should start empirically along with coverage for gonococcal and HSV infections at the time of the initial encounter (Fig. 18.1). Not only does this allow for early treatment of possible infections but also prevents possible adverse reproductive effects and in pregnant women can prevent transmission to neonates. Treatment should be with 1 g of azithromycin given in the office or, alternatively, doxycycline 100 mg twice daily for a total of 7 days (Table 18.2). Alternative regimens recommended by the CDC include treatment with erythromycin or with qui-

nolones such as levofloxacin or ofloxacin; however, each come with their own limitations including GI upset and resulting patient noncompliance or increased cost, respectively [12]. The benefit of azithromycin is that it can be used in those with a penicillin allergy, it is safe in pregnant patients, and it is good for patients with compliance concerns as it is a one-time dose that can be given and directly observed in clinic. Patients should be counseled to abstain from all sexual activity until resolution of symptoms as well as for 7 days from the one-time dose of azithromycin and/or until completion of a 7-day course of doxycycline. Repeat testing should occur at 3 months post-treatment since early testing <3 weeks after completion of therapy can result in false positives given continued shedding of the organisms early after therapy [12]. The exception is in pregnant women where re-testing should occur twice, first at 3–4 weeks after completion of therapy to prevent the sequelae to neonates if infection persists and again at 3 months. Treatment failure; can actually represent reinfection due to sexual activity with an infected and/or untreated partner. Accordingly, patients should be counseled to notify all partners within the last 2 months of their new diagnosis so that they can be evaluated and treated as well.

Efficacy of treatments may differ between genital and extragenital sites with doxycycline having greater efficacy [31]. While antimicrobial resistance is less common with chlamydial infections compared to gonorrheal infections, there are several reports of treatment failure for rectal chlamydial STI treated with azithromycin of up to 20%, as compared to doxycycline [32]. While most of the studies are small and the quality varies, some, including the European guidelines, recommend doxycycline as the first-line agent in rectal-specific chlamydia STI [33, 34].

Lymphogranuloma Venereum

Epidemiology and Presentation

Lymphogranuloma venereum (LGV) is caused by distinct serovars of *Chlamydia trachomatis*, serovars L1–3, with L2 thought to be most responsible for the recent increased prevalence of the disease [35]. Prior to 2003, LGV was thought to be rare in developed countries; however, there has been a recent surge with a predominance in the MSM population, especially those who are HIV positive [36]. Unlike other serovars of *C. trachomatis*, LGV is thought to be more invasive resulting in severe proctitis with ulcers that can lead to abscesses, fistulas, chronic pain, and strictures which can mimic inflammatory bowel disease. LGV also affects the lymphatic system so proctitis is followed and/or accompanied by tender femoral and inguinal lymphadenopathy that is often unilateral and responsible for the classic "bubo" on exam; however, these symptoms are uncommon with genital infection. Patients can also present with rectal pain, tenesmus, mucoid, anal discharge as well as fevers, fatigue, and weight loss.

Diagnosis

Diagnosis for LGV is based on clinical suspicion centered on symptoms and exclusion of IBD as the cause of proctitis, followed by confirmatory testing. In those patients who test positive for *C. trachomatis* from their rectal and/or genital swab NAAT, a subsequent test for LGV should be performed to confirm the diagnosis. Diagnostic testing involves cultures, direct immunofluorescence, or nuclei acid detection [12]. Endoscopic findings in patients with proctocolitis due to LGV include mucosal erythema, friability, and ulcers with biopsies demonstrating lymphocytic infiltrates, crypt abscesses, and even some cases of granulomatous changes which can mimic Crohn's disease [36]. Given the difficulty in distinguishing the diagnosis from IBD as well as varying testing capabilities, the diagnosis of LGV is often delayed or misdiagnosed. Similar to standard *C. trachomatis*, the patient should be tested for other STIs including HIV.

Treatment

The standard treatment for patients with LGV is doxycycline 100 mg twice daily for 21 days since LGV is more invasive and difficult to eradicate than standard genital chlamydia (Table 18.2). For patients with a history and symptoms suspicious for STI, empiric treatment with doxycycline is started, and once chlamydial testing returns positive and subsequent reflexive testing for LGV returns positive, the course of doxycycline therapy should be extended. For those unable to take doxycycline, an erythromycin regimen with four times a day dosing can be used; however, this can be poorly tolerated due to gastrointestinal upset and difficulty with frequent dosing compliance. Local control of any infected lymph nodes or "buboes" may be needed by aspiration and/or incision and drainage to prevent subsequent ulceration or fistulization. Many patients with LGV are coinfected with HIV and should receive the same initial therapy; however, these patients may have delayed symptom resolution and thus require a longer duration of therapy. Due to inconsistent diagnostic testing and risks of failing to treat LGV, any MSM patients who are HIV positive and present with proctitis and positive rectal chlamydial testing should be treated empirically for LGV [36].

Gonorrhea

Epidemiology and Presentation

Neisseria gonorrhoeae is an intracellular diplococci bacterium responsible for the second most common reportable STI in the United States. The incidence of this infection exceeds one million cases each year, with 500,000 new cases reported

to the CDC in 2018 [1]. Similarly, most presentations of chlamydia are asymptomatic. Specifically, in cases of positive cultures 50% of men and upwards of 95% of women remain asymptomatic [37]. Populations at high risk should undergo routine screening as the risks of leaving gonorrhea untreated are severe and include pelvic inflammatory disease (PID), fallopian tube involvement, infertility, and ectopic pregnancies (Table 18.1). Symptoms can vary, and in men, the most common presentation is urethritis with symptoms of painful urination and/or discharge, up to 2 weeks after inoculation. Epididymitis occurs less frequently. Symptomatic women infected with *N. gonorrhea* most commonly present with cervicitis, urethritis, or proctitis; however, the symptoms are usually so mild they are mistaken for a bladder or vaginal infection. Patients with proctitis due to gonorrhea will often present with tenesmus, hematochezia, or mucopurulent discharge, and if untreated, disease progression may result in pelvic pain, fevers, or an abscess. These findings should raise suspicion for PID. *N. gonorrhea* can cause more disseminated disease as well, albeit uncommon, resulting in purulent arthritis as well as polyarthritis, dermatitis, and even more serious diseases such as endocarditis and meningitis [38].

Diagnosis

Anoscopy findings include erythema and friable mucosa with thick mucopurulent discharge from the anal crypts. A vaginal exam should be performed in women to evaluate for concomitant disease, as cervicitis has been reported in 35–50% of woman diagnosed with rectal gonorrhea [39]. Definitive testing should be done with NAAT as it has a sensitivity and specificity of 100% and skampskgt;95%, respectively. Similar to chlamydia, until recently there was no FDA-approved test for extragenital gonorrhea [29, 30].

Gram stain and culture, in addition to NAAT, should be utilized in cases of treatment failure or in symptomatic patients, as it allows for antimicrobial susceptibility testing, and the selectiveness of Thayer-Martin media prevents growth of other endogenous flora. Although the sensitivity of NAAT is 90–100%, this does not allow for antibiotic susceptibility testing which is important given gonococcal resistance and additional treatment options [40]. For symptomatic men, especially MSM, a gram stain of a urethral specimen visualizing intracellular gram-negative diplococci and polymorphonuclear leukocytes is diagnostic; however, a negative test in this asymptomatic cohort does not rule out disease, and further testing is recommended [12].

Treatment

The clinical suspicion of a gonococcal STI should prompt testing followed by empiric treatment. However, gonorrhea is known for its ability to develop antibiotic resistance, initially to fluoroquinolones, followed by some cephalosporins such as cefixime, as well as tetracyclines [41]. Thus, empiric treatment starts with dual therapy against the bacteria utilizing antibiotics with two different mechanisms of action, ceftriaxone 250 mg given once intramuscularly plus 1 g of azithromycin, both of which can be given in office (Fig. 18.2). While this regimen targets chlamydia simultaneously, dual therapy is recommended for an isolated gonorrhea infection to avoid antimicrobial resistance and improve treatment efficacy for both genital and extragenital sites.

Fig. 18.2 Perianal vesicles secondary to herpes simplex virus. (Courtesy of Richard E. Burney, MD, University of Michigan)

Those who undergo successful treatment for gonococcal infection should abstain from sexual intercourse until 7 days after completion of therapy and then undergo repeat testing at 3 months post-treatment. All sexual partners in the last 2 months should be counseled in regard to testing and receiving empiric therapy. If symptoms persist after treatment, cultures should be performed to evaluate for antimicrobial resistance and sensitivities which can help guide future therapeutic options. Treatment failure can be defined as patients who test positive by culture or NAAT and/or have continued symptoms 3–5 days after completion of therapy with no sexual contact in the post-treatment time frame. While persistent symptoms are often due re-infection, in cases of treatment failure, consultation with an infectious disease specialist should be considered as these cases are reportable.

Syphilis

Epidemiology and Presentation

Syphilis is a systemic illness caused by the bacterium and spirochete *Treponema pallidum*, with estimated reports of 35,000 new cases in 2018, a substantial rise of over 70% from 2014 [1]. In the late 1990s and early 2000s, the case numbers of syphilis hit such a nadir that there was discussion regarding the elimination of the disease in the United States

[42, 43]. However, since that time the rate of syphilis has been on the rise with a resurgence of the disease in the MSM and HIV+ MSM populations such that a diagnosis of early syphilis increases the risk of being diagnosed with HIV, and the open ulcers of syphilis are thought to facilitate HIV transmission [44, 45]. However, this increasing incidence extends beyond the MSM population and includes women as well as increased number of cases of congenital syphilis.

Syphilis can present in three stages: primary, secondary, and tertiary. This is defined based on the time from infection as well as clinical presentation. In primary syphilis, an ulcer may present at the site of inoculation 1–21 days after infection; although lesions are commonly painless, extragenital ulcers are more likely to have significant pain. Ulcers often resolve within 3–6 weeks regardless of treatment, and thus only a small portion of patients are diagnosed during this stage. In HIV-positive patients, primary disease is more likely to be asymptomatic; therefore, this cohort more commonly presents in the secondary stage [44]. Secondary disease usually occurs weeks to months after the initial inoculation and can present with more systemic symptoms such as fever, malaise, arthralgias, diffuse lymphadenopathy, a rectal mass, and a rash. The rash, which signifies hematogenous spread, is often characterized by a diffuse maculopapular lesion that can involve the palms of the hands and soles of the feet. A less common presentation includes both nodular and ulcerated lesions. Failure to treat these patients results in progression to a latent asymptomatic stage for a period of 1–30 years following initial infection. Progression to tertiary syphilis occurs in a minority of patients and is characterized by cardiac involvement and gummas, non-cancerous growths with a necrotic and ulcerated center that can develop throughout the body. Neurosyphilis can occur at any stage of disease and is characterized by ocular and/or central nervous system (CNS) involvement of the brain, peripheral nerves, or spinal cord. Symptoms of neurosyphilis include meningitis, cranial nerve palsies, paralysis, dementia, and even death. There is an increase prevalence of neurosyphilis in the HIV-positive population, with findings that support HIV may accelerate the clinical course of neurosyphilis [44].

Diagnosis

Syphilis can present over a spectrum of phases with varying presentations and symptoms; therefore, the diagnosis requires a high clinical suspicion as well as appropriate dual testing to confirm positivity. Historically, the diagnosis was made by visualizing the bacterium using dark-field microscopy. Although this is still recognized as the gold standard when evaluating tissue samples of ulcers and lesions, modern testing uses serologic analysis. Diagnosis starts with nontreponemal testing followed by a treponemal-specific test for confirmation. Nontreponemal testing includes VDRL (venereal disease research laboratory) and RPR (rapid plasma reagin) testing as they are easy and inexpensive. However, they are not specific, and false-positive serologic tests can be seen in non-syphilis cases such as in other infections like HIV, autoimmune diseases, and pregnancy. Thus, patients with a positive nontreponemal test should always undergo confirmatory testing with a treponemal test including antibody testing such as FTA-ABS (fluorescent treponemal absorption tests) and other enzyme immunoassays and immunoblots [12]. Some laboratories have flipped the algorithm and are using "reverse" testing with an automated treponemal test as the initial screening test followed by a nontreponemal test, as treponemal antibodies appear prior to nontreponemal antibodies. However, interpretation is difficult given patients with reactive treponemal-specific tests will likely have reactive tests for the rest of their lives regardless of status or treatment of the disease, and some data suggests "reverse" testing is associated with increased false-positive rates [46].

Patients with clinical symptoms that suggest CNS or optical involvement should undergo organ-specific testing including cerebrospinal fluid testing or a slit lamp ophthalmologic exam. Given the high coinfection rate with syphilis and HIV, all patients should also undergo testing for HIV infection.

Treatment

The treatment of syphilis is penicillin G for all stages of the disease (Table 18.2). The duration of treatment as well as the preparation, i.e., procaine, crystalline, and benzathine, may vary as the disease can reside in sequestered sites of the body which are more difficult to treat, such as the central nervous system. For early stage disease, the recommended treatment is a single intramuscular (IM) dose of benzathine penicillin G 2.4 million units. Patients should be educated about the Jarisch-Herxheimer reaction which is an acute febrile reaction often seen in the treatment of early syphilis and is accompanied by headache, myalgia, and fever and can occur within the first 24 hours after the initiation of therapy. Treatment for this reaction is supportive; however, in pregnant women, this reaction can cause preterm labor, and thus symptoms should be recognized early. In patients with a clinical suspicion of disease but with a negative testing, empiric therapy should be given and repeat testing performed. Treatment for latent and tertiary syphilis requires a longer duration of therapy, and those with a penicillin allergy may necessitate alternative therapies; therefore, these conditions should be managed by an infectious disease specialist.

Following treatment, repeat clinical evaluation and testing should be performed at 6 and 12 months. Treatment failure and/or re-infection should be suspected in patients whose symptoms persist and/or whose antibody titers remain elevated. All persons who have had sexual intercourse with

another person who has been diagnosed with any stage of syphilis in the last 3 months should undergo evaluation and possibly empiric treatment according to CDC guidelines [12].

Chancroid

Epidemiology and Presentation

Chancroid is an anogenital ulcerative infection caused by the bacterium *Haemophilus ducreyi* and one of the reportable STIs in the United States. The overall incidence has been on the decline in the United States over the last several decades with only three cases reported in 2018 [1]. However, accounting for the incidence of this disease is challenging due to diagnostic difficulties, as this bacterium is notoriously hard to culture. Similar to other STIs, transmission is through sexual intercourse and open breaks in the skin which transmit disease. Infection with *H. ducreyi* often presents hours to days after exposure with painful lesions that may start as a papule and progresses to a pustule and open, painful ulcerations. These ulcers are often multiple in cases of chancroid and have ragged borders with overlying exudate. Similar to syphilis and other diseases causing open ulcers and lesions, chancroid can facilitate HIV transmission.

Diagnosis

The combination of a painful genital or anal ulcer along with unilateral suppurative inguinal lymphadenopathy often suggests the diagnosis of chancroid. Gram stain of the ulcer and exudate may show gram-negative rods in a chain, termed the "school of fish" appearance. However, gram stain alone has been demonstrated to have a low sensitivity ranging from 40% to 60% [47, 48]. A positive culture of this bacterium requires multiple media which are not widely available; as a result, identification of this organism is problematic. Polymerase chain reaction (PCR) is the most sensitive test to detect for *H. ducreyi*; however, no FDA-approved PCR test is available in the United States, and thus diagnosis is made based on the following criteria: presence of one or more painful genital ulcers, no evidence of syphilis infection, regional lymphadenopathy, and an ulcer exudate that is negative for HSV [12, 48]. Patients should also be offered testing for other STIs including HIV.

Treatment

Goals of treatment are to improve and resolve symptoms while also preventing transmission. The treatment for chancroid is either single-dose ceftriaxone 250 mg IM or azithromycin 1 g orally, both of which have the benefit of one-time dosing. While there are alternative treatment regimens that include ciprofloxacin and erythromycin, some data suggest intermediate resistance to these drugs [12]. Due to the difficulty of cell culture which allows for antibiotic susceptibilities and resistance, true resistance patterns are hard to define. Patients should be evaluated within 3–7 days after initiation of therapy to assess for resolution of symptoms with the expectation that ulcers will symptomatically improve in 3 days and show objective improvement in 7 days; however, full ulcer healing may take up to 2 weeks. Healing is slower in uncircumscribed men with ulcers under the foreskin, those with coinfection with HIV, and those with antimicrobial resistance and thus may require a longer duration of therapy or change in therapy. All persons diagnosed with chancroid should avoid sexual activity during treatment and while ulcers heal and should undergo repeat testing for HIV and syphilis 3 months after completion of therapy. All partners who had sexual contact with an infected person within 10 days of symptom onset should be referred for evaluation.

Donovanosis

Epidemiology and Presentation

Donovanosis, or granuloma inguinale, is caused by the intracellular bacterium *Klebsiella granulomatis*. The incidence in the United States is rare, and the disease is more prevalent in tropical and developing areas of the world such as Brazil, South Africa, and the Caribbean. Typical presentation involves a non-tender, beefy red ulcer in the genital region that may bleed due to their high vascularity. They can also occur in the anorectal area where some manifest infection with verrucous lesions and/or deep fissures with fibrotic ulcers. These ulcers can present with subcutaneous lesions and granulomas, often referred to as pseudo buboes.

Diagnosis

Like chancroid, the diagnosis of donovanosis can be difficult since the bacterium is difficult to culture. The diagnosis is typically made by identifying Donovan bodies within large mononuclear cells in Giemsa-stained smears of the presenting ulcerative lesion; however, Donovan bodies can be difficult to detect from more fibrotic or necrotic ulcers [49]. PCR has more recently become available to aid in the diagnosis. As with all STIs, patients should undergo testing for possible coinfection, specifically HIV, as this may worsen the course of the disease.

Treatment

Treatment allows for healing of the ulcers starting from the outside moving inward, and thus treatment is often prolonged to allow for full epithelization. First-line treatment recommended by the CDC is azithromycin 1 g orally every week for 3 weeks or 500 mg daily for 3 weeks [12]. If there is no clinical improvement within a few days after initiation of therapy, the addition or an aminoglycoside such as genta-

mycin should be considered. Patients should be followed until all signs and symptoms have resolved, and all partners within the last 2 months should be referred for further evaluation.

Herpes Simplex Virus

Herpes simplex virus type 2 is one of the most prevalent STDs in the United States, with greater than 20% of adults as carriers. This DNA virus is a member of the *Herpesviridae* family and is associated with the development of genital herpes and is one of the most common causes of nongonococcal proctitis in the MSM population [12, 50, 51]. Although HSV-2 is commonly associated with genital lesions, a 2006 report by Ryder and colleagues demonstrated a rising proportion of anogenital herpes secondary to HSV-1 in both heterosexual woman and MSM cohorts. This was thought to be due to a reduction in HSV-1 transmission as a child, therefore leading to a larger population of susceptible adults who engage in both oroanal and orogenital practices [52].

The human body serves as a reservoir for this virus, and transmission occurs through intimate contact. Anal receptive intercourse results in destruction of the mucosa or skin surface barriers which provides a route for inoculation. Unfortunately, most individuals are unaware of their infection status. Recurrent viral infections occur due to immunological shunting between the mucocutaneous surface and sensory nervous system. Following primary infection, the virus moves in a retrograde fashion along axons of the sensory nerve ganglia where it may lay dormant throughout the life of the host. Following reactivation, the virus spreads antegrade down neurons to infect and shed from the mucocutaneous surface. This virus has evolved to develop an intelligent ability to conceal itself from host antibody-mediated defenses, posing an inherent challenge to the immune system [10].

Anorectal herpes is characterized by recurrent blistering lesions of the mucous membranes. Symptoms typically occur 4–21 days after anal receptive intercourse, with most patients experiencing perianal pain, burning, or pruritus [53]. Physical exam of the anorectum may often be challenging due to pain. Early lesions may appear as small vesicles with surrounding erythema on the perianal skin or in the anal canal (Fig. 18.2). These vesicles may subsequently rupture and coalescence into large ulcers (Fig. 18.3). Risk of transmission occurs until an epithelial barrier is formed over the lesion in approximately 3 weeks [11]. Vesicles and pustules are less common in HSV proctitis. Endoscopic findings typically demonstrate friable mucosa and diffuse ulcerations limited to the distal 10 cm of the rectum. Symptoms may include mucoid bowel movements, hematochezia, tenesmus, or systemic symptoms of fevers, chills, and malaise during the primary episode. Lumbosacral radiculopathy may also occur resulting in urinary dysfunction, sacral paresthesia, impotence, and pain [54]. The risk of recurrence in the first year following seroconversion is reported as high as 90% in HSV-2 patients [55]. Recurrent infections typically lack systemic symptoms, are less painful, and occur for a shorter duration as compared to the primary infection. In patients with impaired humoral defenses such as leukemia and HIV or those on T-cell-compromising medications, the genital and mucosal effects of the virus are exacerbated and may result in life-threatening ulcer disease [10].

The diagnoses of HSV include both type-specific virologic and type-specific serologic testing. These results dictate the patient's prognosis and guide counseling and education for the patient and their partner [12]. Cell culture growth may detect viral presence in 90% of active vesicular lesions and has been a primary method of detection for decades. The logistics required of this diagnostic method is challenging; however, it allows for viral typing and antiviral sensitivity testing [56]. The classic use of the Tzanck preparation and direct immunofluorescences is insensitive and lacks accuracy; therefore, they are not recommended [57].

Serologic testing with polymerase chain reaction (PCR) assays allows for nucleic acid amplification of the HSV DNA and is currently the gold standard test for systemic HSV infections of the central nervous system. This rapid and sensitive method of viral detection has become recognized as a feasible option in the diagnosis of all herpes associated lesions. HSV-specific glycoproteins should be requested to detect HSV-1 or HSV-2, as knowledge of the offending organism may guide treatment and counseling for patients. HSV-1 lesions tend to have better outcomes with a shorter duration of viral shedding. Type-specific serologic testing may be utilized in patients without active lesions, and positive results suggest previous infections. Due to its low specificity, high

false-positive rate, and lack of confirmatory testing, the approved and available serologic test for HSV-2 is not a suitable option for screening the general population [6, 56].

Oral systemic antiviral medications are the mainstay in management of genital herpes; however, there is no cure. These agents function to partially decrease the signs and symptoms of episodes when recognized early. Antiviral agents are indicated for the onset of symptoms or as a daily suppressive medication. Once discontinued, this does not affect the risk or timing of recurrence. Three antiviral medications have been validated through randomized controlled trials and include valacyclovir, acyclovir, and famciclovir [58–61]. All patients should be considered for antiviral treatment during their initial clinical episode as this may result in a severe systemic response or neurological injury (Table 18.6) [12]. Once seroconversion occurs, patients may elect to begin continuous suppressive therapy or on-demand treatment when outbreaks occur [59]. Diaz-Mitoma and colleagues demonstrated that daily suppressive famciclovir resulted in a recurrence-free interval three times the rate of the control group, with 70–80% of patient's disease free at 1 year [62]. In addition, patients had an increased satisfaction in their treatment with suppressive therapy; however, this did not meet statistical significance (64% vs. 50%; $p = 0.13$) [63]. Once-daily valacyclovir has been demonstrated to be safe and efficacious in decreasing the risk of transmission of HSV-2 in both heterosexual couples and those with multiple sexual partners [12, 60, 64].

Recommendations supporting the treatment of proctitis secondary to HSV are limited; however, antivirals are recommended to shorten the duration of symptoms [65]. Patients with severe HSV infection, systemic sequelae of the disease, or neurologic complications that necessitate hospitalization should be considered for intravenous acyclovir [12]. As the use of antimicrobial agents increase, therapeutic resistance becomes a significant issue. Acyclovir resistance has been reported at a rate of 5% in HIV-positive patients, with a risk <1% in the immunocompetent population [66]. Albeit low, untreated HSV infection in the immunosuppressed patient may lead to significant consequences to include severe persistent ulcers, aseptic meningitis, and extragenital lesions. The recommended treatment in the setting of drug-resistant HSV infections includes foscarnet or cidofovir, with limited data in the use of topical imiquimod or cidofovir gel [67, 68]. HIV-positive patients should be monitored for persistent disease despite therapy (Table 18.7), and appropriate serological testing should be performed (Table 18.3).

Genital Warts

Human papilloma virus is one of the most prevalent sexually transmitted infections in the world, with over 20 million patients affected in the United States and five million cases diagnosed annually. This virus and its development into genital warts present various indications for treatment by a colorectal surgeon [69, 70]. Anogenital condylomas are common among all genders and sexual orientations; however, this infection is more prevalent among the MSM population, with rates as high as 57% in those HIV-negative and over 90% in HIV-positive patients [71]. Furthermore, HIV-positive MSM are at a twofold increased risk of HPV infection and subsequent condyloma formation as compared to non-MSM patients [72]. There are over 120 known HPV serotypes, with subtype 6 and 11 identified as the most common cause of benign condylomas, typically seen as unsightly warts of the genitalia, anus, and rectum. Subtypes 16 and 18 are more commonly associated with cellular changes in the mucosa resulting in anal dysplasia and invasive carcinoma [73]. These lesions lack a severe inflammatory response; however, in an immunocompromised state, HPV can be challenging to manage.

Transmission typically occurs through sexual contact with a 3-month incubation period. The utilization of condoms may help protect spread of the virus to some degree; however, inoculation may occur from the uncovered skin beyond the latex material. Although intra-anal lesions are more common in those who engage in anal receptive intercourse, autoinoculation has been demonstrated from genitourinary warts to the perianal region without direct contact [74, 75].

Symptoms depend on the degree and location of the lesions. Genital warts are typically diagnosed based on clinical exam and appear as raised gray or pink fleshy, cauliflower-like growths that may result in bleeding, pruritus, pain, or hygiene difficulty (Fig. 18.4). Anoscopy is recommended to evaluate for extension into the anal canal. If small papules are visualized, they rarely develop proximal to the dentate line [76]. Consideration should be given to fully examine the genitalia, perineum, and groins and perform a speculum exam of the vagina with Pap smear in women. Subtyping of the virus is not recommended for ano-

Fig. 18.4 Perianal condylomas secondary to human papilloma virus

Table 18.8 Treatment recommendations for anorectal warts

Patient-applied therapy	Provider-administered therapy	Intra-anal lesion therapy
Imiquimod 3.75% or 5% cream	Cryotherapy	Cryotherapy
Podofilox 0.5% solution or gel	Surgical removal	Surgical removal
Sinecatechins 15% ointment	Trichloroacetic or bichloroacetic acid 80–90% solution	Trichloroacetic or bichloroacetic acid 80–90% solution

genital warts as results are difficult to confirm and do not guide management [12]. Histologic confirmation is only recommended when the patient is immunocompromised, the diagnosis is uncertain, there is failure to respond to therapy, or the lesion worsens during treatment. The clinician should have a greater index of suspicion for malignancy in patients who are immunocompromised, those that have large atypical or pigmented lesions, and disease refractory to standard treatment [77].

High-resolution anoscopy, a technique similar to colposcopy, is a tool utilized to evaluate the anal epithelium and should be considered in high-risk populations such as MSM- and HIV-positive patients. This may be performed in the office setting or operating room with the application of 3% acetic acid or Lugol's solution. Lesions that turn a distinct acetowhite or do not take up the Lugol's solution are at greater risk of dysplasia [78]. Features of dysplasia include punctation, mosaicism, neovascularization, and an abnormal vascular pattern [79, 80].

The management of condylomas is focused on the destruction or clearance of all visible disease while minimizing harm to surrounding tissue (Table 18.3). Similar to HSV, local destruction of HPV does not eradicate the virus. The immunocompetent patient may even spontaneously clear all lesions if left untreated. Treatment options include tangential excision, cryotherapy, fulguration, and topical therapies (Table 18.8). Smaller lesions may be treated under local anesthesia in the outpatient setting, but larger or multiple lesions require treatment in the operating room. Recurrence rates are reported between 4% and 29% and may vary based on the patient's immune function [81, 82]. A single treatment may result in clearance of the virus in up to 75% of patients; however, those with intra-anal lesions, a more extensive initial presentation, and requirement for combination therapy with topical medication and those who have not received the HPV vaccination are at a greater risk of recurrence and need for additional therapy within 2 years [83].

Electrosurgical ablation may be utilized for lesions in any location, and this allows for full-thickness destruction of the condyloma. Adequate fulguration occurs when the superficial layer of the wart is cauterized and the lesion changes to a gray-white appearance. The lesion should then be mechanically debrided with a curette or gauze. Care should be taken to avoid burning into the deep dermis or subcutaneous fat as this can result in significant scaring and poor cosmesis. Carbon dioxide laser therapy is an alternative ablative technique for the appropriately trained clinician. This may be beneficial for large, multiple, or recurrent warts and is particularly useful for intraurethral lesions. In addition, warts can be transected at their base using scissors or a scalpel. Electrodesiccation of anogenital warts should be performed in an appropriately ventilated room utilizing standard precautions and smoke evacuator techniques. Based on the size and extent of the lesion, adjuvant patient-applied topical therapy may be recommended to aid in minimizing the risk of recurrence. Presently, there are no FDA-approved topical therapies for intra-anal lesions.

Trichloroacetic acid and bichloroacetic acid are provider-applied agents that can be placed topically in the clinic and for small lesions in the anal canal or perianal skin. These chemicals are caustic agents that destroy warts through protein coagulation. Care should be taken to avoid contact with healthy tissue as this may result in unnecessary damage. Once the acid is applied, a white frost material forms on the tissue. The chemical should then be allowed to dry before the patient moves. Applying sodium bicarbonate, liquid soap, or powdered talc can neutralize the acid if pain from the application is not well tolerated. Cryotherapy is another provider-applied therapy that causes thermal-induced cytolysis to destroy warts. Patients may experience pain from this application and subsequent tissue necrosis or blistering at the treatment area. Alternative provider-applied therapies include podophyllum resin, intralesional interferon, photodynamic therapy, and topical cidofovir. These agents are less utilized and not recommended for first-line treatment of genital warts due to a paucity of outcomes data and greater side effect profile.

Patient-applied topical therapies for non-intra-anal condylomas include imiquimod 5% cream, podofilox 0.5%, or sinecatechins 15% which is a green tea extract containing catechins as its active component. Imiquimod is a class of medications known as an immune response modifier that has antiviral properties by stimulating interferon activity and cytokines involved in a T-cell-mediated response [84]. Treatment success following a 16-week period is reported as high as 87% with this medication alone, and a combination of imiquimod with laser ablation therapy has additional benefits in sustained wart clearance [85]. The cream may be applied at bedtime three times a week and should be left in place for 6–8 hours and removed with washing. Side effects include pain, burning, itching, irritation, induration, ulcerations, ero-

sions, and even vesicle formation. Treatment may be implemented as initial therapy alone or following other ablative techniques. Patients should be counseled to fully wash off all applied medications prior to engaging in sexual activity as these products may weaken the protective effects of latex condoms, increasing the risk of contracting sexually transmitted organisms. The utilization of imiquimod-containing suppositories following ablation has been investigated for intra-anal lesions with complete clearance of disease and minimal side effects [86].

Application of podofilox 0.5%, an antimitotic drug derived from the plant resin podophyllum, results in wart necrosis. This can be applied twice a day for 3 days followed by a 1-day break. This therapy can be repeated for up to four cycles. Due to the risk of skin irritation and systemic toxicity, the total volume of podofilox should be limited to 0.5 mL per day and should be applied on a cotton swab or finger. Initial treatment application can be performed in the clinic to provide instructions to the patient. The successful rate of wart clearance is reported at 37%, with a 4–38% risk of recurrence [87].

The management of recalcitrant anal warts can be frustrating for both the surgeon and patient alike. Although there is no consensus regarding therapeutic modalities, the utilization of a topical immunotherapy in combination with ablative techniques should be considered. O'Mahony and colleagues recommend the application of topical immunotherapy for 2 months prior to ablative techniques in the initial treatment of patients with greater than five warts. This algorithm could also be considered for recurrent disease [88]. Although ongoing investigations are required, the potential application of the HPV vaccine has been considered in the treatment of existing HPV-related conditions. When administered in the prophylactic setting, this vaccine elicits a virus-neutralizing antibody response to prevent entry of the virus into the host cell. Clinical trials of novel vaccines have reported encouraging results; however, only one case report has demonstrated efficacy of the quadrivalent vaccine in the treatment of anogenital warts [89]. Although data is limited, the current literature and ongoing investigations support the use of the HPV vaccine as an off-label therapeutic agent for HPV-associated cutaneous and mucosal lesions [90, 91]. Intralesional immunotherapy has also been considered as an adjunct in the management of anogenital warts. The local injection of antigens to *Candida albicans*; measles, mumps, and rubella (MMR); *Trichophyton*; and tuberculin antigens have been evaluated. This technique induces a T-cell-mediated response releasing cytokines and interferon. This results in the upregulation of a local immune response targeting the virus. Although further studies are required to fully elucidate the treatment effect of these vaccines, they may be considered in the management of complicated cases or recurrent disease [92].

Fig. 18.5 Giant condyloma acuminata and genital warts secondary to human papilloma virus

Giant Condyloma

Giant condyloma acuminata (GCA) was first described by Bushke and Loewenstein in 1925; however, it was not until 1967 when Knoblich reported the first case of perianal GCA. These lesions are associated with HPV types 6, 11, 16, and 18 but differ from condylomas in that they have marked papillomatosis, acanthosis, and thickened rete ridges with greater mitotic activity. These lesions are more prevalent in immunosuppressed patients and are characterized by large destructive verrucous lesions on the anogenital region (Fig. 18.5) [93]. This entity may represent the continuum of benign condyloma to invasive squamous cell carcinoma [94]. Histologically GCA has been demonstrated to infiltrate tissue and has a risk of malignant transformation in up to 56% of patients [95, 96].

The treatment of choice is wide local excision with one centimeter margins. Aggressive resection is necessary as the risk of recurrence is 65%, with a greater rate in HIV-positive patients [95–97]. Radical excision allows for adequate surgical margins, as well as complete histologic examination to guide additional therapeutic interventions. While most wounds heal by secondary intent, rotational S flaps, advancement flaps, V-Y flaps, or skin grafts may be required to cover large surgical defects [98]. Abdominoperineal resection is required if the anal sphincter is involved. Successful outcomes have been reported with the use of chemoradiation alone in poor surgical candidates or those whom complete surgical margins cannot be safely achieved [99, 100]. Guttadauro describes a sleeve resection of the lesion by creating a cylindrical mucocutaneous excision with a radiofrequency dissector. This allows for removal of the entire lesion creating an anastomosis of proximal viable mucosa to the excised distal margin. This technique places the dentate line

in the correct anatomic position while avoiding a mucosal ectropion. Utilization of this procedures resulted in a short hospital stay, with no incidence of anal stenosis or recurrence at 1 year [98]. GCA may be challenging to manage especially in the immunocompromised patient; therefore, resection and reconstruction should be individualized to minimize the risk of recurrence while avoiding significant morbidity.

Molluscum Contagiosum

Molluscum contagiosum, a member of the poxvirus family, results in small contagious skin lesions. This virus has an incubation period between 1 week and 6 months and could last multiple months if no intervention is rendered. Transmission occurs through direct contact of the skin and mucous membranes of active lesions. In addition, this pathogen is transmitted via fomites, such as towels or other clothing objects. Molluscum has been associated with pools or bathing facilities, and patients can auto inoculate themselves in various locations throughout the body.

The lesions are typically flesh-colored or gray-white, and symptoms include itching and pain. The virus is typically self-limiting in the immunocompetent host; however, in those with an impaired immune system such as HIV, these lesions may become quite large, verrucous, and hyperkeratotic. Treatment with phenol or trichloroacetic acid, tangential excision, electrocautery, or cryotherapy is all effective. In addition, patient-applied topical therapies include podophyllotoxin and imiquimod. These interventions control the risk of transmission and improve potential cosmetic outcomes [101–103].

Human Immunodeficiency Virus

Although the spread of HIV was reported prior to 1980, it was not until 1981 when the Centers for Disease Control and Prevention recognized this viral transmission as an epidemic. HIV is a single-stranded ribonucleic acid (RNA) retrovirus which allows for incorporation into the human genome via reverse transcriptase. The virus initially attacks CD4 receptors to enter the cell, resulting in abnormal immune system activation and eventually the destruction of T lymphocytes. The virus has the ability to become latent for a number of years making treatment strategies and eradication challenging (104). Since its initial report, approximately 1.7 million people have been infected with HIV in the United States, with over 500,000 deaths. Presently, 1.2 million patients are living with the disease, and 14% are unaware of their infectious status. Fortunately, between 2010 and 2016, the annual incidence of HIV has decline by 9% in the United States; however, the prevalence remains greatest in MSM, especially the African American population [12, 104].

The life span of HIV has been divided into three stages. The first, or acute stage, also referred to as HIV-1 infection syndrome, occurs within in a few weeks of transmission. The patient may suffer from flu-like symptoms and a rash [104]. This phase occurs as multiple cells of the immune system and lymphatic tissue are targeted by the virus. Following the acute infection, the virus enters a dormancy phase where reproduction occurs but at a low level. When left untreated, CD4 counts will begin to fall, and once levels are <500 mm^3 the immune system, reserves will be compromised, and resultant viral infections such as HSV or HPV may ensue. Once the CD4 count is <200 mm^3, patients become vulnerable to opportunistic infections and cancer leading to acquired immunodeficiency syndrome (AIDS) or end-stage HIV disease. Disease progression has been shown to be influenced by both physiologic and psychosocial factors. Drug use, high-risk sexual behaviors, and mental health all play a factor in outcomes, as well as the utilization of appropriate treatment and prevention strategies [105]. With the advent of highly active antiretroviral therapy (HAART) and virus-specific intervention, there has been a significant reduction in HIV-related morbidity and mortality. The goal of treatment is to suppress the circulating viral load and preserve immune function. Studies have shown that the implementation of HAART has the ability to recover and restore both adaptive and innate immune parameters [106].

Although HIV does not manifest as a specific anorectal disorder, benign anorectal pathology in the HIV-infected patients is the most common operative indication [107]. Anal pathology can present in three ways: (1) HIV-specific condition (anal ulcer); (2) routine condition (hemorrhoid, fissures, fistulas, perirectal abscess); and (3) routine condition that manifests differently due to HIV status (anal condylomas and herpetic anal ulcers) [108, 109]. In addition, AIDS is associated with malignancies to include anal squamous cell carcinoma, lymphoma, and Kaposi's sarcoma [109]. The surgeon should have an understanding for the patient's disease stage and medication regimen to ensure appropriate treatment is rendered. Previously, surgeons have been hesitant to operate due to the concerns of delayed or poor wound healing secondary to the aggressive nature of the virus, decreased leukocyte and CD4 count, and association with AIDS. Safavi and colleagues demonstrated that T4 cell count had no predictive value associated with wound healing [109]. Furthermore, many studies which have reported poor surgical outcomes in AIDS patients are greater than 20 years old and predate the era of HAART [110–112]. Based on the knowledge regarding immune reconstitution following HAART treatment, HIV-positive patients on appropriate virus-targeted agents are most likely at no increased risk for complications following anorectal surgery, and their pathology should be treated in a standard fashion regardless of their immune status [104].

An anorectal abscess should be drained with a small incision close to the anal verge. Cultures should be obtained, and patients in an immunocompromised state should be placed on antibiotics. Anal fistulas are typically cryptoglandular in origin and should be treated with setons or sphincter-preserving operations. Fistulotomies should be performed in low uncomplicated fistulas. However, prior to any sphincter-sacrificing procedure, a thorough evaluation should be performed to detail the patient's bowel habits, history of diarrhea, and sphincters control. Although these common anorectal manifestations should be treated in a similar fashion, it should be remembered that HIV is not a static disease and the treatment of the current condition may have a significant effect on the patient's quality of life in the future.

Anal fissures among MSM may result from anal receptive intercourse and must be distinguished from HIV-/AIDS-related ulcers and other ulcerating infections such as HSV or syphilis which are more prevalent in the HIV population [109]. HIV-related ulcers are typically tender, necrotic, and exudative with deep irregular overhanging borders. They typically form off the midline; however, when midline, they are more proximal in the anal canal and closer to the dentate line as compared to simple fissures. These lesions tend to be the most disabling of any anal disease and are associated with a hypotonic sphincter. Occasionally there is a superficial layer of purulent material mimicking an abscess [107]. Anal ulcers remain a common disorder in this population, as they are not affected by antiviral medications [113].

Treatment for anal fissures in the HIV-positive population should be similar to the general population; however, internal sphincterotomy is not advised unless the diagnosis is clearly distinguished from ulcerating disease. Those with diarrhea secondary to proctocolitis should be treated appropriately to minimize trauma to the anal canal, and abstinence from anal receptive intercourse is recommended. Safavi and colleagues report the use of intralesional steroids in the treatment of anal ulcers in six patients with significant improvement, suggesting inflammatory mediators contribute to ulcer formation [109]. Ulcer excision followed by mucosal advancement flap should be reserved for those who fail medical treatment; however, a more aggressive surgical approach has been associated with symptomatic relief and successful wound healing [107].

Ectoparasitic Sexually Transmitted Diseases

Pediculosis pubis or pubic lice is an infestation of the parasite *Pthirus pubis*. Transmission is secondary to contamination of pubic hair and the perianal region during close sexual contact. Following egg deposit onto the contaminated surface, the incubation period is less than 1 week, with the entire life cycle of the adult parasite less than 1 month. The primary symptoms are typically pruritus. The affected skin becomes crusted, and rust-colored flecks of fecal material can then be seen. A diagnosis is based on clinical findings; however, a dermascope can visualize the parasites within hair follicles [114].

Table 18.9 Treatment recommendations for ectoparasitic sexually transmitted diseases

Primary treatment	Alternative treatment
Pediculosis pubis	
Permethrin 1% cream; apply and wash off after 10 minutes	Malathion 0.5% lotion; apply and wash off after 8–12 hours
Pyrethrins with piperonyl butoxide; apply and wash off after 10 minutes	Ivermectin 250 μg/kg orally; repeat in 2 weeks
Scabies	
Permethrin 5% cream; apply to affected areas wash off after 8–14 hours	Lindane 1%: 1 oz of lotion or 30 g of cream; apply thin layer, wash off after 8 hours
Ivermectin 200 μg/kg orally; repeat in 2 weeks	

Patients diagnosed with pubic lice should be screened for other sexually transmitted diseases, including HIV, as there is a 30% risk of coinfection [115]. First-line therapy typically involves permethrin 1% cream or pyrethrins with piperonyl butoxide. Alternative therapy options include malathion 0.5% lotion or ivermectin 250 μg/kg orally for 2 weeks. Lindane is an additional treatment option when other therapies fail; however, side effects include aplastic anemia and seizures (Table 18.9) [116]. The skin should be cool and dry prior to applying topical agents. In addition to topical medications, the patient should comb the affected area to remove all nits; however, shaving is generally not necessary. All clothing and bedding should be washed [114]. The patient is considered clear of infestation if no parasites are present 1 week after treatment.

Scabies, or *Sarcoptes scabiei*, is a parasitic infection frequently transmitted in adults through sexual activity [117]. This eight-legged creature can survive up to 36 hours at room temperature and can be transmitted through fomites. Following infection, scabies results in nocturnal pruritus with a symmetrical distribution of papules, pustules, and excoriations. Clinical findings are more common in the interdigital webs, nipples, or genitals. The diagnosis is classically made by identifying the mite in its burrow. Although challenging to capture the organism in this form, the diagnosis is typically made through findings of fecal material. Recommended treatment options include permethrin 5% cream or ivermectin orally for 2 weeks. Lindane is also an alternative treatment options but should be used in limited cases with refractory disease due to toxicity. Caution must be had with all treatment options as they can be caustic to the

skin and result in a contact dermatitis (Table 18.9). As with pediculosis, close contact should be restricted, and all clothing should be carefully washed [118]. To minimize excoriation from scratching, patients should be advised to keep their fingernails short.

The HIV or immunocompromised patient is at increased risk for crusted or Norwegian scabies. This species has a greater ease of transmission in this at-risk population with a significantly aggressive rate of infestation. Combination therapy is recommended with 25% benzyl benzoate or 5% permethrin cream and oral ivermectin. Destructive effects on the skin are severe, and Lindane should be avoided due to increased risk of systemic toxicity [119]. This subgroup of scabies is challenging to eradicate, and close follow-up should be considered at 2 weeks with additional therapy if needed. All sexual contacts should be evaluated and treated accordingly [12].

Conclusion

Despite the advancements in diagnostic and therapeutic modalities, anorectal STIs remain a public health concern. The most effective method of treatment is prevention, and that starts with the education of patients and providers alike. High-risk population, such as MSM and those in a low socioeconomic status, should be screened and offered appropriate vaccines and prevention methods to mitigate the transmission of these infectious organisms. All patients presenting with a concern for an STI require specific testing and screening for all related organisms and HIV. Although effective antibiotic and antiviral therapies exist and operative intervention may not be required for the majority of STIs, the colorectal surgeon should provide an environment of support to ensure patients receive the required treatment and sexual health counseling.

Anal Intraepithelial Neoplasia

19

Wolfgang B. Gaertner and Mukta K. Krane

Key Concepts

- Anal intraepithelial neoplasia is a dysplastic condition and is considered to be a premalignant stage of anal cancer.
- Its histologic and cellular findings mirror cervical dysplasia.
- Anal cytology is a useful tool to identify anal neoplasia in high-risk groups.
- When anal cytology is concerning, high-resolution anoscopy with targeted ablation of dysplasia is indicated.
- Treatment should be individualized according to the degree of dysplasia, risk factors, immune status, symptoms, and the likelihood of progression.

Introduction

AIN is defined as the dysplastic growth of squamous epithelial cells at the transition zone of the anal canal. Cells of the anal and cervical canals share embryologic, cytologic, and histopathologic characteristics. Embryologically, fusion of endodermal and ectodermal tissue forms a squamocolumnar epithelial junction (anal transition zone) at the dentate line. AIN has a clear association with HPV and is more prevalent in at-risk populations, including those with human immunodeficiency virus (HIV), men who have sex with men (MSM), as well as liquid- and solid-organ transplant patients. In these populations, the rates of anal cancer are dramatically elevated, despite it being a relatively uncommon disease [1].

The Lower Anogenital Squamous Terminology Standardization (LAST) project for HPV-associated lesions provided guidelines for a unified nomenclature that includes a two-tiered system, designated as low- or high-grade squamous intraepithelial lesion (LSIL or HSIL, respectively). In the anal canal, LSIL correlates with anal intraepithelial neoplasia (AIN)-1 or anal condyloma, while HSIL correlates with AIN-2 and AIN-3 (Fig. 19.1) [3]. Cytologically, abnormal squamous cells of the anus are classified as (a) atypical squamous cells of undetermined significance (ASCUS); (b) atypical squamous cells, cannot rule out high-grade squamous intraepithelial lesion; (c) low-grade squamous intraepithelial lesion (LSIL); and (d) high-grade squamous intraepithelial lesion (HSIL) [4].

Incidence

The incidence of AIN in the general population is difficult to estimate, and LSIL may regress or progress to HSIL, whereas HSIL typically does not regress, although this may be influenced by the underlying immune status [5]. Although rates of anal cancer are low (approximately 1.8 cases per 100,000) [6], epidemiologic studies have shown increasing rates of high-grade AIN and anal cancer in both men and women, probably reflecting higher rates of screening [7]. Using statistical models for analysis, rates for new anal cancer cases have been rising on average 2% each year over the last 10 years [8].

Most reports on AIN are retrospective and are heavily biased by heterogeneous populations with significant differences in immune status. Within these, AIN (I–III) has been reported in 6–22% of women with genital (cervical, vaginal, and/or vulvar) intraepithelial dysplasia [9, 10]. The rate of conversion of AIN to anal cancer remains controversial. Prospective studies have suggested that the rate is similar to that of cervical cancer, with a reported 9–13% conversion for AIN-3 within a 5-year period for untreated patients [11, 12], but there is also significant variability among different risk populations. A large meta-analysis from 2012 found that the

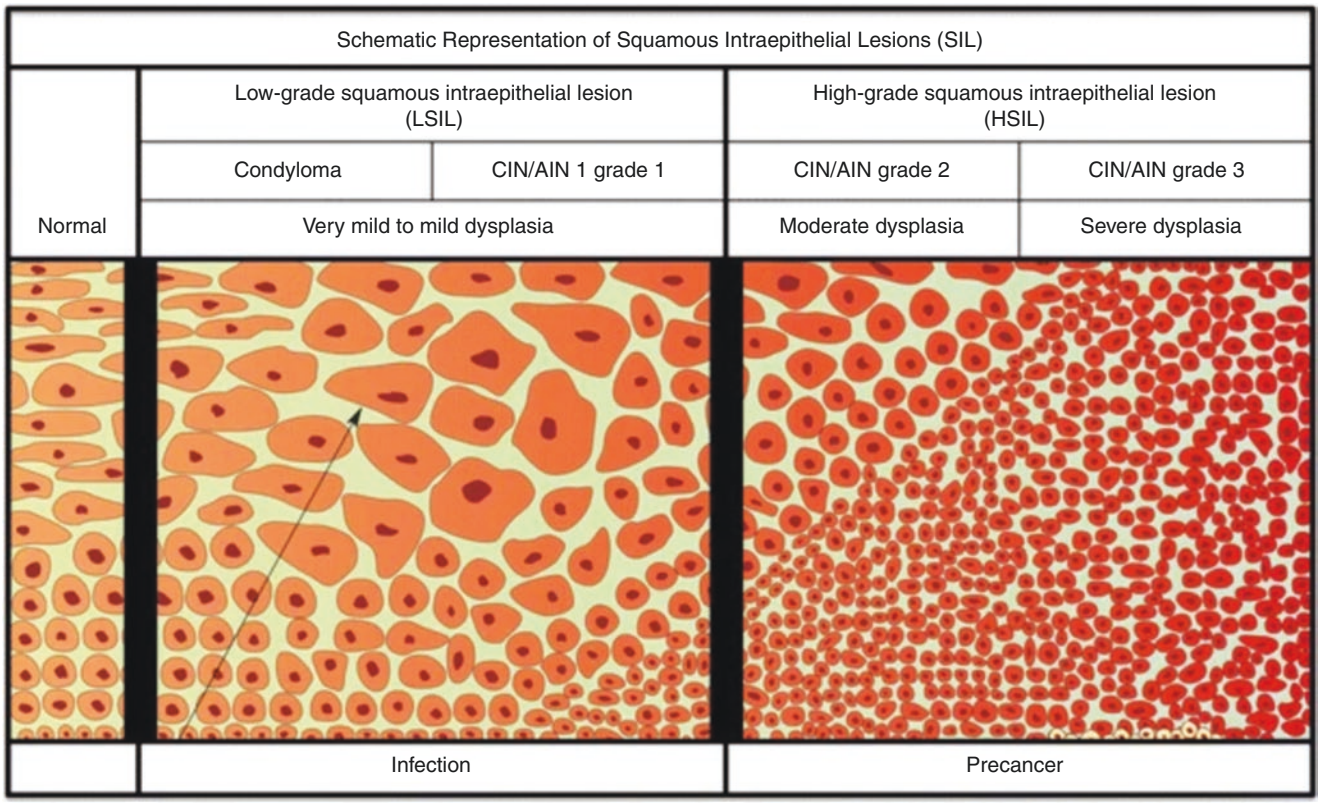

Fig. 19.1 Schematic representation of squamous intraepithelial lesions (SIL). With increasing severity of SIL of the anus, the proportion of the epithelium replaced by immature cells with large nuclear-cytoplasmic ratios increases. Invasive cancer likely arises from one or more foci of high-grade SIL (HSIL). (With permission from Brickman and Palefsky [2]. Copyright © 2015 Springer Nature)

rate of conversion was much lower, with progression rates of 1 in 600 per year for HIV+ MSM and 1 in 4000 per year for HIV– MSM [13]. This discrepancy may be attributed to the mix of AIN-2 and AIN-3 patients within the meta-analysis.

Epidemiology

Anal intraepithelial neoplasia develops from HPV contact generally through direct exposure. The Centers for Disease Control and Prevention indicate that "nearly all sexually active men and women will acquire at least one type of HPV at some point in their lives." In fact, 79 million persons are currently infected with HPV with equal prevalence in both the developed and developing world [14, 15]. Approximately 90% of all immunocompetent patients remain asymptomatic, and those that are infected will resolve without treatment within 2 years [16]. Disease progression and presence of condyloma or neoplasia are likely related to immune status.

HPV infection is mainly subclinical but can present as grossly apparent (i.e., condyloma), microscopically apparent, and latent (i.e., an infection that becomes clinically apparent months or years after exposure) and has the potential to migrate from the genitalia to the anus. Risk factors for HPV infection include uncircumcised men, number of sex partners (directly proportional), sex with a partner who has had many sex partners, sex with uncircumcised men, and first sexual contact at an early age. There are >150 HPV serotypes. Those that are considered high risk include 16, 18, 31, 33, 35, and 45 and produce E6 and E7 proteins, which in turn inhibit two important tumor suppressor proteins, p53 and Rb [15, 17, 18]. HPV subtypes 6 and 11 cause 90% of genital warts [19], while 79% of patients diagnosed with anal squamous cell carcinoma are attributable to type 16 or 18 [15].

With the introduction of the HPV vaccine in 2006, the prevalence of HPV types 6, 11, 16, and 18 identified by cytology specimens decreased by over 50% among teens and young women [20]. Additionally, genital wart cases appear to have decreased since 2011 [21], presumably because of increased vaccination (Fig. 19.2). In 2017, Oliver and colleagues [22] demonstrated a decrease in prevalence of 71% among 14- to 19-year-olds and 61% among 20- to 24-year-olds.

Screening and Surveillance

The majority of patients at risk for anal neoplasia undergo screening with digital rectal examination, anal cytology, and anoscopy. Anal cytology is an easily performed procedure in which an unlubricated, moistened Dacron swab is inserted into the anus about 3–4 cm, then removed slowly in a circular motion, and finally preserved most often in liquid medium used for cervical cytology. Although slide preparation with a fixative is also acceptable, liquid-based is the preferred method as it avoids obscuring factors including fecal material, bacteria, and air-drying artifact; plus, residual tissue may be used for ancillary studies. Bowel preparation before the examination and swabbing is unnecessary, and cytology must be performed before any instrumentation of the anus and before lubrication is used. Following completion, a digital rectal examination and anoscopy can be performed.

Anal cytology is graded with the same classification used in gynecologic samples. This may return as insufficient, normal, atypical squamous cells of undetermined significance (ASCUS), low-grade squamous intraepithelial lesion, high-grade squamous intraepithelial lesion, or anal cancer.

Based on these results, physical examination, and medical history, recommendations may include continued surveillance or more detailed evaluation with high-resolution anoscopy (HRA). Cytology results of ASCUS or higher are typically referred for HRA. Although anal cytology results continue to be difficult to interpret given its sensitivity (69–93%) and specificity (32–59%), this may lead to a considerably large population requiring further evaluation with HRA [23–25]. Also, false-negative rates may differ according to specific risk factors such as MSM (23% in HIV– versus 45% in HIV+) [26]. Recent data from Morency and colleagues [27] including a total of 1185 patients undergoing anal cytology, of which 376 (26.5%) had follow-up biopsy, showed that unsatisfactory cases with squamous intraepithelial lesion (SIL) on biopsy showed LSIL in 19%, ASCUS had an 84% rate of biopsy-proven disease, and sensitivity was higher (92%) for high-grade anal intraepithelial neoplasia or worse (AIN2+). Another retrospective study including a total of 327 anal cytology results demonstrated dysplasia (75% low grade and 25% high grade) in 182 patients. Seventy-five percent of dysplastic anal cytology were followed by clinical examination within 1 year, and 50% were biopsied [28]. The probability of dysplasia on histology after dysplasia on cytology was 72%, and 28% of low-grade cytology results were upgraded to advanced disease (high-grade or invasive cancer) on histology. Although results are not yet available, the Anal Cancer HSIL Outcomes Research (ANCHOR) trial aims to determine whether treating precancerous anal high-grade squamous intraepithelial lesions (HSIL), versus active surveillance, is effective in reducing anal cancer incidence in HIV-infected individuals. At this time, any abnormal cytology indicates the possibility of a high-grade lesion. Likewise, cytology may not correlate with histology. Patients with high-grade cytology, but negative anoscopy and/or pathology, should be followed closely (Fig. 19.3).

The risk of anal neoplasia is highest in immunosuppressed individuals as they appear to have difficulty clearing HPV from their body. Rates of anal dysplasia in all HIV+ patients are substantial regardless of sexual practices, indicating a value for anal cancer screening, although the highest risk has been reported in HIV+ MSM [29–31]. This group should

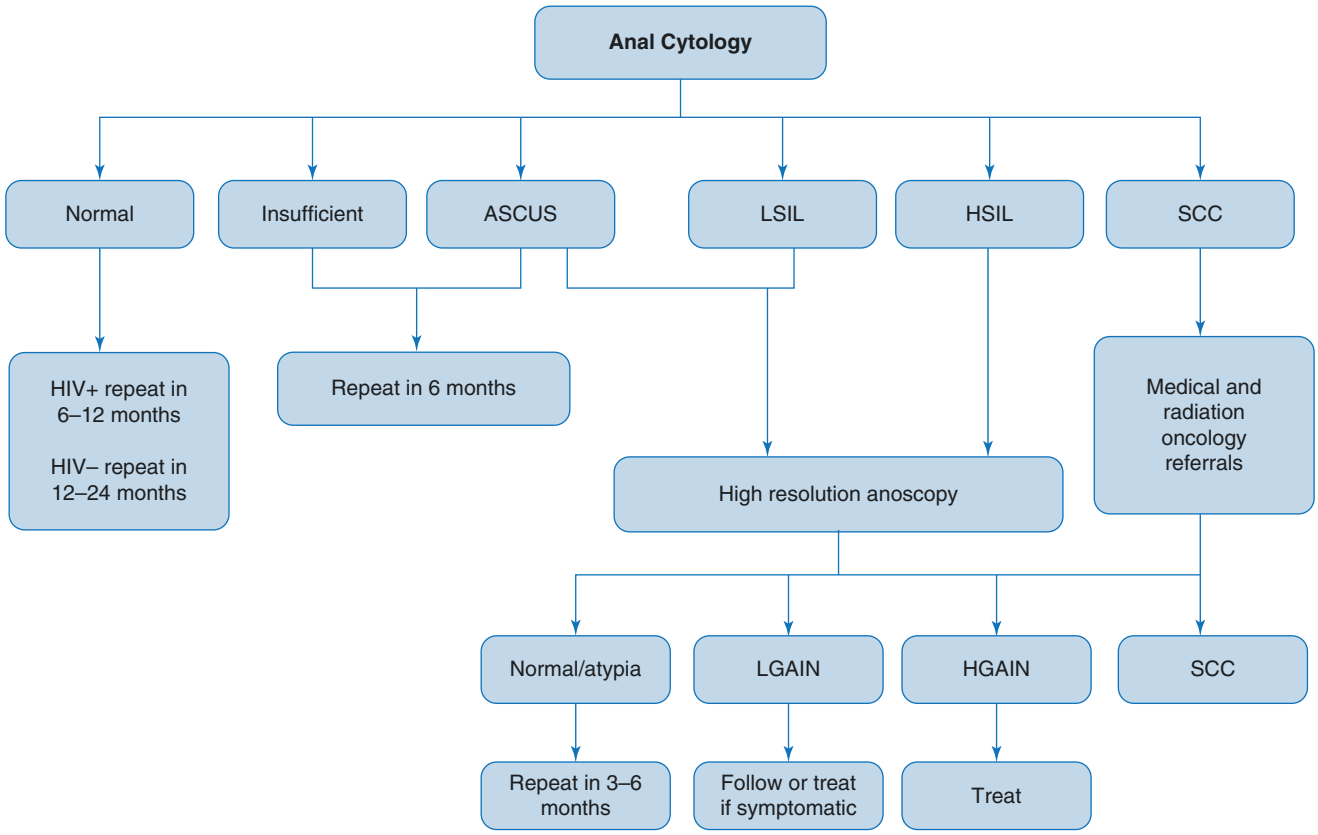

Fig. 19.3 Anal cytology algorithm. Management should be individualized based on many factors, which may increase or decrease the interval of evaluation. *ASCUS* atypical squamous cells of undetermined significance (cannot rule out high-grade squamous intraepithelial lesion); *HGAIN* high-grade anal intraepithelial neoplasia; *HIV* human immunodeficiency virus; *HRA* high-resolution anoscopy; *HSIL* high-grade squamous intraepithelial lesion; *LGAIN* low-grade anal intraepithelial neoplasia; *LSIL* low-grade squamous intraepithelial lesion; *SCC* squamous cell cancer/carcinoma

also include organ transplant patients; women with a past history of cervical, vulvar, or perineal dysplasia; and patients with medically induced immunosuppressive conditions [32–35]. Individuals with a past history of sexually transmitted infections may also represent an important screening population. Although a past history of condyloma is generally a sign of prior contact with HPV, it is unclear whether those individuals have a tendency to develop benign warts rather than cancer. In addition, it is difficult to prove any synergy between HPV and other sexually transmitted infections such as syphilis, gonococci, and herpes simplex that may speed up transformation to AIN [36].

The value of anal cancer screening is difficult to quantify. Screening HIV+ homosexual and bisexual men for anal dysplasia with anal cytology offers quality-adjusted life expectancy benefits at a cost comparable with other accepted clinical preventive interventions [37]. For patients with a history of high-grade dysplasia and immunosuppression, there seems to be a benefit for surveillance given the high rate of recurrence in this population [38]. HRA may be more cost-effective than other strategies; the cost per HSIL found has been estimated to be $809.39. A prospective screening study of 284 high-risk MSM evaluated all 3 modalities of HPV testing, cytology, and HRA [39]. Only 15% of the cohort tested negative for HPV, representing a methodologic weakness in this study. Cytology missed nearly one third of high-risk lesions, suggesting that HRA would have the most clinical use for screening. The effectiveness of HRA to prevent the progression of dysplasia or development of cancer has only been evaluated in retrospective cohort studies. In a retrospective review of 246 patients treated with HRA-targeted destruction of HSIL/LSIL over a 10-year period [40], recurrent HSIL was seen in 57% of patients at an average of 19 months. Despite treatment, only 1.2% progressed to invasive cancer.

Progression

Much of what is known regarding the transformation of AIN to squamous cell cancer has been extracted from the cervical cancer literature. A number of genetic changes are proposed to occur after viral integration leading to phenotypic changes of the squamous epithelium. Abnormalities to chromosomes 1, 3, 7, 8, 11, 15, and 20 have all been reported with varying frequency [41, 42]. One of the most frequently reported changes in chromosomal structure is a gain in the long arm of chromosome 3q [38], which is also reported to occur in the transition from low-grade to severe cervical dysplasia and cervical cancer [41]. Following incorporation of the viral genome into host DNA, cellular changes and atypia of squamous epithelium occur [43–45]. Ultimately these changes correspond to AIN I which then can progress to AIN II and III and ultimately dedifferentiate into squamous cell cancer. It is unclear whether the development of anal neoplasia must traverse all these steps or if a squamous cell cancer can skip one or more phases. Ultimately, the oncogenetic pathway is similar to the pathway described in cervical cancer.

Once the presence of AIN has been established, dysplasia of the anus rarely regresses [46]; however, data proving persistence of AIN are incomplete as many patients do not follow up for surveillance. It is also unclear why anal dysplasia is thought to be more persistent than equivalent degrees of cervical dysplasia given the common pathogenic pathway of these two conditions. In fact, it is estimated that approximately 60% of low-grade cervical lesions will spontaneously regress [47, 48]. Small reports with limited follow-up on the natural history of AIN have shown higher rates of progression to anal cancer, especially in immunosuppressed patients [11, 12]. The rate of progression from AIN to invasive cancer is still unclear at this time due to few studies and limited follow-up periods. Many retrospective studies have associated high-grade squamous intraepithelial lesions as a common precursor in men who have developed anal cancer [44, 49]. Scholefield et al. [11] followed 35 patients (74% women) with AIN III for a median duration of 63 months. All subjects were HIV negative; however, six were on long-term systemic immunosuppressants. Three patients (8.5%) progressed to invasive anal SCC (all of whom were on long-term systemic immunosuppressants). Watson et al. [12] followed 72 patients (72% women) with AIN I–III for a median of 60 months. The majority of patients (94%) had prior genital malignancy, 7% were HIV+, and 23% were on chronic immunosuppression. Fifteen percent of subjects had histologic progression of their disease (AIN II to AIN III, or AIN III to anal SCC), and 11% developed anal SCC.

Diagnosis

AIN is typically asymptomatic but may cause symptoms such as pruritus, bleeding, discharge, irritation, tenesmus, and pain. Direct examination of the anus and a detailed digital rectal exam are important components in the diagnosis of AIN. It is imperative that patients with AIN also have a thorough history and physical examination, with emphasis on other HPV-related diseases such as oral cancer, gynecologic dysplasia [50], and other genital lesions. Physical examination should include a head-to-toe evaluation for squamous cell lesions, considering all lymph node basins. Appropriate referrals to gynecology and urology should be considered on an individual basis.

The diagnosis of AIN is made from cytology or biopsy. The sensitivity of digital rectal exam and anoscopy is fairly low, although anoscopy may identify macroscopic areas of AIN, which often appear to be benign condylomata but may

Fig. 19.4 AIN 3. (Courtesy of Richard Billingham, MD)

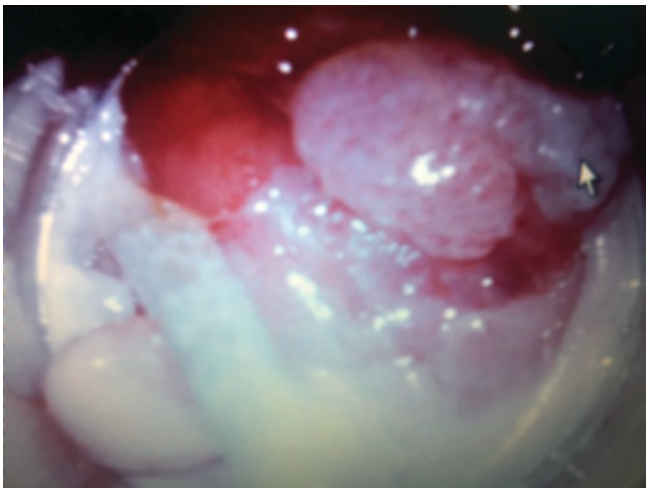

Fig. 19.5 AIN on high-resolution anoscopy. The arrow indicates an area of high-grade dysplasia. (Courtesy of Rocco Ricciardi, MD)

return with AIN on biopsy (Fig. 19.4). If screening is positive for HSIL or LSIL, then patients should be referred to a surgeon who has experience with these lesions, for a formal biopsy. The sensitivity and specificity of anal cytology for the detection of any-grade AIN vary significantly and have been reported to range from 47 to 90% [35, 40] and 32 to 60% [36, 37], respectively. Formal biopsy can be performed via conventional anoscopy or HRA and will typically provide sufficient tissue for microscopic evaluation to determine the presence of LSIL or HSIL. Tissue biopsy allows for a more definitive diagnosis compared to cytology alone.

HRA is an office-based tool, similar to colposcopy of gynecologic neoplasia, which can be utilized to diagnose and treat AIN [51]. HRA is typically performed in the left or right lateral positions, no bowel preparation is necessary, and is most commonly performed without analgesia. After the application of 3–5% acetic acid for 2–5 minutes, a magnifying anoscope is used to examine the anus and lower rectum. Acetic acid causes dysplastic cells to be more visible compared with surrounding tissue. Iodine-based Lugol's solution may also be added to further detect dysplastic tissue. The mechanism for Lugol's utility is that only healthy epithelium absorbs this compound which causes normal tissue to appear wood-like, and dysplastic tissue does not absorb the solution giving these tissues a yellowish hue. Our protocol is to avoid Lugol's solution as it interferes with proper dysplasia differentiation (i.e., AIN I versus AIN II or III), and we believe that acetowhitening from acetic acid is sufficient to identify dysplastic tissues. The entire anal canal and anal verge should be examined, emphasizing detailed visualization of the transition zone. Dysplastic epithelium will absorb acetic acid and appear as scaly white with greater disarray of vascular patterns and tissue friability as the grade of dysplasia increases (Fig. 19.5). The microscopic appearance of variable grades of anal squamous intraepithelial lesions has also been described as similar to those described for the cervix [52].

The impact of HRA was recently evaluated in a cohort of 727 MSM who underwent ablation of all HRA-identified lesions and followed for a median of 2.2 years. With regular follow-up, the rate of recurrence at 1 year was 53% in HIV+ patients and 49% in HIV– patients. Over the follow-up period, five patients developed cancer, with the probability of cancer 1.9% at 3 years [53]. There are few comparisons of HRA with other treatment strategies. A retrospective review of 424 patients compared HRA with expectant management in 2 cohorts, 1 treated by 3 clinicians who followed patients with expectant management and the other treated by 2 clinicians who followed patients with HRA [54]. Anal cancer occurred in one of the HRA patients and two of the expectant management patients. The 5-year progression rate was similar in the two cohorts.

Treatment

Progression of AIN to squamous cell cancer is relatively rare; however, diagnosis and differentiation of AIN and determination of which patients benefit from treatment and with what modality require expertise. It is therefore recommended that patients found to have positive anal cytology or biopsy-proven AIN should be referred to expert centers. Even among those specializing in the identification and treatment of AIN, there is a significant variability in guidelines for management and surveillance paradigms which can lead to confusion and controversy. Currently, the spectrum of management includes observation, topical therapies, local ablations, and surgical excision (Table 19.1). However, recommendations are mostly based on literature from single institution case controls series rather than large randomized trials. The goal of treating dysplastic lesions is to reduce the rate of progression to anal cancer while decreasing morbidity and preserving function.

Table 19.1 Common treatment options for AIN

Treatment	Advantages	Disadvantages	Cure	Recurrence
Observation	Low cost No side effects	Low cure rate Time-consuming	Poor	High
Imiquimod	Minimal pain Easy to use	Burning Moderate cost	Poor	High after stopping
5-FU	Easy to use	Burning Moderate cost	Poor	High after stopping
Infrared coagulation	Clinic-based	Special equipment	Good	Moderate in immunosuppressed
Ablation	Single use	Painful Costly	Good	Moderate in immunosuppressed
Wide local excision	Removes all tissue	Painful Operating room Cosmetic and functional issues	Good	Low

Expectant Management

Observation or an expectant management approach is a conservative strategy that is advocated by some for select patients with AIN [55]. In general, patients with low-grade dysplasia undergo observation alone with close clinical follow-up every 4–6 months. A more intense program including cytology, HRA, and targeted biopsies has demonstrated a clearance rate of 78% with a 1.2% rate of progression to invasive squamous cell cancer over a 10-year period [40]. A recent large retrospective review comparing HRA versus expectant management for AIN demonstrated no difference in progression to squamous cell cancer as long as patients were compliant with frequent follow-up [54]. The expectant management strategy is based on the relatively low rate of disease progression and malignant potential of AIN and the increased rates of adverse effects and morbidity of topical and ablative or surgical treatments [56].

Topical Therapies

Trichloroacetic Acid (TCA)

TCA is generally well tolerated by patients with no reported systemic side effects and can be efficacious after only a few applications with further treatment possible if necessary. It is typically applied by a provider and thus has the advantage over other topical agents of not requiring patient adherence. Two small retrospective studies with biopsy-confirmed AIN have examined the use of TCA. Cranston et al. [57] reviewed the course of 72 patients with HSIL 3–6 months after TCA treatment and noted resolution or downgrading to LSIL in 79% of lesions. Single TCA treatment improved or resolved 49% of lesions with 28% requiring two treatments. However, the recurrence rate was 21%. Singh and colleagues reported that 72% of lesions were either resolved or downgraded to LSIL in 54 men with HSIL [58]. Men who had fewer than three lesions had greater clearance. TCA offers a clinic-based treatment for HSIL with relatively few side effects but may not be appropriate for bulky or more extensive disease.

5-Flurorouracil (5FU)

Two retrospective studies evaluating the use of topical fluorouracil reported response rates of 55–57% [59, 60]. One study of 46 HIV-positive patients with LSIL or HSIL reported a complete response in 12 of the 34 (39%). However, recurrence rates of 50% were observed in the complete responders at 6 months [59]. Seventy-three to 85% of patients report experiencing adverse effects including anal pain, irritation, and hypopigmentation, but only one to two patients in each study discontinued treatment [59, 60].

Cidofovir

One prospective pilot study and one retrospective cohort study have assessed the effectiveness of 1% cidofovir applied three times per week for 4 weeks [61]. Sixteen HIV-positive patients with HSIL were included in the pilot study which demonstrated a complete response rate in 63% at 12 weeks. However, at 24 weeks, 20% of these patients had recurred. A single-arm clinical trial enrolled 33 HIV-positive patients with perianal HSIL to self-apply 1% cidofovir gel to lesions daily for a 2-week cycle consisting of 5 consecutive days on and 9 days without treatment [62]. This was repeated for six cycles with a 79% completion rate. Of the 24 patients that completed treatment, 51% had a response (15% complete and 36% partial). Two patients had progression of their disease over the course of the study. Cidofovir can only be prepared by compounding pharmacies and may not be covered by standard insurance limiting its potential use.

Imiquimod

Imiquimod is the most tested topical agent used in treating SIL and has been examined in two randomized trials and one prospective cohort study. A double-blinded randomized placebo-controlled trial of 64 HIV-positive MSM compared self-application of 5% imiquimod cream versus placebo in the anal canal three times per week for 4 months. Response

rates assessed by cytology, HRA, and biopsy in the 53 patients that completed the study demonstrated superior response with imiquimod (43% vs. 4%), and 61% of imiquimod responders exhibited sustained response at 36 months [63]. A prospective study by van der Snoek et al. [64] aimed to establish the effectiveness of imiquimod found that of 44 patients with histologically proven perianal or intra-anal HSIL treated with 5 consecutive days per week of self-administered 5% imiquimod, complete or partial response was noted in 45% of patients after 16 weeks of treatment. Patients who did not demonstrate a response underwent an additional 16 weeks of treatment resulting in a total response rate of 66%.

Topical therapies are relatively efficacious for patients with LSIL and HSIL and have few severe side effects. The most common is a localized skin reaction at the application site, with erythema, itching, and burning being reported most often. Generally, imiquimod is well accepted, with few patients choosing to discontinue therapy or withdrawal from clinical trials due to intolerable side effects. Patients who find the side effects bothersome typically respond well to topical analgesics, warm baths, and/or dose modification. A substantial number of patients who respond have recurrence once treatment is discontinued, and consideration should be given to using them in patients that cannot undergo ablative therapy or in conjunction with ablative therapy.

Local Ablative Therapies

Local ablative therapy consists of targeted destruction of dysplastic lesions using fulguration with electrocautery, excision, or infrared coagulation (IRC) in conjunction with HRA or anoscopy and is effective in achieving high rates of complete response particularly in immunocompetent patients. Procedures are often performed in the operating room but are increasingly becoming clinic-based using local anesthesia. Ablation is typically targeted to areas with evidence of dysplasia with no need for margins, and as the disease is limited to the epidermis, destruction of deeper dermal tissues is unnecessary.

Rates of response with electrocautery may initially be as high as 75–80%, but recurrence is common. An observational study by Burgos and colleagues of 83 HIV-positive MSM with HSIL demonstrated a 33% complete response and 34% partial response after treatment with electrocautery with increased success seen in patients who underwent multiple sessions. However, consistent with other studies, recurrence was observed in 25% of patients after a median follow-up of 30 months [65].

Short-term efficacy of infrared coagulation was demonstrated in a retrospective clinical study of 74 HIV-positive MSM with HSIL in which 64% of patients were found to have a complete or partial response. Long-term results were assessed in a recent retrospective analysis of 96 MSM with HSIL treated with IRC which demonstrated resolution in 82% of HIV-positive and 90% of HIV-negative [66]. However, after 1 year from first treatment, recurrence (mainly metachronous) was observed in 38% and 61% of HIV-negative and HIV-positive MSM, respectively. An advantage of IRC is that is it associated with less pain and can often be performed in a clinic setting.

In general, local ablative therapies are associated with minimal morbidity and are reasonably well tolerated. Often, multiple sessions are required and recurrence remains common. Care should be taken to avoid large field defects, scarring, or stricture formation, with the goal of preserving healthy tissues as patients will often need further surveillance and intervention.

Wide Local Excision

Historically, mapping biopsies with wide local excision was the mainstay of treatment for AIN. This often resulted in the removal of large amounts of healthy and uninvolved tissue along with the dysplastic lesions. In addition, 9–63% of patients would develop recurrences, with repeated procedures resulting in long-term complications including anal stenosis and fecal incontinence particularly in patient with circumferential lesions or those with significant disease burden [67, 68]. With alternative techniques now available, mapping with wide local excision is not recommended even for cases of diffuse disease.

Treatment Summary

Few studies have compared different treatment modalities. In one study, 148 HIV-positive MSM with SIL (57% with HSIL) were randomized to 4 months of treatment with 2% 5FU, 5% imiquimod, or monthly electrocautery [69]. Complete response as assessed by post-treatment biopsies was 17%, 24%, and 39%, and partial/complete response in the HSIL group was 43%, 46%, and 68%, respectively. Side effects were reported in 27%, 43%, and 18%, and at 72 weeks post-treatment, recurrence rates were 58%, 71%, and 68%, respectively.

Due to the lack of high-quality randomized control trials comparing various treatment strategies, it is difficult to develop guidelines for the care of AIN. We recommend basing treatment decisions on patient goals, history of immunosuppression and dysplasia, comorbidities, and underlying bowel function (Fig. 19.6). For patients with LSIL who will be compliant with surveillance, expectant management with or without the addition of HRA may be the best management

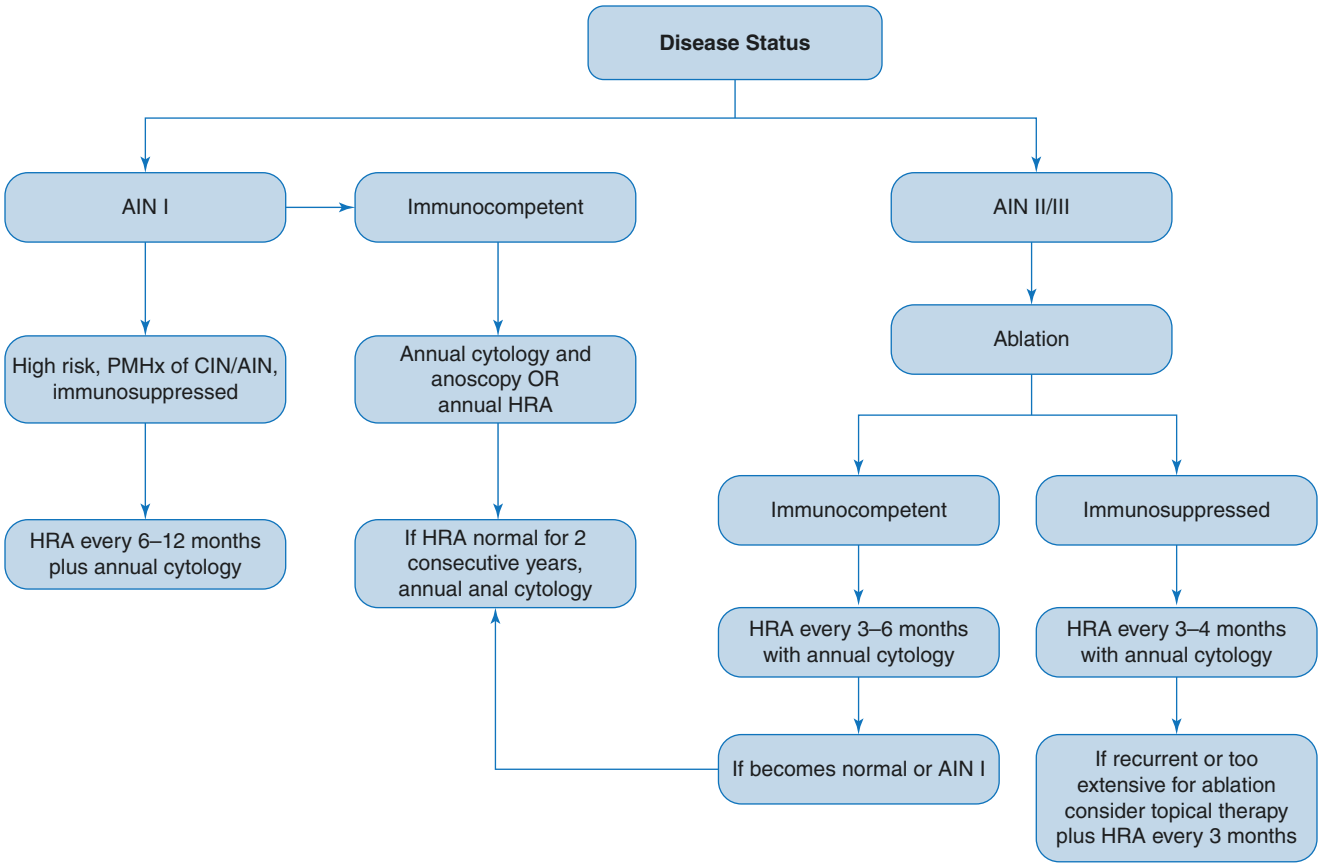

Fig. 19.6 Algorithm for the treatment of AIN based on immune status and biopsy results

strategy. For immunocompetent patients with HSIL, targeted surgical ablation guided by HRA is the most effective at eradicating dysplasia and generally well tolerated. Defining which treatment modality to employ in immunocompromised patients with SIL is more difficult. This population presumably has a higher likelihood of progressing from LSIL to HSIL and squamous cell cancer which would favor more aggressive interventions. However, they also have increased rates of recurrence which would necessitate repeated treatments, potentially resulting in increased scarring and stenosis. In this patient population, the best approach is likely a combination of close observation and topical therapy versus ablative treatments depending on the extent and severity of disease.

Surveillance/Prevention

The recurrence rate of AIN is high after all treatment modalities, and thus surveillance is necessary. However, there are no definitive data or guidelines on what is the appropriate surveillance strategy. In a large retrospective review, patients with biopsy-proven AIN were enrolled in a surveillance program after ablative or topical therapy. All patients were followed with annual digital rectal exams and anal cytology. Of the 424 enrolled patients, 220 underwent regular HRA examinations, while the remaining 204 underwent HRA if DRE or cytology was positive. No significant differences were seen between the groups in the 5-year anal cancer rate. In both groups, those that progressed to squamous cell anal cancer were less compliant with surveillance. Therefore, the authors concluded that the key to reducing progression and recurrence of disease was patient compliance rather than a particular surveillance program [54]. Further studies need to be conducted to help determine best practices for the treatment and follow-up of patients with AIN.

In recent years, there has been increased data suggesting that HPV vaccines may be associated with a decrease in the incidence of AIN. In a large randomized, placebo-controlled, double-blinded clinical trial of over 4000 boys and men, Giuliano et al. demonstrated the efficacy of the HPV quadrivalent vaccine in preventing external genital lesions in patients who had no prior evidence of HPV infection [70]. In a subset analysis of 602 MSM, the efficacy of preventing AIN, including grades 2 and 3, associated with HPV 6, 11, 16, or 18 was 50.3% in the intention-to-treat population and 77.5% in the per-protocol efficacy population [71]. The efficacy in preventing AIN associated with HPV of any type was

25.7% and 54.9% in the intention-to-treat and per-protocol efficacy populations, respectively. A trial aimed at determining the efficacy of the quadrivalent HPV vaccine in prevention of AIN in HIV+ MSM, Vaccine Therapy in Preventing Human Papillomavirus Infection in Young HIV-Positive Male Patients Who Have Sex with Males, is completed, but the results are pending [72]. It is postulated that administration of the HPV vaccine to girls and boys prior to the onset of sexual activity may reduce the incidence of AIN, prevent the recurrence of AIN 2 and 3, and halt progression to squamous cell carcinoma of the anus, but more robust data is needed.

Conclusion

Anal intraepithelial neoplasia is a precursor to squamous cell cancer of the anus. The actual rate of progression from AIN to SCC of the anus is unknown, but detection and treatment of dysplastic lesions likely decrease the risk of progression. Risk factors in the development and progression of AIN include infection with HPV (particularly high-risk strains), HIV positivity, men who have sex with men, and transplant patients. Treatment modalities include expectant management, application of topical agents, local ablation, and surgical excision and need to be individualized based on a number of patient and disease factors. Regardless of treatment approach, recurrence is common, and therefore ongoing surveillance is recommended for all patients with a history of AIN, and patient compliance is critical. In the future we hope to improve prevention and detection of early lesions and develop consensus guidelines regarding nomenclature, treatment, and surveillance.

Part III

Malignant Disease

Anal Cancer

20

Dana R. Sands and Najjia N. Mahmoud

Key Concepts

- Tumors of the anal region are divided into anal and perianal cancers with different paths of lymphatic drainage.
- Squamous cell carcinoma (SCC) is the most common type of anal cancer.
- Chemoradiotherapy is the mainstay for anal (SCCa). The standard chemotherapy consists of 5-FU and mitomycin. The minimum dose of radiation is 45 Gy to the primary tumor.
- Inguinal node metastasis can be diagnosed with PET-CT and managed with radiation.
- Surgery for anal canal cancer is limited to very small lesions and salvage situations following failed chemoradiotherapy.
- Anal adenocarcinoma can arise from an anal gland or chronic fistula tract. They can be difficult to distinguish from distal rectal cancers. These tumors are staged and treated similar to rectal cancers with a lower overall survival.
- Verrucous carcinomas are characterized by large size and lack of invasion. Treatment is mainly wide surgical excision.
- Anal melanoma is a rare and aggressive tumor. Survival is very poor. Abdominoperineal resection may help to control local disease but does not prolong life expectancy; therefore, local excision is often a first choice when possible.
- Perianal Paget's disease – or intraepithelial adenocarcinoma – is frequently associated with other malignancies. Treatment is focused on surgical excision and may require mapping biopsies to plan resection.
- Basal cell carcinoma of the perianal region is treated with wide local excision.
- Gastrointestinal stromal tumors can be managed with wide local excision or radical excision depending on margin status. Preoperative treatment with tyrosine kinase inhibitors may enhance resectability.

Introduction and Epidemiology

Although anal cancers encompass a variety of histologic types, the overwhelming majority of these tumors are of squamous cell origin. Adenocarcinoma, gastrointestinal stromal tumors (GISTs), melanomas, and neuroendocrine tumors can be found in the anal canal as well, and this chapter will touch on those rare tumors, but emphasis will be on the diagnosis, staging, and treatment of anal canal and perianal squamous cell carcinoma.

In contrast to many cancers that have seen a decrease in incidence related to better detection, treatment, and in some cases prevention, the incidence of SCCa continues to rise worldwide [1]. The increased prevalence of human papillomavirus (HPV) infection is thought to be the major driver of this trend. From 2001 to 2015, the incidence of SCCa rose 2.7% per year [2]. The number of those found to have distant disease at the time of diagnosis has tripled in this time period [2]. The rise has not affected all races equally – the rate in young black men has risen fivefold while doubling in whites of both genders [2]. Overall, anal cancer mortality rates have increased 3.1% per year particularly in those greater than 50 years of age [2]. It is estimated that there will be 8590 new cases of anal cancer in 2020 in the United States with a preponderance of women diagnosed (5900 female/2690 male). Deaths from anal cancer will total 1350 (810 female) [3].

Effective treatment of cancer of the anus requires a thorough understanding of the anatomy of the anus and anal canal and of the various histologic types of tumors that can

afflict this area. The most common type of cancer arising from the anus is squamous cell carcinoma, accounting for approximately 85% of cases [4, 5]. Evolution of the treatment of squamous cancer of the anal canal has shifted away from radical surgery toward a nonsurgical multidisciplinary team approach. The cooperation of the members of the team – surgeon, radiologist, medical oncologist, radiation oncologist, and pathologist – has resulted in improved quality of life and survival for patients with squamous cell carcinoma.

While squamous cell cancer is certainly the most common, there are a number of less common tumors that are often associated with abysmal survival rates, as mentioned previously. Table 20.1 summarizes the current World Health Organization histologic classification for tumors of the anus [6]. The widely recognized risk factors for anal carcinoma are summarized in Table 20.2.

Evaluation and Staging

The initial evaluation and staging of patients with anal cancer begins with a history and physical examination. Patients with anal cancer are often diagnosed at an advanced stage because of confusion of symptoms with those of common benign conditions. Pain, bleeding, small masses, and irritation are often misattributed by both patients and physicians alike to hemorrhoids or fissures. Duration of symptoms may be different from benign disease, with those suffering from neoplasia noting a relatively recent onset in pain and bleeding that worsens with time, often with an associated palpable mass and duration of symptom onset of months rather than years.

Duration of symptoms
History of STD/HPV
Anoreceptive intercourse
History of dermatologic conditions
History of other malignancies
Prior colonoscopy

STD sexually transmitted disease, *HPV* human papillomavirus

Social history, including sexual practices and HIV status, is relevant for patients with suspected squamous cell carcinoma. Of particular importance is a history of gynecologic malignancies, abnormal pap smears, or head and neck squamous cell carcinoma, given the common etiology (HPV). Diagnosis of anal dysplasia, the precursor lesion to anal squamous cell carcinoma, or anal squamous cell carcinoma should prompt evaluation for cervical dysplasia in women who lack current testing (within 1 year). Please see Table 20.3 for a list of pertinent historical information [7]. There is no association between squamous cell cancer of the anus and colonic malignancies; thus colonoscopy is not indicated, unless otherwise warranted for colorectal cancer/polyp screening or investigation of other symptoms. However, patients with Paget's disease of the anus should undergo colonoscopy to rule out associated adenocarcinoma.

Physical Examination

A complete physical examination is mandatory, with attention paid to the inguinal region as well as the anus and perineum. The anal examination should carefully characterize the mass. The size and location in the anal canal or perineum, with attention to both laterality and distance from the anal verge, sphincter muscles, and adjacent structures (vagina, prostate), are critical. The mobility of the mass and presence of ulceration should be noted. Abdominal palpation and the assessment for inguinal adenopathy are important. Evaluation of the rest of the anogenital region for any synchronous HPV-related lesions completes the physical

evaluation. HIV testing for newly diagnosed SCCa may help with management of the chemotherapy or radiation regimens and helps evaluate for other health-related issues that may be present. Histologic confirmation of the diagnosis is necessary prior to initiation of treatment, but large excisional biopsies should usually be avoided so as not to delay treatment due to the resultant large wounds. Tissue sampling in the office or operating room should suffice in most cases.

Radiologic Evaluation

Systemic staging is completed with computed tomography (CT) scan of the chest, abdomen, and pelvis. Positron emission tomography (PET) scan can be an important component of the staging and management of patients with anal cancer and should be utilized for evaluation of any suspicious lesions on conventional CT scans. Initial staging PET scan has been shown to alter the field of radiation when compared to standard CT scan [8]. Although it is not recommended routinely, it can result in both up- and downstaging in a small percentage of patients (between 5% and 38%) [9, 10]. Some studies suggest that although it can change locoregional nodal staging in up to 40% of patients, it does not typically change treatment planning and it does not replace the need for a contrast-enhanced CT of the chest, abdomen, and pelvis. Negative post-treatment PET/CT is associated with a very good 2-year disease-free survival (DFS) [11]. Pelvic magnetic resonance imaging (MRI) may be helpful for staging and treatment planning of locally advanced disease.

Table 20.4 Anal cancer TNM staging (AJCC manual 8th edition)

Primary tumor (*T*)			
T category	*T criteria*		
TX	Primary tumor not assessed		
T0	No evidence of primary tumor		
Tis	High-grade squamous intraepithelial lesion (previously deemed carcinoma in situ, Bowen disease, and intraepithelial neoplasia II–III, high-grade anal intraepithelial neoplasia)		
T1	Tumor ≤2 cm		
T2	Tumor >2 cm but ≤5 cm		
T3	Tumor >5 cm		
T4	Tumor of any size invading adjacent organ(s), such as the vagina, urethra, or bladder		
Regional lymph nodes (*N*)			
N category	*N criteria*		
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Metastasis in inguinal, mesorectal, internal iliac, or external iliac nodes		
N1a	Metastasis in inguinal, mesorectal, or internal iliac lymph nodes		
N1b	Metastasis in external iliac lymph nodes		
N1c	Metastasis in external iliac with any N1a nodes		
Distant metastasis (M)			
M category	*M criteria*

Unlike colorectal or anal adenocarcinoma, for which staging is staged based on the depth of invasion, SCCa is staged based on the size of the primary lesion and locoregional lymphadenopathy. The staging of anal squamous and adenocarcinoma is summarized in Table 20.4 according to the eighth edition *AJCC Cancer Staging Manual* [12].

Anal Anatomy

A thorough understanding of the anatomy of the anal canal is necessary to properly categorize anal cancers (Fig. 20.1a, b). The length of the anal canal is somewhat variable but in many adults is between 3 and 4 cm in length. Clinically, the proximal extent of the anal canal is at the apex of the puborectalis sling, which is palpable as the anorectal ring. The distal extent is the mucocutaneous junction with the perianal skin. This includes 1–2 cm of glandular mucosa and the transitional mucosa near the dentate line. The dentate line appears as mucosal undulations formed by the anal glands and the vertical columns of Morgagni. The transition to non-keratinized squamous mucosa occurs at this level. The varied cellularity of this region, also called the "anal transition zone," accounts for the histologically diverse nature of anal cancers. The pathology of anal cancer is of squamous cell origin and has been called "basaloid" in the past to describe the microscopic appearance of the cells. Transformed, carcinogenic squamous cells are thought to originate in the anal transition zone (ATZ) in the anal canal. The more distal the anal canal tumor is, the more likely it is to lack glandular elements and have keratinizing features and appear more like perianal tumors [13].

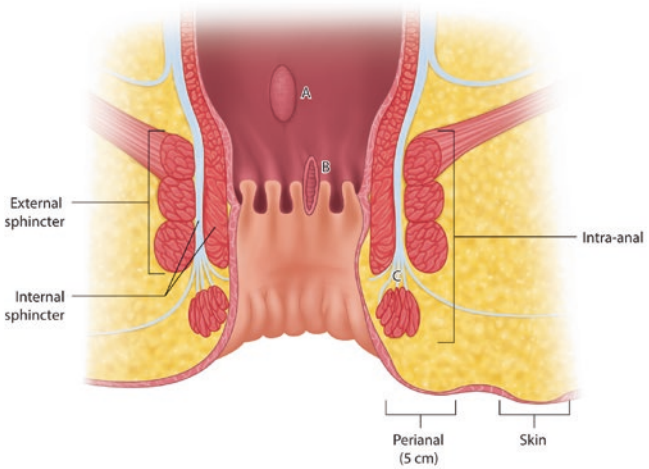

Fig. 20.1 Anatomy of the anal canal with possible locations of anal squamous cell cancers

The dentate line provides a reference point to predict lymphatic drainage. Tumors situated proximal to the dentate line typically drain via the superior rectal channels to the inferior mesenteric nodes and laterally along the middle and inferior rectal vessels to the internal iliac nodes. Lesions distal to the dentate line will have a drainage pattern via the inguinal and femoral lymphatics. Tumors situated at the dentate line can follow any or both of the above patterns. The perianal skin, previously referred to as the anal margin, is characterized by the keratinized stratified squamous epithelium-lined hair-bearing skin beginning at the anal verge and extending 5 cm radially outward. Anal tumors can therefore be categorized as either anal canal or perianal in origin.

Anal canal cancers are tumors that develop from mucosa (either keratinized or non-keratinized) that cannot be visualized entirely while gentle traction is placed on the buttocks. Perianal cancers are tumors that arise within the skin at or distal to the squamous mucocutaneous junction and can typically be seen entirely with gentle traction on the buttocks and are within 5 cm of the anus.

Perianal Squamous Cell Carcinoma

The perianal region is defined as the keratinized squamous epithelium extending from the anal verge radially for a distance of 5 cm. This area was formerly classified as the anal margin. Tumors of the perianal region are five times less common than anal canal tumors and occur with a frequency of 1–1.5 per 100,000 persons [14]. They represent 15% of all tumors of the anal region [15]. It has been suggested that perianal tumors have a different histogenetic origin than their counterparts in the anal canal. As opposed to anal canal carcinomas, perianal carcinomas show expression of CK 5/6 and CK 13, whereas CK7, CK18, and CK19 were rarely expressed [16]. This may account for the different biologic behavior of the two lesions. Few series look exclusively at perianal tumors; thus, characterizing behavior is somewhat challenging. Overall, the prognosis of perianal SCCa is considered better than SCCa of the anal canal [17]. Tumors are typically slow growing and well differentiated, with a female predominance and a peak incidence in the seventh and eighth decade [18]. Metastasis is uncommon. Recurrences are typically locoregional. Small lesions, less than 2 cm, rarely have lymph node metastasis. Nearly one quarter of lesions 2–5 cm in size will have lymph node metastasis, and large tumors have been shown to have nodal spread in 67% of cases [19]. Symptoms of perianal tumors are often attributed to hemorrhoids, often leading to a delay in diagnosis. Jensen et al. noted that SCCa of the perianal

skin is misdiagnosed in nearly 1/3 of cases resulting in a delay in diagnosis of a median of 6 months [20]. Perianal SCCa resembles SCCa of the skin in other areas of the body with a distinct border, raised edge, and central ulceration (Fig. 20.2).

Primary treatment of stage I perianal squamous cell cancer consists of wide local excision with a 1 cm margin when technically feasible. Re-excision is recommended for margin positivity [21]. More advanced lesions are often not amenable to local excision without harm to the anal sphincter and require radiation- and/or chemotherapy-based treatment regimens. Radiotherapy or chemoradiotherapy can be considered as a primary treatment when a perianal tumor is large and/or threatens the anal sphincter muscle or as an adjunct to surgical treatment when there is a close or positive margin and re-excision would require partial anal sphincter resection [22]. Newlin et al. reported use of radiation with or without chemotherapy for a cohort of 19 patients with perianal carcinoma [23]. Local control was achieved in all patients. One patient developed distant disease. No patient required a colostomy. The authors recommended that patients with well or moderately well-differentiated small tumors undergo excision with clear margins and those with poorly differentiated lesions or larger tumors undergo radiotherapy with inguinal node treatment. Chemotherapy was added for T3 and T4 tumors or those patients with involved inguinal nodes. Treatment regimens for both radiotherapy and chemoradiotherapy for perianal tumors, when utilized, are similar to that given for anal canal SCCa.

Anal Canal Squamous Cell Carcinoma

While perianal tumors are typically treated like skin cancer and locally excised as described above, the treatment of anal canal SCCa is fundamentally different. These tumors are not completely visualized with traction of the buttocks and extend into the anal canal. Figure 20.3a, b illustrates the gross and histopathologic appearance of SCCa. Historically treated with wide local excision or abdominoperineal resection (APR), current treatment of SCCa takes advantage of the exquisite sensitivity of anal canal SCCa to the combination of radiation and chemotherapy. Local excision or radical resection of anal canal cancers is reserved for special circumstances, with chemoradiotherapy as the initial treatment in nearly all cases.

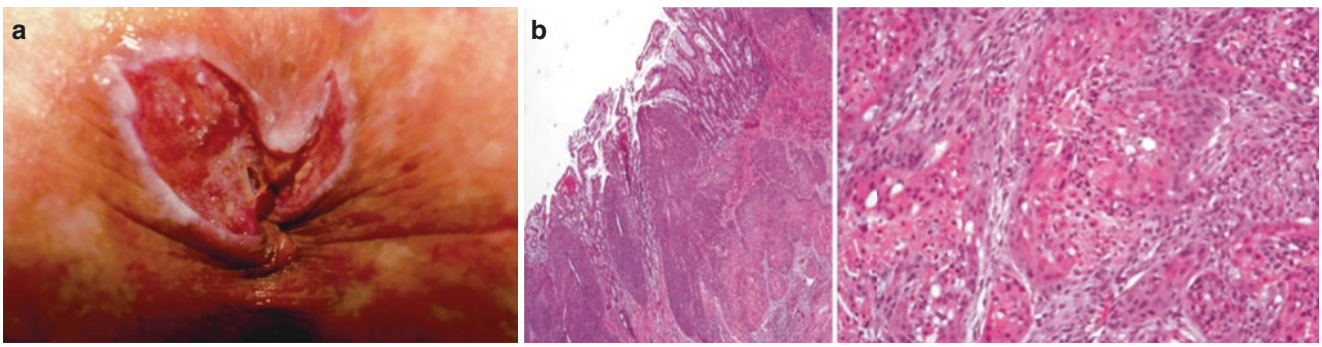

Fig. 20.3 (**a**) Anal canal squamous cell carcinoma. (**b**) Histology of anal squamous cell carcinoma 10× and 40×

Prior to 1974, most anal canal cancers were treated with either wide local excision or APR. Overall survival rates were poor, even after radical resection, ranging from 30% to 70% in most small series with local recurrence rates of 25–70% depending upon stage [24]. In the early 1970s, Norman Nigro, a colorectal surgeon at Wayne State University in Detroit and president of the American Board of Colon and Rectal Surgery, began using neoadjuvant chemoradiotherapy prior to APR and observed a complete histologic response (pCR) in a sizeable fraction of patients after neoadjuvant treatment with a modest dose (3000 Gy) of radiation and 5-fluorouracil (5-FU) and mitomycin C [25]. Based on these encouraging results, Nigro and colleagues then suggested that chemoradiotherapy may be considered as definitive treatment for SCCa. This observation was transformative and provided the foundation for the direction of treatment of SCCa for the next 35 years [26].

Chemotherapy

It has become clear that the addition of chemotherapy to radiotherapy treatment is necessary to maximize clinical and pathologic response. Studies from Europe (EORTC Phase III and the UKCCCR ACT I) comparing the use of 5-FU and mitomycin with radiation alone definitively showed that both locoregional control and overall survival were positively affected by the addition of a chemosensitizing regimen to the use of radiation [27, 28]. An 18% higher rate of local control at 5 years coupled with data showing an increase in median survival from 5.4 in the radiation alone to 7.6 years in those treated with chemoradiation is convincing [27, 28].

Studies aimed at refining the exact chemotherapeutic regimen that is most effective support the use of 5-FU or capecitabine combined with mitomycin C. Efforts to omit mitomycin resulted in a lower 4-year disease-free survival rate of 51% vs 73% for those with combination therapy [29]. Also, the need for salvage surgery increased from 9% to 22% [29]. Capecitabine has been used effectively in rectal adenocarcinoma treatment as an alternative to infusional 5-FU, and retrospective studies evaluating it as a substitute for infusional 5-FU in SCCa treatment support its use in combination with mitomycin C [30]. In multiple small retrospective reviews, efficacy is identical, and in one study, high-grade toxicity was significantly reduced [31–33]. Overall survival, colostomy-free survival, locoregional recurrence rates, and clinical complete response rates are the same, with 6-month locoregional control for stage I–IIII cancers at 86% [34]. In sum, capecitabine is an acceptable alternative to infusional 5-FU in treatment algorithms for stage I–III SCCa.

The role of cisplatin in the treatment of SCCa has been the subject of numerous investigations in an effort to refine and identify the most effective and least toxic regimen. The Phase III ACT I UK trial directly compared the use of cisplatin with mitomycin C [35]. Both trial arms used infusional 5-FU, and both used 50.4 Gy radiation. Additionally, this trial tested the hypothesis that giving more chemotherapy after chemoradiotherapy (5-FU with cisplatin for two cycles) would be beneficial. The trial concluded that there was no difference in any of the primary or secondary trial endpoints (disease-free survival, overall survival, locoregional recurrence, or colostomy-free survival) between the two groups. Furthermore, the addition of more chemotherapy as an adjunct treatment failed to improve long-term disease-specific metrics [35]. Similarly, the RTOG 98-11 trial compared mitomycin with cisplatin but added the two cycles of 5-FU and cisplatin prior to chemoradiation. In contrast to the ACT I study, the RTOG 98-11 trial found that the mitomycin arm had a superior 5-year DFS and OS with a 5-year colostomy-free survival that trended toward an advantage [36].

Retrospective studies and a recent meta-analysis have examined the use of chemotherapy without radiation in the neoadjuvant setting in the treatment of anal cancer, and there seems to be no clear advantage [37, 38]. However, patients with T4 lesions, in special circumstances, may benefit from induction chemotherapy [37]. Patients who have been treated with prior pelvic radiation and those who are minimally symptomatic or have widespread systemic disease may be candidates for this approach.

Other approaches to chemotherapy for SCCa have included the use of concurrent cisplatin and mitomycin as well as a regimen that includes the use of the epidermal growth factor receptor (EGFR) inhibitor cetuximab. Both strategies resulted in unacceptable toxicity that abbreviated the clinical trials that featured them [39–42].

Radiation Therapy

The most efficacious dose of radiation associated with least toxicity is desired when treating anal cancer. In general, increasing dosages of radiation correlate with increased local control and disease-free survival; however, increased dosage can be accompanied by symptoms that necessitate treatment breaks such as local tissue destruction, fatigue, nausea, and pain [43, 44]. Treatment breaks during radiation are associated with reduced locoregional control, so striking a balance between dosage, symptoms, and efficacy is of paramount importance [45]. The RTOG 98-11 trial set forth protocols that are considered optimal for both tumor control and symptom mitigation, and recommendations regarding doses follow the multifield technique used in this trial. All patients should receive a minimum radiation dose of 45 Gy to the primary tumor. The recommended initial dose is 30.6 Gy to the pelvis, anus, perineum, and inguinal nodes with patients

clinically staged as node-positive or T2–T4 receiving an additional boost of 9–14 Gy. Carefully planned intensity-modulated radiation therapy (IMRT) is preferred over 3D conformal radiation therapy in the treatment of anal carcinoma as outlined by NCCN guidelines [46].

Complications of radiation therapy are particularly difficult in those with anal canal cancer. The radiation fields affect the perineum, sphincter complex, and pelvic bones. Both acute and chronic problems may result from radiation and can be dose related. Acute radiation injury to the perineal skin, vagina, and urinary bladder can produce pain, bleeding, and urinary frequency. Chronic injury can result in vaginal stenosis, fecal incontinence, impotence, and pelvic or hip fractures. It is important to counsel patients in advance that these symptoms may develop. Efforts to mitigate damage in the acute and chronic phase include barrier ointments, creams, and mechanical aids such as vaginal dilators to alleviate stenosis. Patients who experience acute effects of radiation can be expected to improve gradually over time; however, the interval it takes to see improvement may take months, and some symptoms, like fecal incontinence and impotence, may improve but never fully resolve.

Inguinal Lymph Node Metastases

Recent data suggests that inguinal lymph node metastases detected via palpation or through imaging are present in about 13% of patients who have SCCa [47]. Evidence from case series indicates that the presence of inguinal lymph node metastases increases with tumor size or stage and with age. Older patients with larger tumors harbor these metastases in 20–25% of cases [47]. These data support administration of routine inguinal radiation as part of initial therapy. As expected, inguinal node tumor recurrence is stage dependent – for patients with N0 or N1 disease at presentation, the rate of development of post-radiation malignant inguinal adenopathy is less than 2%. For those who present with N3 or N4 disease, that rate increases to 11–15% [48]. Radiation is effective at treating both occult, latent inguinal disease and more obvious cases detected at initial diagnosis by physical exam or imaging.

Some advocate fine needle aspiration (FNA) of palpable inguinal enlarged lymph nodes prior to treatment of SCCa. If positive for tumor, FNA establishes a baseline should the groin basin be resistant to treatment or develop a recurrence post-therapy. It can also help establish accurate staging in cases where the primary is inaccessible (completely excised for example), an additional or different malignancy is suspected, or if concomitant infection clouds the diagnostic picture. FNA is not helpful in routine cases given the possibility of sampling error, the relative accuracy of CT-PET, and the fact that treatment rarely changes based on the results of FNA. It is not necessary to surgically excise suspicious LNs or do a superficial inguinal groin dissection pre-chemoradiation – the morbidity and high rate of wound complications for this operation could compromise timely administration of therapy that is very effective for treatment of both the primary and the inguinal nodal metastasis. Those with inguinal nodal metastases that are not palpable, but are suspicious on CT scan, do not require FNA. NCCN guidelines suggest that radiation planning or simulation be accomplished via PET-CT; therefore, a metabolic signal would be seen prior to treatment if it were indeed neoplastic, as anal squamous tumors are typically FDG avid and signal strongly with PET imaging. Comparison of pre- and post-PET images can, in most of these cases, establish the diagnosis and be used for surveillance [49].

Surgery

Local excision is utilized rarely in the treatment of anal canal SCCa, although it is the predominant therapy used for perianal squamous tumors. However, there are several situations where local excision followed by close local surveillance may be appropriate. APR for anal cancer is typically reserved as a salvage therapy in those patients with a persistent primary tumor despite chemoradiotherapy, although there are rare situations where surgery as a primary approach may be indicated.

Superficially invasive anal cancer, defined as anal cancer that is excised with negative margins, with less than 3 mm basement membrane invasion and a maximal spread of less than 7 mm (T1NX) may be treated with excision alone [50]. These lesions are seen with growing frequency because anal cancer screening in high-risk populations has become more common. Small cancers are often completely excised at the time of biopsy, and local surgical resection with negative margins may be adequate treatment. Studies done in patients with close surgical margins (less than 2 mm) or with microscopically positive margins subsequently treated with radiation therapy showed no difference in 5-year outcomes when compared with those who had superficial locally excised anal canal cancers with negative margins and no chemoradiation [51].

A retrospective cohort study that included 2243 adults from the National Cancer Database diagnosed with T1N0 anal canal cancer between 2004 and 2012 found that the use of local excision in this population increased over time (17.3% in 2004 to 30.8% in 2012; $P < .001$). No significant difference in 5-year OS was seen based on management strategy (85.3% for local excision; 86.8% for chemoradiotherapy; $P = .93$) [52]. The limitations of this study should be noted – it was a large database review, and local and regional recurrence rates were not available. An older but more spe-

cific study, with good follow-up, suggests that small (specifically ≤1 cm), well-differentiated anal canal SCCas that are completely excised with negative margins are safe to excise locally with no adjuvant or neoadjuvant treatment [53]. Overall, it is likely that only those with small, well-differentiated superficially invasive anal cancers that can be excised with negative margins qualify for consideration of a local excision strategy. Although this is sometimes intentionally done, local excision is often done unintentionally while excising anal lesions for therapeutic or diagnostic reasons.

The goal of surveillance in the post-treatment period is centered around the concept of early detection and the potential for "salvage" surgery to provide a second chance for cure. There is evidence that tumor regression can occur for up to 6 months following the end of radiotherapy treatment. Close monitoring in the time following the conclusion of radiotherapy, typically starting 8–12 weeks following the last dose of radiation (when post-irradiation inflammation has lessened), is done via direct examination with digital rectal examination and anoscopy. Routine biopsy of residual, but shrinking, lesions in the anal canal is not generally indicated until the 6th month following radiotherapy, to allow time for tumor regression and healing. After that time, persistent ulcers or masses should be evaluated via biopsy [54]. However, a tumor that appears to be regrowing after chemoradiotherapy prior to the 6-month window should be biopsied at the time regrowth is suspected and treatment initiated if biopsies are positive.

Although chemoradiation is an effective initial treatment for anal canal SCCa, about 10–30% of patients will suffer from persistent/recurrent tumor, mostly in a locoregional pattern. The risk of persistence/recurrence parallels stage. Prior to initiating salvage therapy, patients should be restaged, typically with physical examination and biopsy confirming the presence of tumor, CT/PET, and pelvic MR in select cases of locally advanced disease. Contraindications to salvage surgery include very poor performance status combined with advanced age, incurable distant metastatic disease, and pelvic sidewall/levator or nerve root invasion. For those without these concerning features, APR is appropriate prior to administration of systemic chemotherapy. With APR, the 5-year survival rate is about 50–60%, better than with salvage chemotherapy or chemoradiotherapy where salvage rates in small series are only 30% [54, 55]. Positive margins, involved nodes, and distant metastatic disease are poor prognostic indicators postoperatively. En bloc resection of locally invaded resectable structures (vagina, prostate, distal sacrum) is possible and advisable with planning and involvement of a multidisciplinary team. Soft tissue flap reconstruction of the perineum is often necessary with or without additional organ involvement. Highly irradiated perineal tissue makes wound healing challenging, and these patients have a higher rate of perineal wound infection and dehiscence when compared to those undergoing APR for adenocarcinoma. Comparison of perineal wound closure with and without flap shows that those closed with flaps are also subject to infection or dehiscence, albeit at a lower rate, and wound healing progresses faster with flaps than with primary closure [56]. In other words, flap closure does not necessarily prevent wound infection from occurring but does reduce the size of the wound, and its presence speeds wound healing if infection or superficial dehiscence does occur. VRAM or vertical rectus abdominis myocutaneous flaps are most effective for closing large perineal wounds (Fig. 20.4a, b) [57, 58]. Perineal wound complications are more likely in patients with bulkier tumors and larger perineal defects.

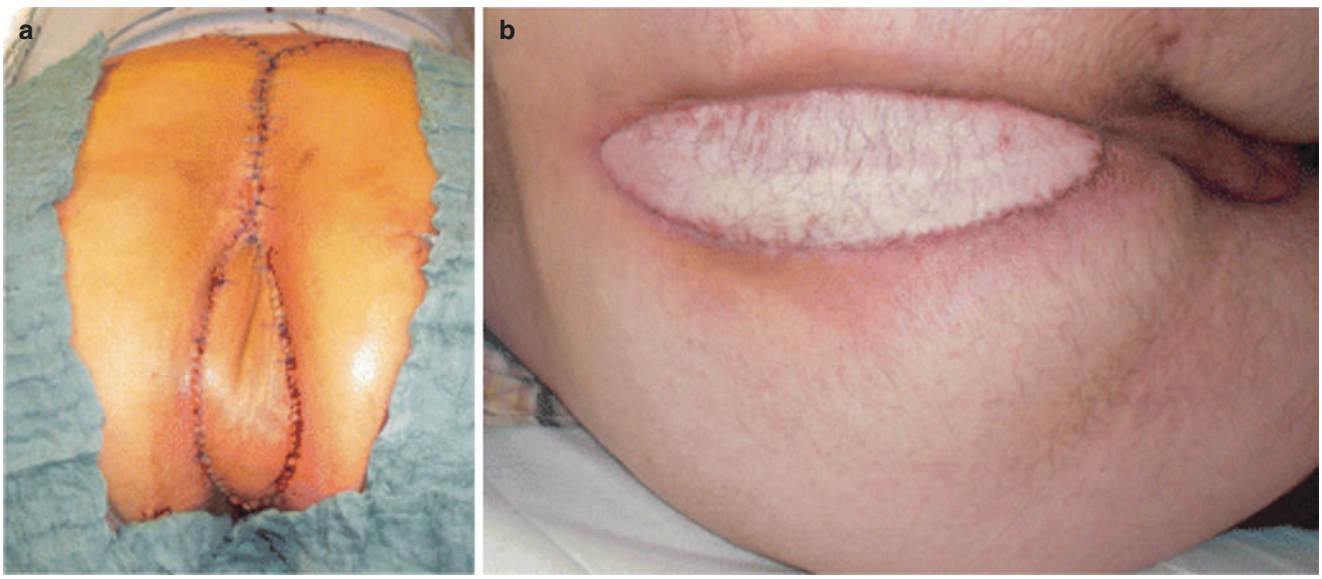

Fig. 20.4 (**a**) VRAM flap with bilateral gluteus advancements. (**b**) VRAM flap, early postoperative phase. (Reused with permission Horch et al. [126]. Copyright Springer Nature)

Those patients with isolated inguinal nodal recurrence represent a distinct subset of metastatic disease that may be considered for resection with intent to cure. It is possible to have a complete clinical response at the primary site with an isolated inguinal metastasis amenable to superficial inguinal groin dissection. If there is no evidence of additional distant or regional disease on re-staging studies (contrast CT of the chest, abdomen, and pelvis and/or PET-CT), patients with isolated inguinal metastases can be considered for superficial inguinal lymph node dissection, typically followed by systemic therapy. FNA of the area to confirm the diagnosis of SCCa is important, as morbidity of groin dissection can be substantial. Although complication rates for groin dissection following radiation are fairly high (wound dehiscence, surgical site infection, edema), long-term outcomes from smaller studies suggest that it is reasonably effective in treating isolated locoregional recurrent disease. 5-year DFS rates of 55% have been observed in select patients meeting criteria for resection [48].

Anal Cancer and HIV

Patients living with HIV (PLWH) have a higher incidence of anal cancer and comprise a known high-risk group. Comparisons of the PLWH population with HIV-negative cohorts have been mostly from larger database studies but have confirmed that 5-year OS and rates of complete response are similar [59, 60]. Other studies examining treatment course and tolerance between PLWH and HIV-negative patients found that treatment paradigms used were the same and there was no difference in tolerance or toxicity of chemoradiation. Some small retrospective studies seem to indicate that radiation-related morbidity in the form of skin inflammation and pain may be greater in the immunocompromised [60]. NCCN Guidelines for Cancer in PLWH state that PLWH who have anal cancer should be treated as per guidelines used for HIV-negative patients and that modifications to treatment should not be made solely on the basis of HIV status [49]. Use of normal tissue-sparing radiation techniques (IMRT) and consideration of nonmalignant causes for lymphadenopathy may deserve more attention in this cohort along with the need for more frequent post-treatment surveillance anal examinations.

Surveillance

Follow-up of patients after treatment of primary anal canal or perianal cancer is essential. Initial physical examination is typically done 8–12 weeks following the last dose of radiation. Examination of the anal canal or perianal area by digital rectal exam and direct visual inspection of the area by anoscopy (if the lesion originally extended into the anal canal) should be performed. Careful documentation of the extent of the response should be made. It is often helpful to include a digital photograph of the tumor/tumor treatment site in the electronic medical record, both at initial diagnosis and at surveillance examinations, as subtle changes in the tumor treatment site may be the first sign of persistence/recurrence, and examiners may change with time. The rationale for waiting for 6 months to perform biopsy in patients whose tumors are stable or regressing is that the ionizing effect of radiation on tumor cells extends well into the post-treatment period. The data to support this strategy comes from observational studies and the ACT II trial. The ACT II study compared the use of either mitomycin or cisplatin for anal cancer and showed that there was no difference in either OS or PFS between the two drugs. It did show, however, that up to 72% of patients who failed to show a complete response at 11 weeks did respond completely by 26 weeks with no evidence of residual visual evidence of tumor, ulceration, or mass present [35]. Routine biopsy is not indicated in the absence of a mass or ulcer. However, as noted above, patients who have an enlarging mass or other evidence of progression on physical examination should have a biopsy at the time that progression is noted and the histologic results interpreted in the context of the clinical situation.

It is recommended that contrast CT scan of the chest, abdomen, and pelvis be performed annually for 3 years for those with large or clinically node-positive tumors. Digital rectal examination with anoscopy and inguinal nodal palpation should be done every 3–6 months for 4–5 years [49].

Anal Adenocarcinoma

Anal adenocarcinoma differs from rectal adenocarcinoma in location and prognosis. It is often difficult to differentiate between a distal rectal tumor invading the anal canal and a primary anal adenocarcinoma (Fig. 20.5). The latter typically present with a mass in the anal canal with a minimal mucosal component. Mucoid discharge is a frequent complaint. Anal adenocarcinoma can arise directly from an anal gland or can be found in proximity to chronic fistula tracts, particularly in patients with Crohn's disease, which can present diagnostic challenges leading to delays in diagnosis [61]. Anal adenocarcinoma accounts for approximately 20% of all anal cancers [62]. They may appear morphologically similar to rectal adenocarcinoma but will have an increased risk of inguinal lymph node metastasis [63].

Anal adenocarcinomas are both staged and treated similarly to rectal cancers. Large prospective series are lacking due to the rarity of the disease, but neoadjuvant radiotherapy or chemoradiotherapy prior to APR has been associated with

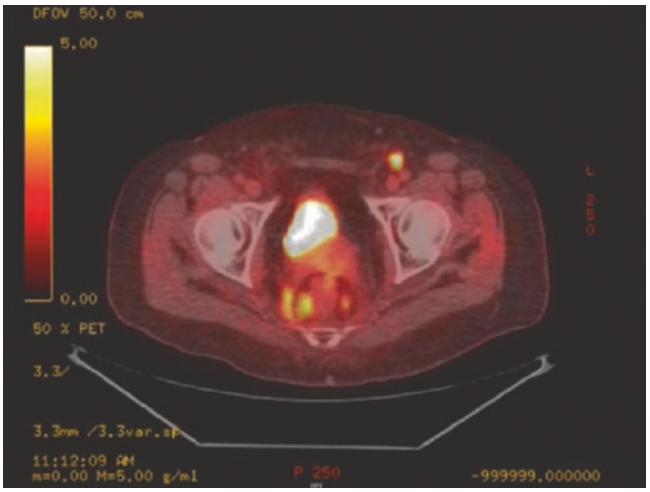

Fig. 20.5 Anal adenocarcinoma with left inguinal lymph node positivity

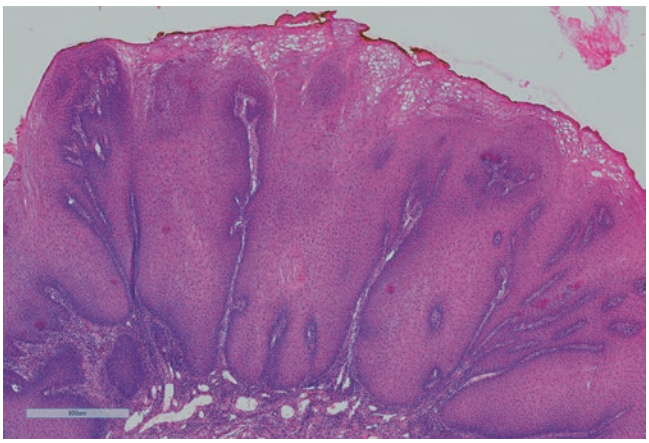

Fig. 20.6 Verrucous anal carcinoma with locally invasive histologic features. (Reused with permission from Pathology Outlines. © Copyright PathologyOutlines.com, Inc. www.PathologyOutlines.com)

improved disease-free survival and local control as compared to upfront surgery [64, 65].

Comparing the frequency and survival of anal adenocarcinoma to that of rectal adenocarcinoma and anal squamous cell carcinoma, it is noted that both the frequency and overall survival for anal adenocarcinoma are lowest. Comparisons of survival (all stages) in 57,369 cases of anorectal cancer revealed that anal adenocarcinoma represented only 0.8% of cases with a mean survival of 33 months, compared to rectal adenocarcinoma representing 87.8% of cases with a mean survival of 68 months and SCCa representing 11.4% of cases with a mean survival of 118 months [66]. A study using the National Cancer Database revealed that patients with anal adenocarcinoma had statistically worse survival when compared to both rectal adenocarcinoma and anal squamous carcinoma. Decreased survival in the anal adenocarcinoma group was associated with proctectomy and the use of chemotherapy, most likely reflecting more advanced disease at diagnosis [67]. It should be remembered, however, that studies of anal adenocarcinoma are hampered by accuracy of diagnosis, as it is often extremely difficult to distinguish whether a patient has true anal versus distal rectal adenocarcinoma.

Verrucous Carcinoma

Verrucous carcinomas of the anus are also known as Buschke-Lowenstein tumors. It was first described by Buschke and Lowenstein in 1925 and is also known as giant condylomata [68]. It presents as a large exophytic cauliflower-like lesion on the perianal skin. These lesions are characterized by their large size and their ability to infiltrate surrounding tissues (Fig. 20.6). There has been controversy as to whether a true Buschke-Lowenstein tumor should be considered benign and defined by its lack of invasion of the basement membrane (giant condylomata) or should be considered a slowly growing squamous cell carcinoma with tendency toward local invasion [69]. The lack of clarity in the definition has hampered scientific study. These tumors are often associated with HPV types 6 and 11 [70]. Following excision, substantial local recurrence rates of over 50% have been reported in meta-analysis [71]. Malignant transformation has been reported in 40–60% of cases [72]. The average time to transformation to malignancy is approximately 5 years following initial diagnosis [71].

Wide surgical excision is the mainstay of treatment. Chemoradiation, laser therapy, photodynamic therapy, antiretroviral therapy, and intralesional injection have all been reported with less success than local excision [73–76]. If mesorectal lymph node metastasis is suspected or there is local destruction of the anal canal, a more aggressive approach to treatment that may include chemoradiotherapy and/or abdominoperineal resection may be indicated.

Melanoma

Melanoma of the anus is a rare and aggressive tumor. First described in 1857 by Moore [77], the reported incidence of mucosal melanoma is between 1% and 2% of all melanomas affecting approximately 2 per million persons per year [78]. It has been estimated that anal melanoma accounts for 0.05% of all colorectal malignancies diagnosed each year [79].

Anal melanoma is most commonly seen in the sixth decade of life, with a female predominance [80]. It is unclear if the poor prognosis is related to biologic factors or simply late stage at diagnosis. As with other tumors of the anal region, patients will often attribute their symptoms of bleed-

ing and pain to hemorrhoids, thereby delaying diagnosis. A pigmented ulcerated mass in the region enhances the suspicion of melanoma (Fig. 20.7); however, it is recognized that up to 30% of anal melanomas are amelanotic [81]. These tumors can be found incidentally in hemorrhoidectomy specimens, and this scenario is one of the rare times when the tumor may be curable.

The extent of disease is assessed with pelvic MRI, PET-CT scan, colonoscopy, and complete dermatologic and ophthalmologic examination. The use of sentinel lymph node mapping is controversial with unproven survival benefit. The nodal basin is variable in the inguinal region and can be either unilateral or bilateral. While hematologic spread occurs, lymphatic spread to mesorectal nodes is not uncommon [82].

There is no TNM staging system specifically for anorectal melanoma. The staging for anorectal lesions has historically been based on clinical findings: stage I and II, local disease; stage III, regional lymph node involvement; and stage IV, distant metastatic disease [83]. Based on the findings that depth of muscle penetration impacts survival, a newer staging classification was proposed by Falch et al. (Table 20.5) [84].

The treatment for anorectal melanoma has historically been abdominoperineal resection. However, many studies have shown no survival benefit for this procedure compared to wide local excision, and it is recognized that most, but not all, treatment failures are from distant metastatic disease [85–87]. There is, however, improved local control with APR compared to wide local excision in some studies, and the use of APR for larger lesions or for salvage and palliation can be considered in select cases. The addition of radiotherapy has been proposed to augment local control after wide local excision, but it is not routinely used, as melanomas are not considered radiosensitive tumors [88, 89]. A study of 570 patients who underwent surgical resection (67% wide local excision vs 33% APR) showed that the 5-year overall survival was 21% in both groups regardless of the ability to achieve an R0 resection [90]. Similarly, a review of 653 patients with anal melanoma found comparable overall survival in both the radical and local excision groups [91]. These dismal statistics speak to the fact that death from anal melanoma is most frequently caused by the presence of distant metastatic disease, not from failure of local control.

Molecular diagnostic testing has gained importance in the characterization and management of anal melanoma. The mutations which are most commonly tested are BRAF and c-KIT. BRAF mutations may direct therapy with BRAF inhibitors in cutaneous melanomas [92]. Tyrosine kinase inhibitors such as imatinib have been targeted for treatment of patients with c-KIT (+) mutations [93].

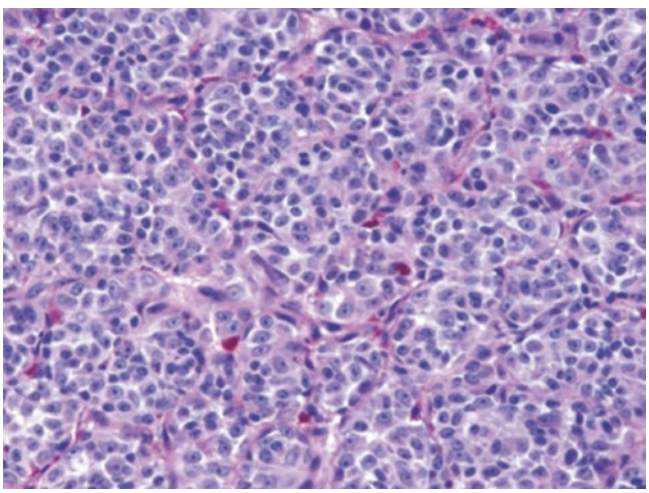

Fig. 20.7 Histology of anal melanoma

Table 20.5 Staging classification of primary anorectal malignant melanomas

Stage	Tumor spread
I	Local tumor spread without infiltration of the muscular layer
II	Local tumor spread with infiltration of the muscular layer
III	Regional tumor spread and/or positive lymph node metastasis
IV	Disseminated tumor spread

Perianal Paget's Disease (Intraepithelial Adenocarcinoma)

Extramammary perianal Paget's disease, or intraepithelial adenocarcinoma, was first reported in 1889 [94]. It is a rare skin condition arising from the apocrine glands, frequently presenting as a scaly lesion on the perianal skin (Fig. 20.8). It is estimated that 6% to 20% of all cases of extramammary Paget's disease occur in the perianal region [95–97]. It is more common in women with incidence rising starting in the fifth decade [98]. The lesion can be weeping and ulcerative and accompanied by bleeding pruritus or pain. Misdiagnosis as other more common skin conditions is not unusual, with biopsy prompted only after failure of topical steroid treatment [99]. Three types of extramammary Paget's disease have been described: those with no associated malignancy, those associated with an apocrine tumor in proximity, and those associated with internal gastrointestinal or genitourinary malignancy. This underscores the importance of a thorough search for associated malignancies [100]. In a recent review of 108 patients with anal Paget's disease, the rate of colorectal adenocarcinoma was 18.5% [101].

Histopathologic diagnosis is confirmed with the findings of classic Paget's cells with abundant cytoplasm, prominent nucleoli, and pleomorphic nuclei (Fig. 20.9) [102]. The surrounding keratinized cells are compressed. Immunohistochemical staining for cytokeratins, mucins,

gross cystic disease fluid protein, and carcinoembryonic antigen has all been utilized in the diagnosis. Epidermal disease does not invade the dermis, while intradermal

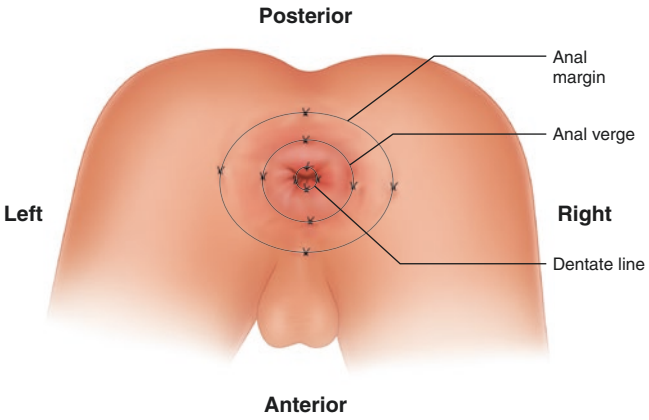

Fig. 20.10 Biopsy mapping chart of anal Paget's disease

growth pattern is less common [99]. Primary extramammary Paget's disease is thought to result from carcinoma in situ of the apocrine gland ducts, whereas secondary Paget's is thought to arise from intraepithelial spread of underlying carcinoma [103]. Because the incidence of extramammary perianal Paget's disease is so low, the majority of the literature is comprised of case reports or retrospective reviews of small series ranging from 20 to 108 cases reported sporadically over a span of decades [99, 101, 104–106]. This haphazard reporting has created dilemmas in treatment because of lack of standardization or contribution of prospective studies.

Achieving adequate surgical margins is a challenge in perianal Paget's disease because it is hard to detect grossly. Histologically, the disease can be present in normal-appearing surrounding tissues due to the multifocal or projection like growth pattern. The anatomic constraints of the anal canal can preclude adequate local excision of lesions that extend proximally. Mapping biopsies of the perianal region have been shown to be useful in avoiding overtreatment and achieving clear margins (Fig. 20.10) [102, 107]. Depending on the extent of excision, reconstruction may be necessary with skin grafts or flaps and may require a temporary diversion for proper healing. Mohs surgery with repeated frozen section analysis at a single setting has been used as a tool to tailor the excision with appropriate pathologic margins, but exposure is challenging, and the length of time it takes to perform the surgery in the prone or lithotomy position may limit the utilization of this technique [102]. The central focus of treatment is wide local excision with clear margins. However, if clear margins cannot be obtained in the anal canal with preservation of sphincter integrity or there is an associated malignancy in the anus or rectum, an abdominoperineal resection may be necessary.

Table 20.6 Classification and treatment of extramammary Paget's disease

Stage	Description	Management
I	Epidermal/intradermal Paget's cells found in perineal, scrotal, or vulvar area	WLE/MMS/TSE; if not amenable to resection or patient refusal of surgical treatment, consider 5% imiquimod
IIA	Epidermal/intradermal Paget's disease with involvement of anal canal	WLE plus transanal resection
IIB	Epidermal/intradermal Paget's with synchronous malignancies	Treat malignancy accordingly (e.g., abdominoperineal resection for rectal malignancy)
III	Epidermal/intradermal Paget's with node involvement (inguinal, iliac)	Chemotherapy
IV	Paget's disease with distant metastases of associated carcinoma	Chemotherapy, radiotherapy, local palliative management

WLE wide local excision, *MMS* Mohs micrographic surgery, *TSE* traditional surgical excision

Due to the morbidity associated with local excision and/or abdominoperineal resection, other strategies have been employed in the management of extramammary perianal Paget's disease with variable success. The use of topical imiquimod has been reported [100, 108]. Treatment with radiation therapy has been reported for primary and recurrent disease. The majority of the published studies are case reports or very small series precluding guiding conclusions as to efficacy. While there is no standardized treatment algorithm, nonsurgical treatments avoiding disfiguring surgical excision may be effective in select cases [109–111]. Photodynamic therapy has been utilized to avoid surgical resection [112]. In one of the largest series of patients with Paget's disease reported, however, recurrence rates were substantial. Half of the patients with invasive and one fourth of those with noninvasive Paget's disease recurred after complete resection, underscoring the rationale for exploring other nonsurgical treatments for this disease [106]. Moller et al. proposed a classification and treatment scheme based on stage of disease (Table 20.6) [113].

Basal Cell Carcinoma

Basal cell carcinoma is the most frequent malignant neoplasia of the skin, compromising 75% of nonmelanocytic tumors [114]. Tumors arising in non-sun-exposed areas are rare. As one might expect, perianal basal cell carcinoma is very rare, representing 0.1% of all basal cell tumors and 0.2% of all perianal tumors [115]. There has been association of these tumors with synchronous lesions in other locations in the body [116]. Therefore, a thorough examination of the entire skin surface should be performed. These tumors have no association with HPV. Treatment is local surgical excision with negative margins.

Gastrointestinal Stromal Tumor (GIST)

Gastrointestinal stromal tumors are the most common mesenchymal tumors of the GI tract, most often located in the stomach and small bowel [117]. The interstitial cells of Cajal are the cells of origin for these tumors [118]. Anorectal GISTs account for only 5% of all GISTs, with those located in the anal canal comprising only 2% of this subgroup [119]. There is a male predominance, with diagnosis typically in the sixth to seventh decade [119]. The tumor presents as a well-circumscribed hypoechoic mass in the intersphincteric space, as seen on endoanal ultrasound [117]. On physical exam, these lesions can present as entirely submucosal or as an ulcerated mass with a large non-luminal, submucosal component. Evaluation of proximity to adjacent structures like the vagina or prostate should be done. Biopsy is appropriate if the mass is larger and ulcerated as a chemotherapy neoadjuvant approach may be beneficial. Diagnosis with endoanal ultrasound or, more commonly, MRI for locoregional staging is appropriate, with a CT scan of the chest, abdomen, or pelvis or a PET-CT providing distant staging information. Because spread of these mesenchymal tumors is mostly hematogenous, GISTs rarely spread to locoregional lymph nodes [120]. Surgical excision is the mainstay of treatment for smaller tumors. Targeted therapy with tyrosine kinase inhibitors such as imatinib (Gleevec©) is often performed to reduce the size of larger, ulcerated, or high mitotic GIST tumors to facilitate local resection in those tumors that are proto-oncogene c-KIT (CD117) positive [121]. It has been suggested that low-risk GISTs with a diameter <2 cm and mitosis <5 per 50 per high-powered field may be considered for local excision if sphincter-saving surgery is technically feasible with or without preoperative tyrosine kinase inhibitor treatment (Fig. 20.11a, b). There are few large case series analyzing treatment for anal GIST. One of the larger reports of 18 patients noted local recurrence in 6 of 10 patients treated with local excision compared to none of the 8 patients treated with radical surgery. There was, however, no difference in survival in the two groups [122]. Evidence suggests that GISTs that are more aggressive should be treated with radical excision as well as chemotherapy [123]. Long periods of latency, exceeding 10 years, between initial treatment and development of recurrence, either local or distant, have been reported [119, 123, 124]. This underscores the potential benefit of extended surveillance of these patients.

Conclusion

In conclusion, malignancies of the anus are diverse and relatively rare, but the overwhelming majority of cancers are squamous cell carcinomas. These cancers are increasing in incidence but are imminently curable at early stages and amenable to early detection. Most, but not all, are HPV mediated and thus may be preventable. Protocols for treatment of anal squamous cell carcinoma, both in the anal canal and perianal region, are well-studied, and patients typically enjoy favorable outcomes. A high index of suspicion for anal cancer when persistent anorectal symptoms occur and a willingness to quickly examine and biopsy suspicious lesions may limit morbidity and mortality from both anal squamous cell carcinoma and in those anal cancers that are less common and more lethal.

Presacral Tumors

21

Scott R. Kelley and Eric J. Dozois

Key Concepts

- The presacral (retrorectal) space is the location of a wide range of rare tumors with incidence as low as 1 in 40,000–60,000 hospital admissions. Discovery in asymptomatic patients is increasing due to expanded use of cross-sectional imaging.
- Advances in cross-sectional imaging and understanding of tumor biology have led to better outcomes for these challenging patients.
- MRI is the best imaging study to assist in diagnosis and operative planning.
- Most benign lesions have malignant potential and observation alone in some patients is acceptable when a dedicated surveillance protocol is in place.
- When performed appropriately and selectively, a CT-guided biopsy of the lesion may assist in management of solid and heterogeneous cystic lesions.
- The surgical principles that should guide a surgeon who manages these lesions are a function-sparing approach for benign lesions and an en bloc approach for malignant lesions.

Introduction

The presacral (retrorectal) space is a potential space and the location of a wide range of rare tumors. Reports from referral centers have indicated the incidence may be as low as 1 in 40,000–60,000 hospital admissions [1–4]. Detection is frequently delayed since patients are often asymptomatic until tumors reach considerable size. Advances in cross-sectional imaging and understanding of tumor biology have led to better outcomes for these challenging patients. Although most surgeons will encounter a patient with a presacral tumor in their career, few will have the opportunity to treat a large volume of these complex lesions. The care of these patients can be greatly optimized by an experienced multidisciplinary team (MDT).

Anatomic Considerations

Evaluation and management of presacral tumors require a thorough understanding of the anatomic relationships of the pelvic viscera, the bony confines of the pelvis, and the neuromuscular structures. Anteriorly the presacral space is bordered by the mesorectum, posteriorly by the anterior table of the sacrum, inferiorly by the levator muscles, and laterally by the lumbosacral plexus, ureters, and iliac vessels (Fig. 21.1).

Several important vascular and neural structures are located where presacral tumors occur. Injury to these may have important physiological, neurologic, and musculoskeletal consequences. Knowledge of anatomy of the thigh and lower extremity is also necessary in complex cases utilizing muscle or other soft tissue flap coverage. When sacrectomy is required, a multidisciplinary surgical team familiar with the anatomy of the sacrotuberous and sacrospinous ligaments, sciatic nerve, piriformis muscle, the thecal (dural) sac, and sacral nerve roots is necessary (Fig. 21.2a and b). Knowledge of sacral nerve root function is important in order to be able to counsel patients on potential functional sequelae that can influence their quality of life. Todd and colleagues evaluated bowel and bladder function in a group of patients following sacral resection. They found that if bilateral S2–S5 nerve roots were removed patients had complete loss of bladder and bowel function. If bilateral S3–S5 were removed, 40% had normal bowel function and 25% had nor-

mal bladder function. If bilateral S4–S5 were taken, 100% had normal bowel function and 69% had normal bladder function. If unilateral S1–S5 were taken, 87% had normal bowel function and 89% had normal bladder function [5]. If the S1 nerve root or sciatic nerve is resected foot drop can occur, severely impairing ambulatory function [6]. In addition to functional consequences, when high sacrectomy is performed, pelvic stability can be compromised if more than half of the S1 vertebral body is resected. Moreover, preoperative radiotherapy can increase the risk of stress fractures destabilizing the pelvic ring. When spinopelvic stability is a concern, patients undergo sacropelvic reconstruction with metallic fixation, bone grafting, or 3D printed titanium prostheses [7].

Clinical Presentations

Presacral tumors are often discovered incidentally during routine pelvic/rectal examination, or on imaging for other purposes [8]. If symptoms are present, pain is typically vague, of long duration, and in the pelvis, perineum, and/or low back. The vague nature of pain can make diagnosis difficult, and at times patients are referred to a psychiatrist when no obvious etiology is found on routine physical examination. Typically, pain is heightened by sitting and improved by standing or walking. Pain is more often associated with malignant lesions and can be an ominous sign [2]. Constipation, urinary and fecal incontinence, and sexual dysfunction are typically seen with sacral nerve involvement from advanced tumors. Leg and gluteal symptoms are often associated with extension and mass effect.

Occasionally patients complain of longstanding perineal/sacrococcygeal discharge and their symptoms may be confused with perianal fistulas or pilonidal disease. Singer and colleagues reported on seven patients with presacral cysts (six females, one male). All patients had previously been misdiagnosed and treated for pilonidal cysts, perirectal abscesses, fistula in ano, psychogenic disorder, proctalgia fugax, and posttraumatic or postpartum pain before the correct diagnosis was made. Patients underwent an average of

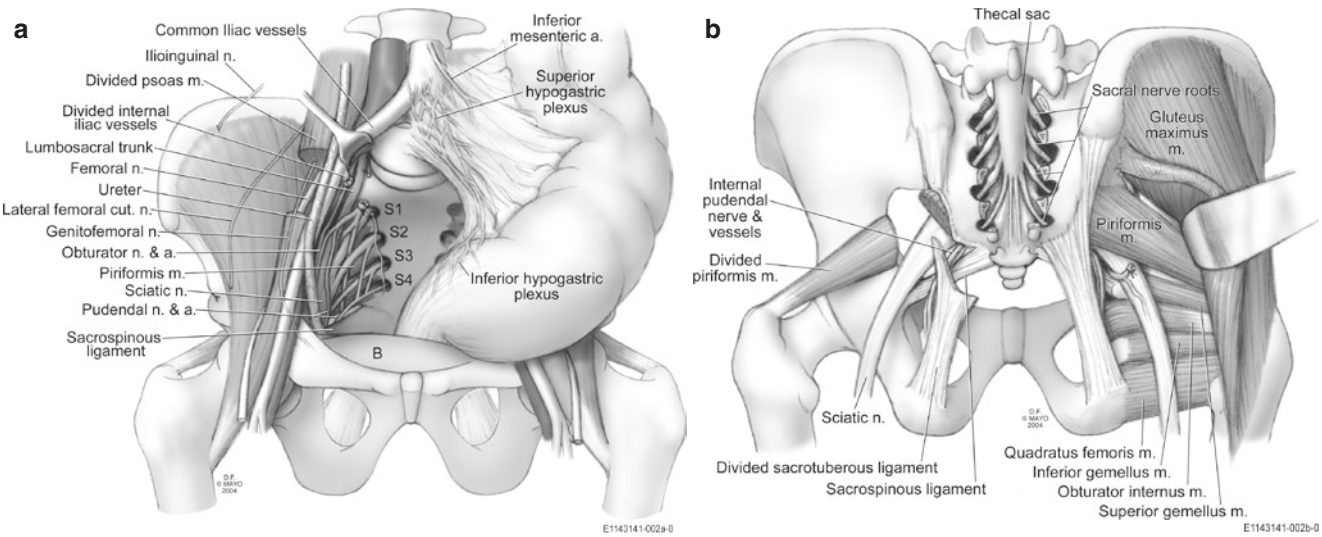

Fig. 21.2 (**a**) Anterior view of the pelvic anatomy. (**b**) Posterior view of the pelvic anatomy. (Reused with permission of Mayo Foundation for Medical Education and Research, all rights reserved)

4.1 prior operative procedures. All patients were successfully treated with resection through a parasacrococcygeal approach after the correct diagnosis was made [9]. Multiple unsuccessful attempts at treatment of anal fistula or pilonidal disease should alert the surgeon to the possibility of a presacral cystic lesion.

Physical Examination

Physical examination should focus on the perineum and rectum. In all but a very small percentage of patients' digital rectal examination will reveal the presence of an extra-rectal mass displacing the rectum anteriorly [2]. It also allows one to determine fixation to the rectal wall and relation to surrounding structures such as the prostate, vagina, and coccyx/sacrum. Evaluation for a post-anal dimple should also be performed. A rigid or flexible proctosigmoidoscopy should be completed to evaluate the mucosa and potentially the upper and lower extent of the tumor. The most common endoscopic appearance is normal mucosa with extrarectal mass effect. The presence of abnormal and/or inflamed mucosa is often suggestive of infection/prior infection or erosion into the rectal wall. Neurologic evaluation of musculoskeletal reflexes and sacral nerve function should be performed if clinically indicated.

Imaging Studies

Anterior/posterior and lateral radiographs are of limited utility, but if obtained can identify osseous expansion, destruction, and/or calcifications of soft tissue occupying masses. In patients with an anterior meningocele, the characteristic "scimitar sign" can often be seen on sacral views. Endorectal ultrasound can be performed at the same time as flexible sigmoidoscopy to assess for invasion of the rectal wall or anal sphincter complex.

Computed tomography (CT) and magnetic resonance imaging (MRI) have dramatically changed the way presacral tumors are evaluated. Both CT and MRI can distinguish between cystic, solid, or mixed (cystic and solid) tumors, and can determine if other pelvic structures (rectum, bladder, ureters, etc.) are involved. Each modality can also define the anatomic extent of the mass, facilitate an accurate diagnosis, and establish the optimal surgical approach (anterior, posterior, or combination). Given the high soft tissue resolution, MRI has become the gold standard imaging modality for evaluating presacral tumors [10, 11]. Magnetic resonance imaging is more sensitive than CT for determining associated cord abnormalities such as sacral nerve root involvement, foraminal encroachment, and dural sac compression [12]. The improved resolution of MRI more clearly defines bony involvement, pelvic sidewall invasion, arterial and venous anatomy, and invasion of surrounding structures (rectum, bladder, ureters, etc.) [11, 13]. Contrast enhanced MRI with gadolinium can also detect meningoceles, thus avoiding the risks associated with myelogram. CT or MR angiography/venography may provide additional information regarding vascular involvement. Preoperative diagnostic accuracy of MRI has been reported to be as high as 100%, with 50–88% sensitivity and 92–97% specificity for differentiating benign from malignant [14, 15]. Low T1 and high T2 signal, gadolinium enhancement, irregular or infiltrative margins, and lesions with heterogeneous and/or solid components are more often associated with malignancy [10, 14, 16].

Hosseini-Nik and colleagues developed an algorithmic approach for MR imaging of presacral tumors. They subdivided fat-containing masses into solid, cystic, or complex lesions. Solid lesions were further subdivided into well and ill defined. Non-fat containing masses were classified as solid or complex, and cystic. Cystic lesions were sub classified as unilocular or multilocular, and solid lesions were differentiated based on the presence or absence of sacral destruction. In addition, they also outlined an optimal MR imaging protocol. They recommend imaging of the pelvis utilizing 1.5 T or 3 T systems with multi-channel phased array torso coils. Multiplanar 2D or high spatial-resolution 3D T2-weighted (T2-W) pulse sequences, together with obliquely oriented 2D T2-W sequences along the long axis of the sacrum helps assess the relationship of the mass to the rectum, sacrum, sacral foramina, and nerve roots. Frequency-selective or inversion recovery fat-suppressed T2-weighted pulse sequences improves the dynamic range for T2-weighting and tissue contrast and also confirms the presence of macroscopic fat. Routine T1-weighted (T1-W) sequences with and without fat saturation examines for macroscopic fat and multiphasic contrast-enhanced acquisitions must be acquired for appropriate characterization. In-phase (IP) and out of phase (OP) T1 gradient-echo imaging is helpful in identifying intracellular lipid [11].

For patients with a presacral cystic lesion thought to be the source of a chronically draining sinus, a fistulogram may help clarify the diagnosis. Our study of choice in this situation is an MRI using fistula-protocol sequences similar to evaluations done in patients with perianal Crohn's disease or suspected occult cryptoglandular fistula-in-ano.

Preoperative Biopsy

Preoperative biopsies have been an ongoing topic of debate [8, 17–20]. Advances in high-resolution imaging have increased the ability to accurately diagnose presacral tumors without tissue [10, 14, 21]. The need for biopsy is predicated on whether the result will change preoperative or operative management. For example, the surgical approach and necessary margins differ significantly for neurofibroma as com-

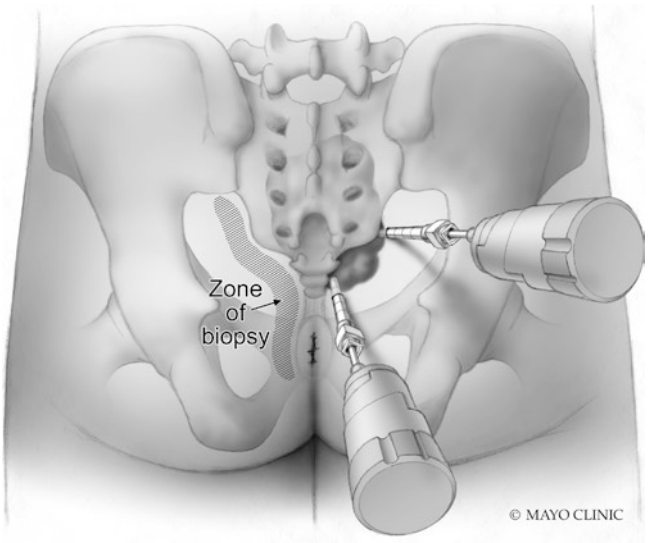

Fig. 21.3 Preoperative biopsy technique using CT guidance. (Reused with permission of Mayo Foundation for Medical Education and Research, all rights reserved)

pared to neurofibrosarcoma. If biopsy is necessary, the intended operative approach should be discussed with the interventional radiologist performing the procedure. Either transperineal or parasacral approaches may be considered depending on the anticipated field of resection (parasacral for planned sacral resection). Needle biopsies should be performed within the field of the proposed area of resection so the needle tract can be resected en bloc with the specimen to decrease the risk of seeding and local recurrence (Fig. 21.3). The external needle entry site can be spot tattooed to aid in future identification. Transperitoneal, transrectal, and transvaginal biopsies should be avoided. If histopathology reveals malignancy, en bloc complete or partial excision of the rectum or vagina with the presacral mass becomes necessary if the biopsy tract traversed one of these organs. In addition, biopsies of tumors in this area can result in bowel perforation, bleeding, and fistulas. Biopsy of cystic lesions increases the risk of secondary infection, and recurrence after resection. Inadvertent biopsy of a meningocele may lead to disastrous sequel such as meningitis and death.

Although historically surgeons have recommended complete excision of any biopsy tract, recently there has been discussion on leaving the biopsy tract in situ. Messick and colleagues reported on 87 presacral tumors, of which preoperative tissue biopsies were obtained in 24/87 (28%). Only 4/24 (17%) underwent excision of the biopsy site to evaluate the tissue (all negative for malignancy). The remaining 20 did not undergo surgical excision of the biopsy site and were followed clinically (or by radiographic imaging) with no reported tumor recurrences in the tract site [4]. Further investigation and evidence is needed before any definitive recommendations can be made on avoidance of biopsy site excision for malignant tumors.

Some patients benefit from neoadjuvant chemotherapy, radiation, hormonal, or immunotherapy, and a tissue diagnosis is often required to make that determination. Large pelvic desmoids can be removed more easily after reducing their size with neoadjuvant radiotherapy. Preoperative chemotherapy and radiotherapy improves outcomes with osseous tumors such as Ewing's sarcoma, osteogenic sarcoma, and neurofibrosarcoma. Hormonal therapy has shown benefit in reducing the size of giant aggressive angiomyxomas, and immunotherapy is showing promise for treating advanced chordomas [22–24]. Thus, when performed safely, a preoperative biopsy can optimize overall management [4, 19].

Classification

The presacral space is primarily composed of connective tissue, nerves, fat, and blood vessels. Totipotential cells that differentiate into three germ cell layers (endoderm, ectoderm, mesoderm) make up the complex embryologic potential space, which can lead to the development of a multitude of tumor types. The original classification described by Uhlig and Johnson divided tumors into congenital, neurogenic, osseous, and miscellaneous [29]. We have modified and updated the classification scheme to subcategorize tumors as malignant or benign, as this greatly impacts therapeutic approaches (Table 21.1).

Lesions found in the presacral space can be broadly classified as congenital or acquired and benign or malignant. Congenital lesions result from abnormalities in embryological processes (fusion of hindgut and proctodeum, degeneration of the notochord, etc.), whereas acquired tumors develop from remnant embryonic or other differentiated tissues found in the presacral space. In general, two-thirds are congenital, of which two-thirds are developmental cysts, with the next most common masses being neurogenic tumors [30]. Around 45–50% are malignant or have malignant change within them [2, 31]. Understanding the various subtypes, disease behavior, and malignant potential is essential to tailor treatment [16].

Epidermoid and Dermoid Cysts

Epidermoid and dermoid cysts (Fig. 21.4) are more common in females, tend to be well circumscribed, have a thin outer layer, result from defects during closure of the ectodermal layer, and are typically benign. They occasionally communicate with the skin surface creating a characteristic postanal dimple and are histologically composed of keratinized stratified squamous epithelium. The cysts are often misdiagnosed

Table 21.1 Mayo classification of presacral tumors

	Benign	Malignant
Congenital	Adrenal rest tumor	Chordoma
	Anterior sacral meningocele	Germ cell tumor
	Developmental cysts (dermoid, epidermoid [aka epidermal], enterogenous [aka rectal duplication], tailgut [aka cystic hamartomas/mucous secreting], teratoma)	Malignant developmental cysts
		Teratocarcinoma
Neurogenic	Ganglioneuroma	Ependymoma
	Neurofibroma	Ganglioneuroblastoma
	Schwannoma (aka neurilemoma)	Malignant schwannoma
		Neuroblastoma
		Peripheral nerve sheath tumors (aka neurofibrosarcoma)
		Primitive neuroectodermal
Osseous	Aneurysmal bone cyst	Chondrosarcoma
	Giant cell tumor	Ewing's sarcoma
	Osteoblastoma	Giant cell tumor
	Osteoma	Myeloma
	Simple bone cyst	Osteogenic sarcoma
		Plasmacytoma
		Reticulum cell sarcoma
		Spindle cell sarcoma
Miscellaneous	Aggressive angiomyxoma	Angiosarcoma
	Benign GIST	Carcinomasarcoma
	Benign hemagiopericytoma	Degenerated hamartoma
	Desmoid (aka fibromatosis)	Epithelioid sarcoma
	Ectopic kidney	Fibrosarcoma
	Endothelioma	Fibromyxoid sarcoma
	Fibroma	Histiosarcoma
	Hamartoma	Hydatid cyst
	Hemangioma	Leiomyosarcoma
	Leiomyoma	Liposarcoma
	Lipoma	Lymphoma
	Lipofibroma	Malignant desmoid
	Myelolipoma	Malignant hemagiopericytoma
	Pecoma	Malignant GIST
	Solitary fibrous tumor	Malignant solitary fibrous tumor
	Tuberculosis	Metastatic carcinoma
		Myeloliposarcoma
		Neuroendocrine tumors
		Rhabdomyosarcoma
		Small cell tumor
		Spindle cell tumor
		Squamous cell carcinoma
		Undifferentiated sarcoma

GIST gastrointestinal stromal tumor

as perirectal abscesses and can become infected with manipulation. Recurrently infected cysts have been associated with the development of squamous cell carcinoma [1]. Dermoid cysts may contain skin appendages (sweat glands, hair follicles, sebaceous cysts) whereas epidermoid cysts do not [9].

Tailgut Cysts

Tailgut cysts (cystic hamartomas/mucous secreting cysts) are congenital lesions arising from remnants of normally regressing postanal primitive hindgut and are more common in females. The cysts are lined with columnar epithelium and can morphologically resemble the adult or fetal intestinal tract [32]. They do not communicate with the rectal lumen and are often multiloculated or biloculated, and well defined and homogenous (Fig. 21.5). The presence of glandular or transitional epithelium differentiates them from epidermoid and dermoid cysts. Malignant transformation has been reported in some series [27, 33–35].

Enterogenous Cysts

Enterogenous cysts (rectal duplication cysts) are more common in women, often in communication with the rectum, and are thought to derive from the developing hindgut. Since they originate from endodermal tissue they can be lined with squamous, cuboidal, columnar, or transitional

epithelium. Unlike epidermoid, dermoid, and tailgut cysts they have a well-defined muscular wall with a myenteric plexus. The lesions tend to be multi-lobular with one dominant and smaller satellite cysts. In order to be classified as a rectal duplication cysts three anatomic criteria must be met: the cyst must be attached to the alimentary tract; it must be lined by a mucous membrane similar to that part of the gastrointestinal tract; and it must possess a smooth muscular coat. Enterogenous cysts are generally benign, but there are case reports describing malignant transformation [25, 36].

Fig. 21.5 MRI of tailgut cyst. (Reused with permission of Mayo Foundation for Medical Education and Research, all rights reserved)

Teratomas

Sacrococcygeal teratomas are neoplasms that may include all three germ layers (totipotential cells), can contain both solid and cystic components, and are more common in the pediatric age group and females. These tumors can contain tissues from almost any organ system including digestive, nervous, respiratory, and skeletal [37]. Histologically, tumors are referred to as either mature or immature, which reflects the degree of cellular differentiation. The more recognizable the elements (hair, bone, teeth) the more likely the tumor is to be benign, although all should be viewed as potentially malignant. Cystic components are typically benign whereas solid components are more often associated with malignant degeneration. The tumors can reach considerable size and diagnosis is often delayed (Fig. 21.6a–c). Teratomas are often associated with anomalies of the vertebra, urinary tract, and anorectum [38]. The rate of malignancy correlates strongly with age, being much less common beyond the second decade [20, 39]. In infants only 7% of girls and 10% of boys presented with malignancy prior to 2 months, whereas the rates can be as high as 48% and 67%, respectively, after 2 months of age [40]. Malignant degeneration can occur in adults, and incomplete or intralesional resection increases the likelihood of malignant degeneration [41–43]. Because of the diverse germ cell layers these lesions can transform into squamous cell carcinoma (ectodermal origin), rhabdomyosarcoma (mesenchymal origin), or anaplastic (indeterminate cell of origin) tumors [3].

Chordomas

Sacrococcygeal chordomas are the most common malignant tumor of the presacral space. The lesions are more common in male patients and rarely encountered in those less than 30 years of age [2, 44]. They are thought to arise from vesti-

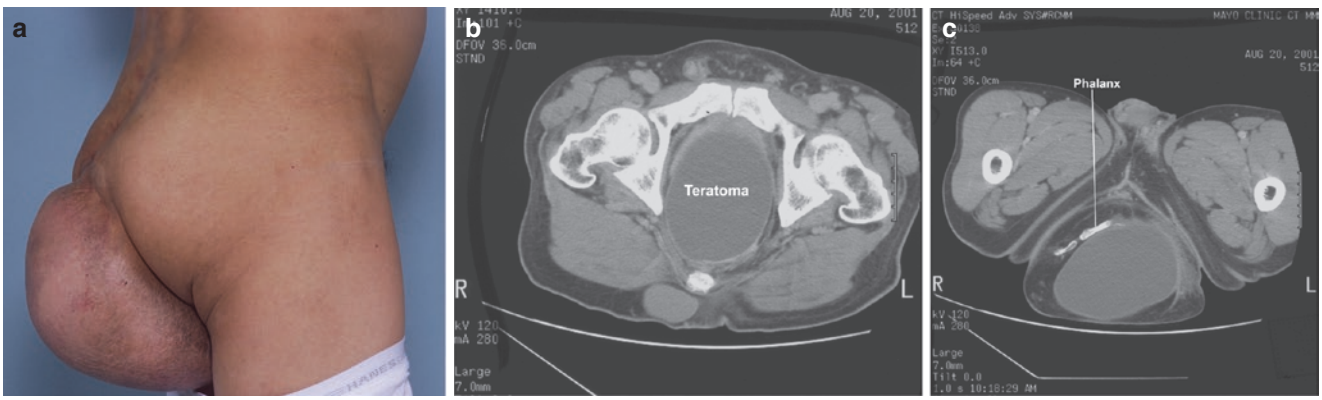

Fig. 21.6 (**a**) Massive cystic teratoma with sacral appendage. (**b**) CT of intrapelvic portion. (**c**) CT of extrapelvic portion with fully developed phalanx. (Reused with permission of Mayo Foundation for Medical Education and Research, all rights reserved)

gial notochord tissue, which embryologically extends from the base of the occiput to the caudal limit in the embryo. The lesions can occur almost anywhere on the spinal cord but are most commonly found in the pheno-occipital region at the base of the skull and the sacrococcygeal region in the pelvis [45, 46]. Symptoms are often vague and include low back, pelvic, and buttock pain, which is aggravated by sitting and alleviated by standing. As a result of the vague symptomology diagnosis is often delayed and the tumors can reach considerable size and result in constipation, fecal and urinary incontinence, and sexual dysfunction. Centrally chordomas contain extracellular mucin and can be soft, firm, or gelatinous. The tumors often contain areas of hemorrhage and can invade or destroy bone and soft tissues and distend into adjacent regions. Local and distant recurrence rates have been documented as 43% and 22%, respectively, and 5- and 10-year survival rates are 67% and 40% [47]. Resection with negative margins is the treatment of choice [47–50].

Meningoceles

Anterior sacral meningoceles arise from protrusions of the thecal sac through a defect in the sacrum, contain cerebrospinal fluid, and can be seen in conjunction with presacral cysts and lipomas. The classic radiographic finding is the "scimitar sign" (sickle-shaped sacrum/hemisacral agenesis), which is a unilateral well-marginated, crescent-shaped defect in the lateral sacrum (Fig. 21.7). Symptoms can include headaches related to postural changes and the Valsalva maneuver (straining/coughing), low back and pelvic pain, constipation/defecatory dysfunction, dyspareunia, and urinary urgency, retention, or incontinence [51]. Anterior sacral meningoceles can be associated with other congenital anomalies including urinary tract and/or anal malformations, uterine and/or vaginal duplication, tethered spinal cord, and spina bifida. These lesions should not be biopsied due to the risk of bacterial contamination of the cerebrospinal fluid and development of iatrogenic meningitis [52]. Surgical treatment consists of obliterating the communication between the subarachnoid space and herniated sac, detethering the spinal cord, and resecting the congenital tumor [53].

Fig. 21.7 CT pelvis scimitar sign. (Reused with permission of Mayo Foundation for Medical Education and Research, all rights reserved)

Neurogenic Tumors

Neurogenic tumors arise from the peripheral pelvic nerve plexus (Fig. 21.8a and b), make up approximately 10–15% of all presacral masses, and typically affect younger patients (median age 38). Although the vast majority (>90%) are benign, at times differentiating benign from malignant tumors can be difficult without a tissue biopsy. Schwannomas and ependymomas are the two most commonly encountered lesions [2, 26, 48]. Presenting symptoms can include neuropathies and low back and pelvic pain. Benign and malignant tumors have a high local recurrence rate, and survival for malignant tumors is poor. Early detection and aggressive surgical intervention are necessary to improve outcomes. With the use of a nerve-sparing technique a function-preserving resection can be safely completed with an overall improvement in symptoms [54, 55]. The goal is sacral nerve root preservation, but sacrifice may be required for extended resections for malignant tumors.

Osseous Tumors

Osseous lesions that grow into the presacral space make up less than 10% of presacral tumors and can arise from bone, cartilage, fibrous tissue, and marrow. They are more commonly found in males and half are malignant at the time of diagnosis [18]. Osseous tumors can reach considerable size and cause significant local destruction. They have pronounced metastatic potential, with pulmonary being the most common [56]. Although benign, giant cell tumors of the sacrum can metastasize to the lung and transform to a fulminate malignant variant, which has a very poor prognosis [57].

Miscellaneous Lesions

Miscellaneous masses in the presacral space can include heterogeneous pathologies including carcinoids, gastrointestinal stromal tumors, dermoids, angiomyxomas, metastatic deposits, ectopic kidneys, and hematomas [58].

Currarino Syndrome

Surgeons seeing patients with presacral tumors should be familiar with Currarino syndrome. Currarino syndrome, described in 1981 is a rare congenital malformation associated with three main features: sacral malformation (agenesis or sickle shape), hindgut anomaly, and presacral tumor [59]. It is an autosomal dominant disorder linked to mutations in the HLXB9 gene, although sporadic cases have been described [59, 60]. To date, 43 heterozygous mutations have been reported [61]. As a result, patients can present with variable phenotypes including spinal cord anomalies (tethered cord, thickened filum, syrinx), genitourinary malformations, anorectal and gynecological anomalies, and presacral lesions. More than one presacral lesion can occur in the same patient [62]. The most commonly associated presacral mass is dermoid cyst, although teratomas have been identified in 25–40% of cases. Malignancy in Currarino syndrome is rare and only a small number of adult (19–45 years old) patients with malignant teratoma have been described [39, 63]. An abnormal looking sacrum on imaging is often the tip off that a patient has Currarino syndrome.

Management

The recommendation for treating presacral tumors has historically been surgical resection. Operative indications include known malignancy, concern for future malignant transformation, alleviation of symptoms, and a consistent increase in size (which may make future resection more risky). Small tumors can be addressed independently by colon and rectal surgeons specifically trained to manage these lesions. Larger lesions, or those associated with neuromusculoskeletal structures, are best managed by a multidisciplinary team that can bring specialty expertise to decision-making and assist in a safe surgical approach. For locally adherent malignant tumors, en bloc removal of adjacent organs, soft tissue, and bone is the goal of oncologic resection. At our institution, we have established a decision-making algorithm to guide the management of presacral tumors (Fig. 21.9a and b). The principles that should guide the surgical team include a function-sparing approach for benign lesions and an en bloc oncologic approach for malignant lesions.

There is recent literature supporting nonoperative surveillance (serial imaging) for small cystic lesions without symptoms or suspicious radiologic features [28], although the proof for advisability of this approach needs further investigation. Hopper and colleagues followed six cystic lesions with serial imaging for a median of 20 months (range, 5–66). Interval imaging ranged from every 6 months to every 2 years. At last follow-up, four (67%) were noted to be stable in size [28]. In our own practice, we consider an observational approach for small (<5 cm), asymptomatic neurogenic tumors.

Multidisciplinary Team

An experienced multidisciplinary team is critical for optimal outcomes in patients with complex presacral tumors

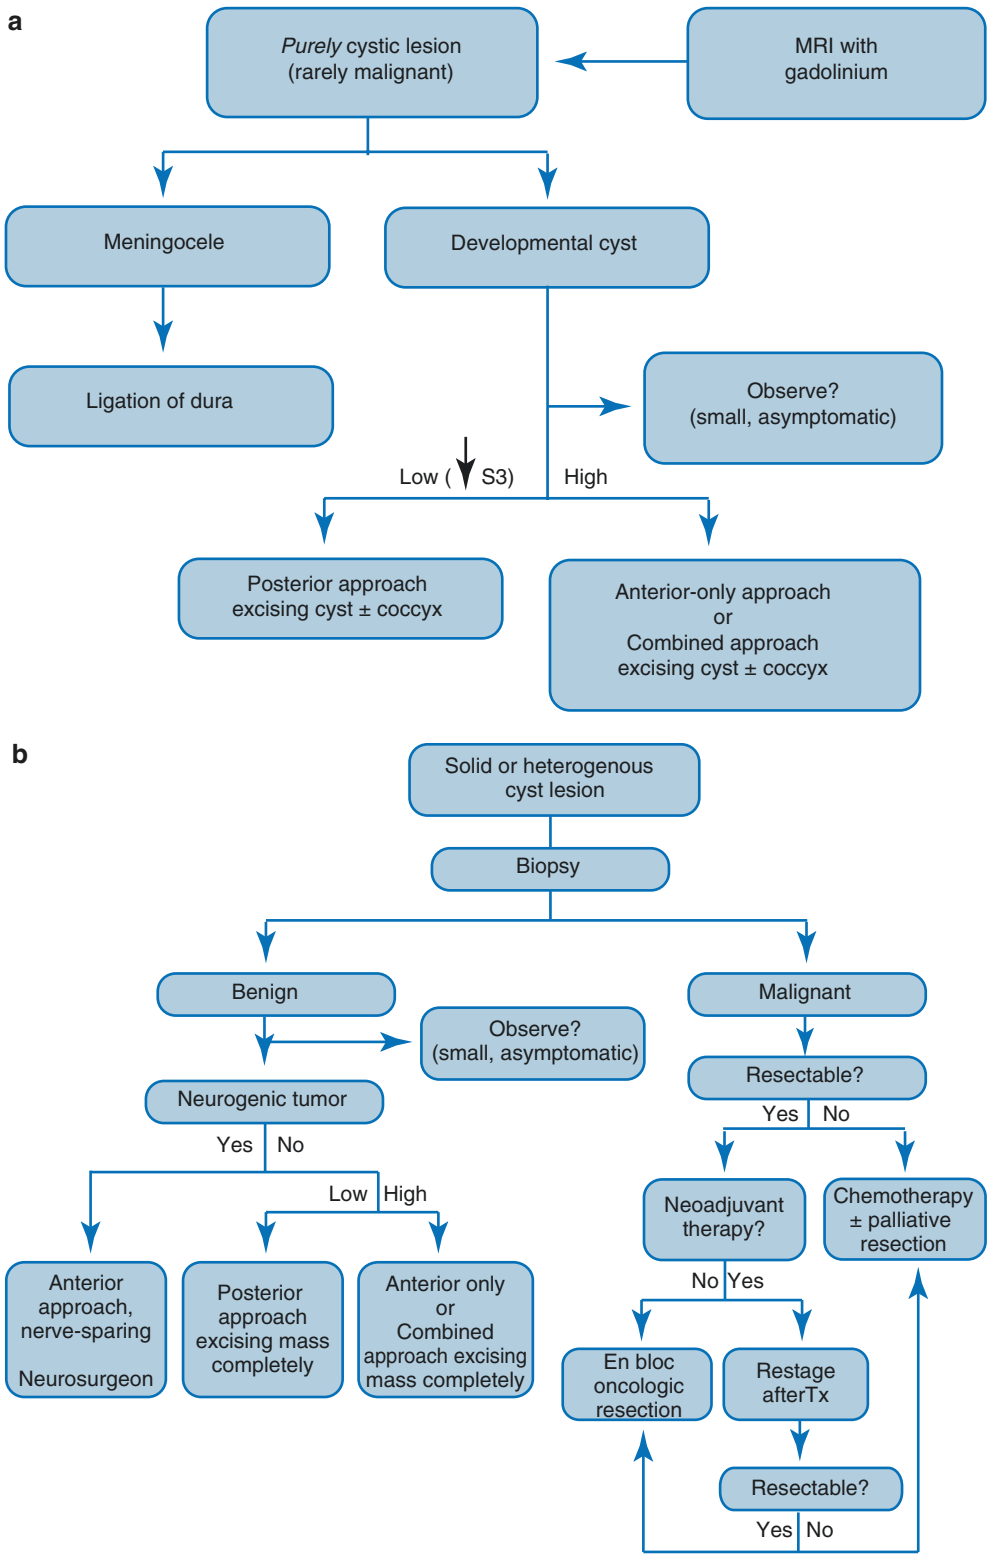

Fig. 21.9 (**a**) Proposed treatment algorithm for purely cystic lesions. (**b**) Proposed treatment algorithm for solid or heterogenous cystic lesions. (Reused with permission of Mayo Foundation for Medical Education and Research, all rights reserved)

[64]. The team may consist of surgeons from colorectal, orthopedic oncology, spine, neurosurgery, urology, vascular, and plastic surgery, as well as medical oncology, radiation oncology, musculoskeletal radiologists, and anesthesiologists with special expertise in complex presacral tumors [26, 65]. A formal discussion at multidisciplinary team conferences is essential for perioperative planning and treatment.

Neoadjuvant Therapy

Although many malignant presacral tumors, such as chondrosarcomas and chordomas, are poorly responsive to radiotherapy and chemotherapy, there are a number which are responsive. The addition of neoadjuvant therapy can decrease tumor size, increase resectability, and potentially decrease the rate of local recurrence. Compared to postoperative administration, the irradiation treatment field in the preoperative setting is smaller and results in less morbidity. Ewing's and osteogenic sarcomas are often associated with metastasis and neoadjuvant chemotherapy is a cornerstone of therapy. Providing chemotherapy in a neoadjuvant setting allows for treatment of micrometastatic disease prior to surgery, as well as decreases delays in chemotherapy treatment that may occur should the patient suffer postoperative complications.

The use of neoadjuvant therapy for presacral sarcomas has been extrapolated from protocols for treating soft tissue sarcomas. Radiation therapy has been shown to decrease local recurrence following resection of both retroperitoneal and extremity sarcomas [66, 67]. Others have shown chemotherapy, with and without radiation, trends toward an improved survival and decreases local and distant relapses for extremity and retroperitoneal sarcomas [26, 68–70].

Due to small case series and heterogeneity in patient populations, it is unclear if patients with malignant cysts benefit from neoadjuvant chemoradiotherapy. We have used this approach in patients with malignant cysts that have either squamous cell carcinomas or adenocarcinomas within them, with the rationale that chemoradiotherapy works well in patients with adenocarcinomas of the rectum and squamous cancers of the anus.

Preoperative Considerations

Optimizing patients for surgery is of paramount importance. When possible, anemia should be improved, protein calorie malnutrition enhanced, and debility reduced. For patients presenting in a debilitated state, social work consultation prior to surgery is important for postoperative rehabilitation and care planning. To decrease intraoperative bleeding, preoperative selective coil embolization of feeding vessels may be useful in some patients with large vascular tumors like hemangiopericytomas (Fig. 21.10a–c) [71].

For complex tumors, the multidisciplinary team should review films and operative planning together before surgery. Significant bleeding can occur with complex resections, and the blood bank should be alerted ahead of time to make sure adequate product is available. An operating room team (anesthesiologists, nurses, assistants, etc.) comfortable with complex pelvic surgery is needed for these procedures.

Surgical Approach

The location, involvement of other pelvic structures, and surgeon experience dictates the operative approach. For tumors superior to the S3–4 sacral bodies, a purely abdominal (anterior) approach should be pursued, while lesions entirely inferior to the S3–4 sacral bodies can be approached through a posterior sacral incision. For tumors extending both proximal and distal to the S3–4 sacral bodies, a combined anterior and posterior approach is often utilized (Fig. 21.11) [10, 21, 65].

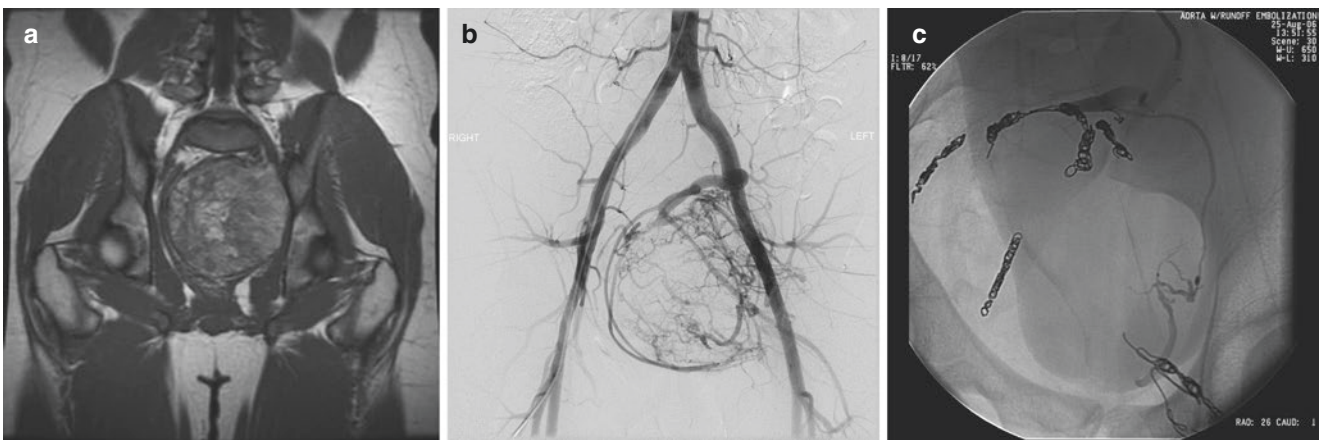

Fig. 21.10 (**a**) MRI of hemangiopericytoma. (**b**) Angiogram of hemangiopericytoma. (**c**) Post-coil embolization of hemangiopericytoma. (Reused with permission of Mayo Foundation for Medical Education and Research, all rights reserved)

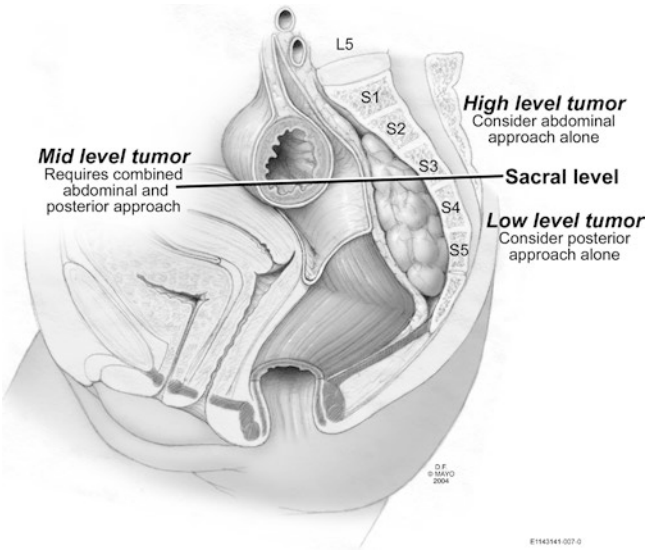

Fig. 21.11 Relationship of tumor to sacral level and proposed approach. (Reused with permission of Mayo Foundation for Medical Education and Research, all rights reserved)

Posterior Approach

The patient is placed in a prone jackknife position and the buttocks are taped apart (Fig. 21.12a). Depending on surgeon experience and preference, an incision (midline, parasacral, paracoccygeal, transverse, and curvilinear to the left of the lower sacrum/coccyx and into the intergluteal fold) is created. The dissection is carried down to the distal sacrum/coccyx and through the anococcygeal ligament, taking care to avoid damage to the sphincter complex. The centrally decussating muscle fibers of the levator muscle (levator plate region) are removed from the tip of the coccyx allowing entry into the presacral space. A pseudocapsule is often encountered and helps facilitate a safe dissection from surrounding tissues including the rectum. A coccygectomy can be performed to facilitate exposure and resection of larger tumors or ones tethered to the coccyx (Fig. 21.12b). The surgeon may double-glove the non-dominant hand, and with the index finger in the anal canal and lower rectum, push the lesion outward to assist with dissection of the tumor from the posterior wall of the rectum (Fig. 21.12c). If necessary, the lower sacrum and/or coccyx can also be excised en bloc with the tumor. If there is concern for local invasion a portion of the rectal wall may need to be excised and the defect closed in layers, otherwise the rectum should be left intact. Rectal integrity can be evaluated with a rigid or flexible endoscope and an air leak test performed by submerging the open operative field with irrigation.

There has been ongoing debate regarding the utility of coccygectomy for every low presacral tumor. Some authors advocate that coccygectomy improves exposure and decreases the risk of recurrence, as the coccyx may harbor a nidus of totipotential cellular remnants that may later evolve into a recurrent cyst [31, 38, 42]. However, multiple studies demonstrating low recurrence rates without coccygectomy support the idea that routine coccygectomy is unnecessary and potentially adds morbidity to patients. Singer et al. did not perform a coccygectomy in six of the seven patients (86%) with benign lesions in their study and saw no difference in recurrence [9]. Mathis and colleagues performed a coccygectomy in 7/28 patients, all of whom underwent resection of presacral tailgut cysts, and reported only a single recurrence (4%) [27]. Messick et al. performed a coccygectomy in 51% of the patients in their series (44/87) and did not appreciate a difference in recurrence for those who did (14%) and did not (20%) undergo resection of the coccyx [4]. We favor coccygectomy in patients with sacrococcygeal teratomas which are uniformly adherent to the coccyx and likely have the highest risk of recurrence if any cyst components are left behind.

Abdominal and Combined Anterior and Posterior Approach

For tumors completely above S3–S4 with no sacral involvement a transabdominal approach can be utilized. If the upper pole of the tumor extends above S3 a combined anterior and posterior approach is usually indicated. Patients can be placed in a variety of positions including supine, synchronous (modified dorsal lithotomy), and modified "sloppy" lateral (Fig. 21.13a–c). For larger tumors bilateral ureteral stents can be placed after induction.

Depending on tumor characteristics (benign/malignant, local invasion) and surgeon experience and comfort either an open or minimally invasive approach is utilized. The abdomen is carefully explored to rule out disseminated disease and other pathology. The lateral attachments of the sigmoid colon are mobilized and the presacral space entered. Ureters and superior hypogastric nerves are identified and preserved. The mesorectum is dissected off the presacral fascia to the level of the upper extension of the tumor. The rectum is mobilized to facilitate identification and exposure of the pathologic area of interest. If the tumor can be safely separated circumferentially from the rectum, presacral fascia, and lateral pelvic sidewalls the dissection can proceed until the mass is removed. Bulky tumors make visualization difficult and may preclude safe dissection between the lesion and rectum. In this event the rectum can be excised en bloc with the tumor, and intestinal continuity reestablished following removal. If the tumor invades both S2 or S3 nerve roots excision of the rectum en bloc with the mass and creation of a permanent colostomy is appropriate since the patient will be rendered incontinent. During mobilization of malignant tumors, no structures attached to the specimen should be

separated (ureter, bone, vasculature, nerve, etc.), instead they should be removed en bloc with the tumor.

Substantial blood loss can occur during resection of large presacral tumors, especially in those requiring en bloc sacrectomy. Middle sacral vessels are often significantly enlarged. Selective ligation of the middle sacral artery and in some cases, the internal iliac vessels and their branches, can reduce blood loss (Fig. 21.14). Preoperative catheter based venous and/or arterial embolization can be considered when significant bleeding is anticipated. Preservation of the anterior division of the internal iliac artery and internal gluteal branches reduces the risk of perineal and gluteal necrosis. Multidisciplinary planning with vascular surgery is prudent for cases where significant vascular dissection is anticipated, especially for patients with prior irradiation or anticipated distorted vascular anatomy.

For expected large pelvic or postsacral defects, a plastic surgeon should be involved for tissue interposition/reconstruction. Multiple options are available such as vertical rectus abdominis myocutaneous (VRAM) flap, transverse rectus abdominis (TRAM) flap, omental pedicle flap, gracilis flaps, and gluteus myocutaneous flap (local or V–Y advancement) closures.

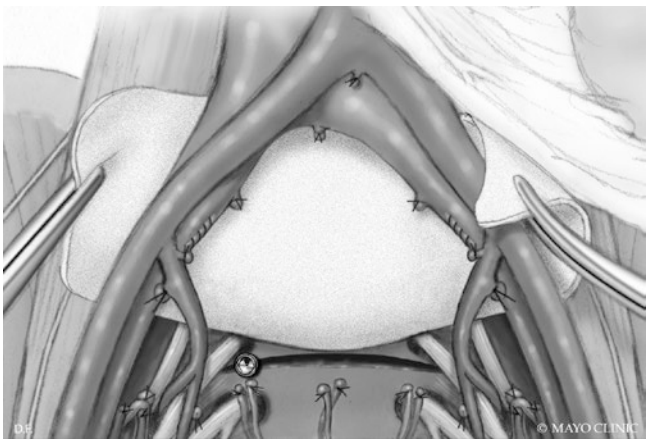

Fig. 21.15 Placement of silastic mesh to protect pelvic vasculature during posterior osteotomies. (Reused with permission of Mayo Foundation for Medical Education and Research, all rights reserved)

For extended sacral involvement it is often necessary to change patient positioning. After the anterior dissection is completed, the abdomen closed, and colostomy matured, the patient is placed in a prone position for the posterior dissection. To reduce injury to vital structures (arteries/veins/ureters) when performing the posterior sacral transection a protective barrier (thick piece of silastic mesh or plastic sheeting, laparotomy pads, etc.) can be placed directly anterior to the sacrum (Fig. 21.15). The mesh will also help protect a pedicled flap that has been placed in the pelvis in preparation for later extraction for perineal reconstruction once the sacrum has been removed. After placing in a prone

position, a midline incision is made over the sacrum and coccyx down to the anus. The anococcygeal ligament is ligated and levator muscles retracted bilaterally. Orthopedic surgery can then continue with dissection of the gluteus maximus muscles bilaterally, transection of the sacrotuberous and sacrospinous ligaments (Fig. 21.16a), and division of the piriformis muscles to expose the sciatic nerves (Fig. 21.16b). An osteotomy is then performed at the desired level exposing and preserving uninvolved sacral nerve roots. For sacral resection in the region of S2–S3 or higher, the thecal sac should be closed with an absorbable suture to decrease issues with cerebrospinal fluid leak or life threatening intra-dural infection (Fig. 21.16c). The tumor is then removed en bloc with the sacrum, coccyx, and involved sacral nerve roots, with or without the rectum. If both S3 nerve roots are sacrificed a permanent colostomy is often necessary.

Minimally Invasive Approaches

Minimally invasive surgery (MIS) has the potential to minimize morbidity and enhance recovery. Laparoscopic and robotic techniques are being more commonly described as safe and feasible means for removing presacral tumors in selected patients (Figs. 21.17 and 21.18) [23, 72–78]. Conditions in which a MIS only approach may not be feasible are very large tumors or malignant tumors that involve the pelvic sidewall, sacrum, or multiple viscera. The overall goals of the surgery must be kept in mind when making a decision on the approach and include complete tumor resection, avoiding disruption of the tumor, and avoidance of injury to surrounding anatomical structures.

Mullaney and colleagues at Mayo Clinic recently performed a systematic review of the literature to determine the feasibility and surgical outcomes of presacral tumors approached using MIS techniques [79]. A total of 82 patients were found that met inclusion criteria. The majority of patients were female (n = 65; 79.2%), with a mean age of 41.7 years (range, 18–89 years). Seventy-three patients (89.0%) underwent laparoscopic or combined laparoscopic-perineal resection, and nine (10.8%) a robotic approach. The conversion rate was 5.5%. The overall 30-day morbidity rate was 15.7%, including one intraoperative rectal injury (1.2%). Ninety-five percent (n = 78) of the tumors were benign. Median length of stay was 4 days for both laparoscopic and robotic groups. No tumor recurrence was noted during follow-up [median 28 months (range, 5–71 months)]. They compared their data from select patients to historical controls from a systematic review of 1064 patients having an open operation. Patients who undergo a minimally invasive approach had a similar mean operating time (155 ± 63 vs. 175 ± 126 min), shorter hospital length of stay (4 vs. 9 days) and comparable 30-day postoperative complications (16% vs. 12.2%) [58]. Selection bias is obviously inherent to the study design, and thus one technique cannot be considered to be superior to another. However, these data suggest that MIS approaches to presacral tumors are reasonably safe and efficacious in select patients when undergoing operation by highly experienced surgeons.

Outcomes

Due to the heterogeneity and rarity of presacral tumors, it is difficult to draw any firm conclusions regarding outcomes following treatment from the published literature. Most reported series come from tertiary/quaternary referral centers, with cases accumulated over many years, or decades. As one might expect, there is great variability in follow-up regimens. This fact, and the absence of time-to-event (Kaplan–Meier) calculation of recurrence rates in many series, renders it impossible for the reader to gain more than a general impression of outcomes.

The largest series published since 1975, when Uhlig and Johnson updated the presacral tumor classification system, are outlined in Tables 21.2 and 21.3 [2, 4, 8, 10, 14, 17, 18, 20, 26, 27, 29, 46, 47, 49, 50, 65, 80–82]. For ease of interpretability the tables are separated into benign (Table 21.2) and malignant (Table 21.3), and provide a high-level overview of the numbers and types of tumors presented. Series of both benign and malignant tumors present data ranging from 8 to 48 years. Recurrence rates for benign masses range from 0% to 35%, with the highest recurrences noted for neurogenic tumors. Recurrence rates for malignant lesions range from 0% to 48%, and it is uniformly noted that a R0 resection with wide surgical margins is associated with lower rates of local recurrence.

MSKCC Memorial Sloan Kettering Cancer Center, *n* number, *NCI* National Cancer Institute

The largest body of literature regarding outcomes following treatment of presacral masses is focused on chordomas. McMaster et al. from the National Cancer Institute used data from the Surveillance, Epidemiology and End Results (SEER) database, over a 22-year period (1973–1995). Of 400 cases 33% were spinal, 32% cranial, 29% sacral, and 6% were extra-axial. Fuchs et al. at Mayo Clinic reported on 52 patients who underwent surgical treatment for sacrococcygeal chordoma between 1980 and 2001 (21 years). They found the most important predictor of survival was a wide margin. All patients with a wide margin survived, and the survival rate was significantly different from that for patients who had either marginal or intra lesional excision. Lung metastasis developed in 16 (31%), and all but three of those patients also had a local recurrence [50]. Pan et al. from Xiangya Hospital, China used the SEER database to identify all patients diagnosed with primary spinal chordoma from 1973 to 2014. A total of 808 patients were identified and the overall rate of distant metastatic cases was 8%. Three hundred fifty-seven spinal chordomas (44%) were located in the vertebral column, while 451 (56%) were located in the sacrum or pelvis. Multivariate models showed age ≥60 years, distant metastasis, and non-surgical therapies were independently associated with reduced survival. Tumor site (vertebrae vs. sacrum/pelvis) was not associated with survival for primary spinal chordoma [46]. Kerekes and colleagues from Johns Hopkins, Duke, and the Netherlands completed a systematic review and pooled cohort analysis (1980–2016) of local and distant recurrence in patients undergoing resection of sacral chordomas. They found 57 studies and 1235 cases for review, and noted wide surgical margin was associated with a lower rate of local recurrence; and wide surgical margin, female sex, and patient age ≥65 years was associated with lower rates of distant recurrence [47].

Follow-Up and Observation-Only Patients

There are limited data on which to base any firm recommendations regarding follow-up. In our practice we typically recommend an annual visit with digital rectal examination to assess for recurrence in patients who had benign lesions resected. A pelvic MRI is obtained 1-year post-resection, and then again at 5 years. In the interim, if a mass is palpated, pelvic imaging is performed. For malignant tumors, patients typically undergo an annual physical examination, pelvic MRI, and CT of the chest and abdomen for 5 years. Collaboration with colleagues in medical and radiation oncology is critical as part of postoperative surveillance and need for adjuvant therapy. Recurrences, when they occur, are considered for re-resection if a complete resection is possible.

Patients with small, benign, asymptomatic tumors can safely be approached in a nonoperative fashion and followed if the patient is comfortable with this plan. For cystic lesions, we recommend pelvic MRI every 5 years for a period of 10 years to assess the natural history of the lesion. If little change to the size or morphology of the lesion is noted, longer intervals between imaging can be considered. Decision-making is on a case-by-case basis. Patients should be counseled that if any change in symptoms occur, it should prompt a clinical and radiographic evaluation. For patients with benign solid tumors such as schwannomas, we recommend a similar follow-up.

Conclusions

Presacral tumors represent a rare group of both benign and malignant lesions. Most benign lesions have malignant potential and must be followed carefully if nonoperative treatment is chosen. MRI is the best overall imaging study to assist in diagnosis and operative planning. When performed appropriately and selectively, a biopsy of the lesion may assist in management of solid and heterogeneous cystic lesions. The surgical principles that should guide a surgeon who manages these lesions are a function-sparing approach for benign lesions and an en bloc approach for malignant lesions. Observation alone in some patients is acceptable when a dedicated surveillance protocol is in place. As the discovery of these tumors increases, more surgeons will be asked to evaluate these patients. Given the broad differential and significant implications of mismanagement, presacral tumors should be evaluated and treated by surgeons at centers that have a large experience in managing these complex tumors.

Sporadic and Inherited Colorectal Cancer: How Epidemiology and Molecular Biology Guide Screening and Treatment

22

Sean C. Glasgow and Karin M. Hardiman

Key Concepts

- Colorectal cancer is caused by the accumulation of a variety of genetic alterations in colonic mucosa.
- Colorectal cancer can be hereditary or sporadic (not inherited). Both forms share many of the same genetic alterations.
- Multiple hereditary forms of colorectal cancer have an expected phenotype due to the genetic alteration that increases the likelihood of the cancer.
- Screening algorithms for colorectal cancer differ between hereditary and sporadic cancer based on the time expected for an adenoma to become a carcinoma in that patient.
- Hereditary forms of colorectal cancer are more commonly seen in patients with young onset colorectal cancer.
- Treatment algorithms for hereditary colorectal cancer are directed towards removal of the cancer and decreasing future risk of additional cancers.

Introduction

This chapter outlines the basic molecular biology of both inherited and sporadic colorectal cancer (CRC). An understanding of the molecular mechanisms underlying CRC is important for clinicians, as it explains the epidemiology of the disease and often informs treatment decisions.

Sporadic Versus Inherited Colorectal Cancer

CRC is the third leading cause of cancer-related death worldwide [1]. Cancer can either be inherited, meaning that it is passed down genetically within the patient's family or sporadic, meaning that it was not inherited. This is somewhat simplified because there are clearly families with multiple members with CRC such that it is likely that they carry a genetic propensity for the disease, but no known genetic alteration can be identified on testing. The cause is likely either a genetic alteration that is yet to be identified or a collection in an individual of low-penetrance alterations that each increase risks to a lesser degree. This level of complexity is beyond the scope of this chapter. Most CRCs are considered sporadic, and the genetics of sporadic cancer, in many ways, mirrors that of inherited CRC.

Sporadic Colorectal Cancer

Approximately 80% of CRC is considered sporadic [2]. Sporadic cancers are caused by genetic alterations in the tissue that becomes the tumor, whereas inherited cancers are caused by genetic alterations within the entire patient (germline mutations) that then secondarily lead to further alterations within the tissue that becomes the tumor. These alterations are typically in the same genes and pathways, but the pace and age at which they occur differ.

Epidemiology of Sporadic CRC

CRC is the third most common cancer in the United States and globally [1, 3]. Approximately 47% of cases are in women [3]. Most new CRC cases are in those over age 65 (58%), but 39% of females and 45% of males are diagnosed under age 65. Mean age of colon diagnosis is 68 for men and 72 for women, whereas the mean age of diagnosis of rectal cancer is 63 for both men and women. CRC incidence and mortality vary by ethnicity, with the highest rate in Alaskan Natives (2010–2013 incidence of 91 per 100,000) and African Americans (49 per 100,000) and the lowest in Asian Americans (32 per 100,000). The accumulation of genetic alterations causing CRC is thought to progress over several

years. CRC is most commonly located in the right colon (41%) or the rectum (28%) [3]. Right-sided lesions are more common in older patients, and distal tumors are more common in younger patients. Current endoscopic screening guidelines for average risk patients recommend starting at age 45 with repeat every 10 years if patients are not found to have adenomas. These are based on the typical time to progression from an adenoma to a carcinoma [4].

Risk Factors for Sporadic Colorectal Cancer

The underlying causes of CRC are not clear but likely are an interplay between predisposing genetic factors and lifestyle, dietary factors, and environmental and other exposures including the gut microbiome. Individual studies as well as multiple systematic reviews support the role of diet as a risk factor for the development of CRC. Vieira et al. performed a meta-analysis of 111 studies and showed that the risk of CRC increases by 12% for every 100 g/day increase in intake of red and processed meat and 7% for every 10 g/day of alcohol intake but decreases 17% for every 90 g/day of whole grains and 13% for every 400 g/day of dairy [5]. The particular mechanism whereby diet alters risk of CRC is not known but could, in part, be via changes in the microbiome. The gut microbiome differs significantly between patients with and without CRC [6]. The changes in the microbiome of patients with CRC are more similar to those in people who have a diet high in red meat. In addition to dietary factors, sedentary lifestyle and obesity have been associated with most types of cancer. Increased physical activity to levels concordant with national guidelines resulted in a deceased relative risk of CRC of approximately 19% in a recent meta-analysis [7]. The mechanism whereby sedentary lifestyle predisposes to CRC may be via altered metabolism and oxidative stress [8].

Molecular Biology of Sporadic Colorectal Cancer

Genetic mutations accumulate in the colon and rectum over time as cells replicate in the mucosa of the bowel due to a combination of exposure and somatic alterations. These alterations can be nucleotide changes in the coding region of genes causing the product of these genes to be dysfunctional (as in the case of tumor suppressors), increased function of oncogenes, copy number changes where chromosomes are amplified or deleted, or epigenetic alterations causing altered transcription of genes through promoter methylation (Table 22.1). In general, sporadic CRC can be split into hypermutated tumors, which often have over 1000 mutations and very few copy number changes, and non-hypermutated tumors with fewer mutations and more copy number changes [9]. Because cellular functions are caused not just by individual proteins but by groups of them working together in a pathway, alterations in individual genes can be assessed across known pathways to identify important pathways. In CRC, the recurrently altered pathways are in WNT, MAPK, PI3K, TGF-β, and p53 pathways. Genetic alterations are only clinically relevant if they are shown to be biomarkers of disease or if they can be targeted with treatment. Thus far, most alterations in CRC are neither.

Table 22.1 Sporadic colorectal cancer molecular genetics

Sporadic colorectal cancer	
Topic	Summary
Genetic alterations	CIN: Accumulation of CNV with varied karyotypes from cell to cell and LOH leading to loss of tumor suppressor genes and mutations in key driver genes CIMP: Tumors are hypermutated, BRAF mutation common, widespread epigenetic promoter methylation of DNA Gene point mutations, insertions, deletions: 60–1000's of mutations per tumor
Pathways/ genes	Wnt pathway; *APC*, *TP53*; TGF-β and EMT; *PI3K*
Consensus molecular subtypes	CMS1: MSI immune, 14%, hypermutated, more often right-sided
	CMS2: Canonical, 37%, Wnt and MYC activation, CNV high, more often left-sided
	CMS3: Metabolic, 13%, CNV and CIMP low
	CMS4: Mesenchymal, 23%, CNV high, EMT, worse survival

CIN chromosomal instability, *MSI* microsatellite instability, *CIMP* CpG island methylator phenotype, *EMT* epithelial-to-mesenchymal transition, *CNV* copy number variation

Adenoma to Carcinoma Pathway

In 1990, after in-depth studies of various stages of CRC, Fearon and Vogelstein outlined a model of CRC development that proposed that the progressive accumulation of alterations in the genome caused abnormal growth, starting with normal colonic mucosa, progressing to adenoma and then to adenocarcinoma. This early description described alterations in the genome that were found commonly in certain genes in CRC via mutation, copy number change, or hypomethylation [10]. They highlighted loss of tumor suppressors as well as alterations in oncogenes (Table 22.1). Since that time, our understanding of CRC progression has advanced, but many of the original concepts remain.

Mutations

With the advent of next-generation sequencing came the ability to know the genetic alterations in solid tumors. For any two patients with CRC, they likely share alterations in only one or two genes, as there is substantial inter-tumor heterogeneity in CRC. Because of the inherent genome instability found in tumors, many of the mutations identified in sequencing studies are not clinically consequential. Since so many mutations may occur and they differ from one tumor to another, predictive models are used to determine whether alterations in any one gene are important. These important mutations are called "driver mutations" meaning

that they promote tumorigenesis and tumor progression. The most common driver mutations in CRC have been described in a series of publications and include mutations in *APC*, *TP53*, *KRAS*, and *PIK3CA* [9, 11]. For example, *APC* is the most commonly mutated gene in CRC (72% mutation rate in The Cancer Genome Atlas) and is important as an early driver of adenoma formation. The APC protein acts as a tumor suppressor. Alteration in *APC* causes accumulation of beta-catenin which translocates to the nucleus and binds to LEF and TCF, causing transcription upregulating multiple pathways. In addition, loss or mutation of *APC* can lead to transcriptional activation independent of ß-catenin. *TP53* mutation is the second most common alteration in CRC. It is more commonly altered in patients with more advanced disease and is considered a late driver. It is a tumor suppressor gene because its normal function is to cause damaged cells to stop dividing until the DNA can be repaired and to undergo apoptosis if the DNA cannot be repaired. Mutation or loss of TP53 results in increased proliferation, decreased DNA repair, and decreased apoptosis. Mutations of clinical relevance include *RAS* mutations which occur in about half of patients with CRC including *KRAS* and *NRAS*. These are important because patients with RAS mutations do not benefit from treatment with anti-epidermal growth factor receptor (EGFR) agents [12]. Additionally, around 10% of patients have tumors containing mutations in *BRAF*, which is important because this is a biomarker of worse survival in stage 4 patients [13]. Although BRAF inhibitors can improve outcome in other tumor types with these mutations, in 95% of CRCs are resistant to BRAF inhibition via redundant alterations in the MAPK pathway [14]. Another key pathway in CRC that is especially important in metastasis is the epithelial-to-mesenchymal transition (EMT). [15] EMT is the process whereby epithelial cells acquire mesenchymal properties. This allows the cells to change their architecture, interact differently with their microenvironment, and become invasive. Proteins important in EMT in CRC are ZEB1 and ZEB2, TGF-β, SNAIL, and vimentin. EMT and ZEB2 specifically have such an important role in metastasis that small trials have shown that addition of nuclear ZEB2 staining in CRC to the staging system will improve patient stratification for prediction of outcome [16].

Most tumors contain 100–200 mutations, while about 15% of tumors contain 1000s of mutations. These hypermutated tumors typically harbor genetic or epigenetic alterations in the mismatch repair genes causing rapid accumulation of mutations; thus, they are called hypermutated tumors. The inherited form of this is called Lynch syndrome (LS) which is caused by somatic mutations in the mismatch repair pathway genes and will be covered later in the chapter. Stage for stage, these tumors have better outcome than CRCs without a high mutation burden, and studies have shown that these tumors are responsive to immunotherapy, whereas most non-Lynch tumors are not [17].

In addition to the inter-tumor genetic heterogeneity, there is also intra-tumor genetic heterogeneity whereby different areas of a tumor and its associated metastasis can harbor different mutations and copy number changes because tumors are made up of many genetically related sub-clones [18–20]. These sub-clones can have different abilities and drug resistance profiles with substantive clinical implications.

Chromosomal Alterations

About 85% of CRCs harbor substantial chromosomal alterations. This is called chromosome instability or CIN. Hypermutated tumors, which make up about 15% of tumors, are the exception and have few copy number changes. Common copy number variations in tumors affected by CIN include loss of 8p, 17p, and 18q and gains in chromosomes 8q, 13, and 20q [9, 21, 22]. These gains and losses affect the genes on these chromosomes which can have profound implications for tumors. For example, the tumor suppressor *TP53* is on 17p which is commonly lost.

Epigenetic Alterations in Colorectal Cancer

CpG islands are commonly found in the promoters of genes. When these islands are hypermethylated, the downstream gene can be silenced. This is the mechanism for many sporadic microsatellite unstable (MSI-high, or MSI-H) tumors whereby the promoter of the mismatch repair *MLH1* gene is silenced by hypermethylation [23]. These tumors then lack functional MLH1 protein and then accumulate genetic mutations quickly because they lack this form of DNA repair. This CpG island methylator phenotype (CIMP) is found in sessile serrated adenomas and the cancers that arise from them [24]. These tumors commonly harbor *BRAF* mutations.

Molecular Subtypes of CRC

Due to genetic heterogeneity and differences in the effects of genetic mutations, gene expression is critical in tumor phenotype. In 2015, an international group of researchers published the most comprehensive study to date of gene transcription data from 4151 patients [25]. Using multiple classification algorithms and network clustering, they categorized tumors into four consensus molecular subtypes. These subtypes, called consensus molecular subtype (CMS) 1–4, recognize the heterogeneity that makes up CRC (Table 22.1). CMS1 tumors are hypermutated, MSI-high tumors with a high immune infiltrate. Tumors with an increased number of copy number variations are CMS2–4. CMS2 tumors have alterations described as canonical with upregulation of WNT and MYC targets along with increased expression of EGFR and HER2. CMS3 tumors are classified by metabolic dysregulation and characterized by KRAS

mutations. CMS4 tumors have activated EMT with increased TGFβ, extracellular matrix, and integrins. These classifications have clinical relevance. CMS4 tumors have the worst outcome and CMS2 have the best. The full ramifications of these classifications are yet to come.

Right vs. Left CRC

The right and left colon have distinct embryologic origins as well as differences in their microbiome and exposure to toxins such as bile acids, and thus, it is not surprising that they would have somewhat different molecular phenotypes for tumors developing in the two areas [26]. Right-sided tumors are more likely to be hypermutated and are more common in older patients, whereas left-sided tumors are more likely to be found in younger patients. The sides have different distributions of the consensus molecular phenotypes with CMS1 and 3 subtypes being more common on the right and CMS2 and 4 more common on the left. This has therapeutic implications; whereby early, right-sided tumors have a better prognosis, but once metastatic, they have a worse outcome [27, 28]. This difference based on sidedness with metastasis may be because of the high rate of BRAF mutations in metastatic right-sided tumors which have a poor prognosis. Differences in survival between patients with right- and left-sided tumors may also be due to differences in response to treatment. A 2018 study of response to bevacizumab and cetuximab in metastatic CRC found that primary tumor site was associated with response to biologic therapy [29]. Right-sided primary tumor location was associated with higher mortality regardless of biologic therapy type. In patients with wild-type KRAS tumors, treatment with cetuximab benefited only those with left-sided primary tumors and was associated with significantly poorer survival among those with right-sided primary tumors. This study highlights the need for better understanding of prognostic factors to guide treatment.

Screening for Sporadic CRC

Screening guidelines for CRC directly relate to the time that it takes for a polyp to become an adenocarcinoma and at what age does the risk of developing CRC increase to the point where screening is more efficacious than harmful. If an average-risk patient has a low risk of CRC based on finding no polyps on their initial screening colonoscopy, then another intervention is likely not needed for 10 years. However, when patients are found to have polyps, particularly when there are multiple lesions or high-risk lesions, the patient has proven that for genetic or environmental reasons, they are at increased risk and their screening interval should be shorter.

Treatment for Sporadic CRC

As will be discussed to a greater extent elsewhere, the treatment of CRC is based upon the stage at which it is identified. Early stage intraperitoneal colon tumors (stages I–II) are typically treated with surgical resection alone, whereas later stage tumors, which have demonstrated the ability to move from where they started and invade nearby lymph nodes (stage III) or distant organs (stage IV), are typically treated with chemotherapy either as an adjunct to surgical resection or as a primary palliative treatment. The typical chemotherapeutic regimen used to treat CRC is the combination of 5-fleurouracil, oxaliplatin, and leucovorin (FOLFOX). This combination yields survival benefit for patients with stage III and IV disease. Together, these drugs have a high response rate in CRC. They are not molecularly targeted. Targeted therapies directed at VEGF, EGFR, and kinases are available for metastatic CRC. Many patients are resistant to these drugs, likely due to redundancies between different pathways in CRC such that tumors can increase untargeted pathways to become resistant to targeted therapies.

Young Onset CRC

Epidemiology

In many countries around the world, there is an increasing incidence of CRC in people under the age of 50, referred to as young-onset CRC (YO-CRC) [30, 31]. The incidence of YO-CRC has increased significantly over the past 20 years for unknown reasons. The increase is predominantly left-sided, especially rectal. These patients often present with symptomatic tumors due to the location, and the younger they are, the more likely they are to present at an advanced stage [32]. Due to the increased risk of CRC in young adults, the American Cancer Society has decreased its recommended age to start screening in average-risk patients to 45 years old, but the recommendation by the National Comprehensive Cancer Network (NCCN) to start screening at age 50 has not changed [33].

Management

The assessment and treatment of patients presenting with YO-CRC is similar to tumors in older patients except that they are more likely to need urgent intervention for obstruction [34, 35]. YO-CRC patients have a high prevalence of inherited CRC and should undergo testing. As little is known about differences in treatment response in YO-CRC patients, recommendations for management remain largely unchanged.

Genetics of YO-CRC

YO-CRC patients should undergo genetic testing, as heritable CRC will be found in 16–20% of YO-CRC patients [2, 36]. Many of these patients (75%) will not have a first-degree relative with CRC [2]. The increasing incidence of CRC in those under the age of 50 does not appear to be due to an

increase in inherited CRC, but this is difficult to distinguish given changes in testing and evolution of understanding of the causes of inherited CRC over time. The testing strategy will vary by institution, but testing should be directed by clinical phenotype and family history. If neither point to a particular genetic syndrome, then broader panel testing should be considered. Even for those patients where a heritable form of CRC is not found, the genetics of the tumor itself differ from tumors in older patients. YO-CRC that is sporadic typically has increased copy number change and is microsatellite stable [37]. Lieu and colleagues assessed the mutation rate across 403 cancer-related genes in 18,218 patients and found that those under the age of 50 had more alterations in *TP53* and *CTNNB1* but fewer mutations in *APC*, *KRAS*, *BRAF*, and *FAM123B*. How these and other genetic alterations change the biology of YO-CRC and its response to treatment is yet to be determined.

Inherited CRC

Inherited CRC is defined as CRC that is inherited through the transfer of an increased risk for CRC due to genetic alterations that have been passed on from one's parents. Each inherited genetic alteration causes a somewhat variable phenotype, and each has CRC as a part of the multiple phenotypic expressions of that genotype. Inherited CRC falls into two basic categories, those related to inherited polyposis and those that are not due to polyposis. Patients with polyposis develop polyps of the colon or rectum earlier and in greater number than patients with sporadic polyps. Patients with non-polyposis inherited CRC have an increased chance that a polyp will progress more rapidly to a cancer than a sporadic polyp does. The genetic alterations that cause inherited CRC have, in many cases, not been known before the phenotype of the disease was known, and so the syndromes are often defined by their phenotype rather than the mutation itself, as multiple different genetic alterations can lead to similar phenotypes. When thinking of treatment of these patients, it is important to remember to treat the phenotype of the patient and family rather than only their mutation status since a substantial percentage of patients with an apparently familial cancer will not have a known mutation identified [38]. This is likely due to our lack of knowledge of all the genetic mutations that produce an increased risk phenotype, rather than a true lack of a genetic alteration.

Lynch Syndrome (Hereditary Non-polyposis CRC)

LS is the most common inherited CRC syndrome, with Lynch-associated genetic defects identified in approximately 3% of CRC patients [39]. LS is inherited in an autosomal dominant manner. Family history plays an important role in identifying affected probands and prompting screening of at-risk family members, although establishing the diagnosis of LS requires testing for specific germline mutations in mismatch repair (MMR) genes. Once diagnosed with LS, recommendations for screening and treatment can be tailored for the patient and their at-risk relatives.

The designation of *hereditary non-polyposis CRC* (or HNPCC) denotes a familial CRC syndrome that meets certain criteria based on presenting factors and family history, while the "LS" designation is reserved for patients in whom germline genetic testing confirms specific mutations in MMR genes. The term "non-polyposis" may be misconstrued to mean that LS-associated CRCs do not follow a typical progression from adenoma to invasive carcinoma. On the contrary, most (but perhaps not all) CRCs in MMR-deficient patients do arise from adenomatous polyps. In fact, LS patients have a similar incidence of adenomas as patients with sporadic CRC [40]. However, LS-related carcinogenesis progresses more rapidly than sporadic carcinogenesis, some developing from seemingly normal mucosa in as quickly as a year [41].

Genetic Mutation

The genetic alteration causing malignancy in patients with LS is a defect in the mechanisms for repairing acquired genetic defects. During DNA replication, mistakes are made at a rate of about 1 in every 10,000 bases which is called mismatch. The four major genes responsible for mismatch repair (MMR) are *MLH1*, *MSH2*, *MSH6*, and *PMS2*. In addition, deletions in the 3′ end of *EPCAM* leads to methylation of the promoter region of *MSH2*, resulting in silencing of this gene and clinical presentation similar to genetic mutation of *MSH2* itself. Patients with LS have an inherited defect in a specific MMR gene and then acquire a "second hit" to their remaining functional copy. This leads to complete loss of function of MMR and subsequent accumulation of genetic errors throughout the genome, leading to cancers mostly in organs with a higher rate of cellular turnover such as the colon, endometrium, stomach, and urologic system.

Tumors with defective MMR often display high levels of microsatellite instability (MSI). Microsatellites are tandem base pair repeats in the DNA, typically 1–3 nucleotides in length. Impaired mismatch repair mechanisms allow these microsatellites to proliferate. MSI can be detected using polymerase chain reaction (PCR) assays. Cleaving of DNA during PCR leads to irregular strand lengths at specific intervals and the designation of instability. By definition, tumors that are high in instability measurements (MSI-H) have greater than 30% instability at common loci.

Overall, approximately 15% of CRCs are MSI-H, reflecting a possible deficiency in MMR [42]. However, not all MSI results from inherited mutations in MMR genes. Approximately 70% of MMR deficiency is caused by sporadic hypermethylation of MLH1, leading to suppressed

expression of this particular gene repair product and the subsequent accumulation of genetic damage. Hypermethylation is strongly associated with a specific somatic mutation in the BRAF oncogene (specifically, the V600E mutation) which is found in 69% of hypermethylated tumors; thus, loss of expression of MLH1 should prompt further investigation of the status of BRAF [43]. In general, if a patient has an MLH1-deficient tumor, and a BRAF mutation is found, it is unlikely the patient has Lynch. However, if BRAF is normal, the patient should be considered for germline mutational analysis to look for Lynch-associated mutations.

Clinically, MMR gene function is assessed either by MSI measurement using PCR or direct staining for specific gene products using immunohistochemistry (IHC for MMR). MSI and IHC testing has comparable sensitivity and specificity for defects in MMR gene function; the preferred testing approach is institution dependent, although IHC tends to be less expensive than MSI testing and has supplanted MSI testing in many areas [44]. It is important to note that MSI and IHC testing of the tumor is an evaluation of the phenotype of the tumor itself, and thus neither MSI nor IHC testing confirms the diagnosis of LS. LS is confirmed only by finding germline mutations on subsequent genetic testing.

Additionally, specific patterns of differential expression may be observed. For instance, MLH1 and PMS2 proteins function as a heterodimer; loss of expression of both indicates either an alteration in MLH1 due to somatic methylation (sporadic cancer) or MLH1 germline mutation (as in LS) [45]. For these reasons, loss of expression of MLH1 should lead to further tumor-specific genetic testing. Conversely, functional absences of MSH2, MSH6, or PMS2 typically arise from germline mutations.

Diagnosis and Histology

The initial identification of a "family cancer syndrome" by Henry Lynch and colleagues in 1966 described two Midwestern kindreds who exhibited multigenerational autosomal dominant inheritance of colorectal, endometrial, and other malignancies [46]. The authors noted that family members likely represented "carcinoma-susceptible genotypes." In 1991, the clinical context was further refined by the International Collaborative Group on HNPCC meeting in Amsterdam, with the development of guidelines for identifying potentially affected individuals. These definitions were broadened in 1999 by the Amsterdam II criteria to include non-colonic malignancies. The Bethesda criteria were subsequently developed to better refine which patients may benefit from additional workup with genetic testing. Over the last two decades, additional research has focused on improving the sensitivity and specificity of these parameters. Clinical online or downloadable risk prediction models exist for determining the likelihood a family member of a patient with CRC has LS. Both PREMM5 (premm.dfci.harvard.edu) and MMRpro (projects.iq.harvard.edu/bayesmendel/mmrpro) assess the risk in unaffected individuals. In the setting of a suggestive family history, use of these models may reduce unnecessary genetic testing [44]. Ultimately, routine MMR testing of biopsied or resected CRCs has largely supplanted reliance on family history for identifying potential LS. Figure 22.1 depicts one proposed pathway for reliably confirming LS while eliminating possible confounding conditions. When establishing the diagnosis of LS, it remains important to advise patients of the risk for other family members. Since LS is inherited in an autosomal dominant manner, offspring of the proband have a 50% chance of being affected. Genetic counseling and germline testing are recommended for all immediate family members of LS patients.

As previously mentioned, routine testing for MMR pathway function in resected colorectal and endometrial cancers has become standard in most facilities. The most recent guidelines from the NCCN and the American Gastroenterological Association recommend universal screening for MMR function in all resected CRC specimens [44, 47]. This may be accomplished either with determination of MSI status or IHC staining for MMR proteins. Rectal cancer biopsy specimens should also undergo routine screening, as rectal cancer patients are often treated with neoadjuvant therapy which may interfere with this analysis post hoc. An exciting near-term alternative to sequential MSI or IHC testing followed by germline evaluation is next-generation sequencing of the tumor biopsy itself. Compared to traditional multiple sequential evaluation for LS (e.g., MSI/IHC, followed by germline blood or buccal testing), up-front tumor sequencing demonstrated equivalent specificity and superior sensitivity for LS in a prospective cohort of CRC patients [43]. Next-generation tumor sequencing has the added benefit of off-target testing for other mutations such as *KRAS/NRAS* and *DPYD* that may influence chemotherapeutic decision-making, and it may shorten the time to final diagnosis of LS, thereby providing the surgeon and patient more complete information prior to surgery.

LS-related CRCs have certain phenotypic and histologic findings. MMR-deficient cancers may present at an earlier stage; deficient MMR is seen in 20% of stage II, 11% of stage III, and only 3.5% of stage IV CRCs [45, 48]. MMR-deficient colon cancers more commonly arise on the right side, although MMR-deficient cancers in the descending or sigmoid colon or rectal cancer may certainly occur. Compared to sporadic tumors, LS-associated CRC is more often poorly differentiated and presents with mucinous or signet ring cell features on histology. Tumor-infiltrating lymphocytes (TILs) are commonly observed as well [42]. The robust immune response by TILs relates to the greater expression of tumor-related antigens present in tumors with high mutational rates, particularly the accumulation of

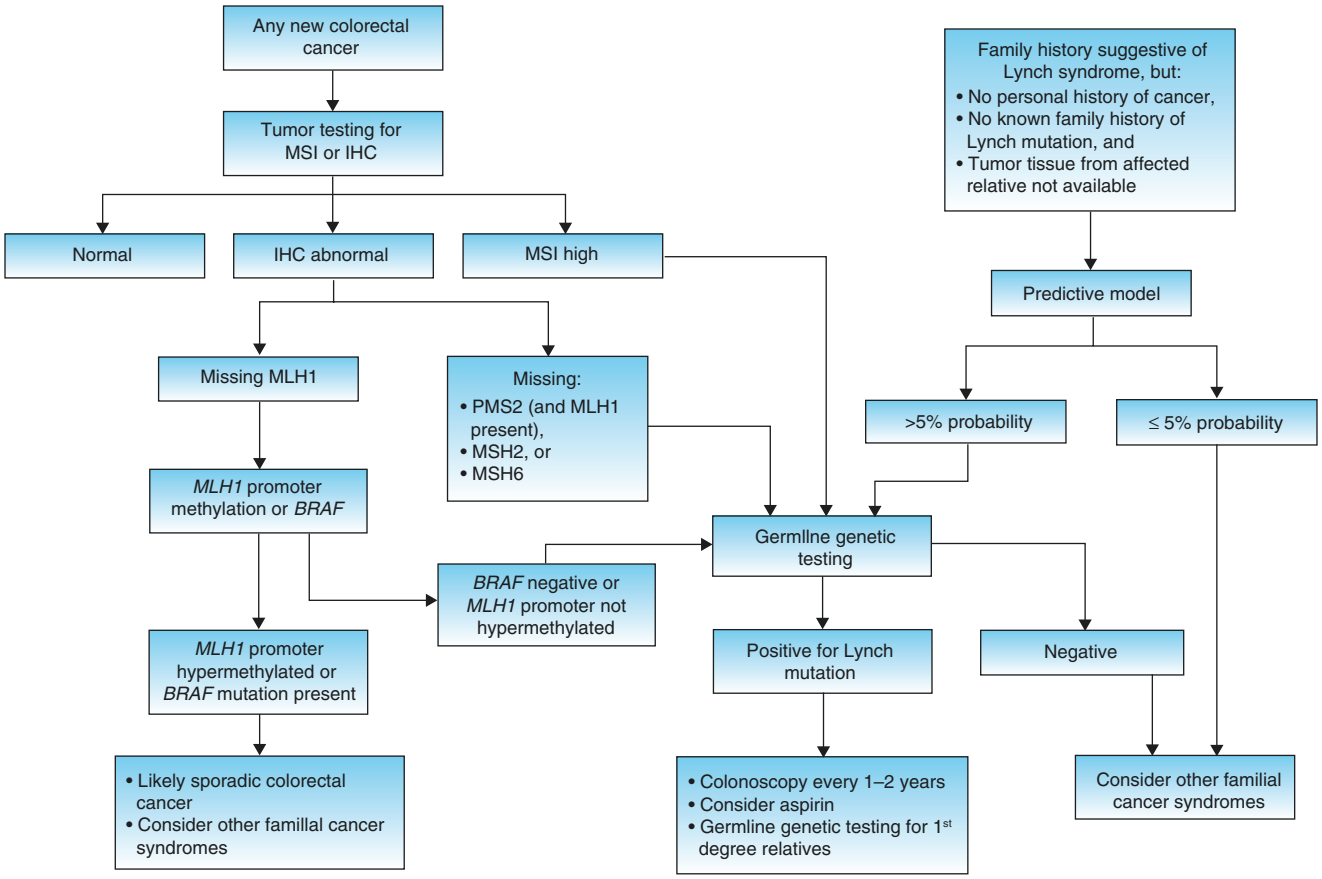

Fig. 22.1 A proposed algorithm for evaluating patients with newly diagnosed colorectal cancer for Lynch syndrome. (Used with permission from Rubenstein et al. [44]. Copyright © 2015 Elsevier)

frameshift mutations that lead to synthesis of neoantigens recognized by CD8+ T cells [42, 49].

Lynch Syndrome Variants

Turcot Syndrome

In addition to CRC, patients with Turcot syndrome develop tumors of the central nervous system. Also termed "brain tumor polyposis syndrome" or BTPS, Turcot syndrome can be due to mismatch repair deficiencies as seen in Lynch (type 1) or related to biallelic loss of the APC gene as seen with familial adenomatous polyposis (FAP) (type 2) [50]. Glioblastoma multiforme is the most common neurological cancer in type 1, while patients with type 2 may develop medulloblastomas.

Muir-Torre Syndrome

Patients with Muir-Torre syndrome (MTS) present with skin structure-related neoplasms, predominantly sebaceous gland tumors. While most commonly caused by loss of genes involved in LS, approximately one-third of MTS may be related to MUTYH-associated polyposis [51]. Sebaceous adenomas and carcinomas are rarely seen outside of MTS, and genetic counseling should be considered for any patient diagnosed with a sebaceous tumor [51]. Use of immunosuppressant medications may unmask MTS as an underlying condition.

Familial CRC X

Patients who meet clinical guidelines for HNPCC based on family history and age at presentation (e.g., Bethesda criteria) but have microsatellite-stable (MSS) tumors are designated as having familial CRC X syndrome. Such patients tend to present at a later age than those with LS, colon cancers occur distally more often, and they seemingly do not have similar risk for extra-colonic malignancies [52, 53]. While the exact genetic mechanism is unknown, unlike LS cancers which tend to have stable chromosomal length, familial CRC X-related cancers demonstrate a high degree of chromosomal instability more similar to sporadic cancers.

Screening Recommendations

Large population-based retrospective studies suggest that while routine biannual colonoscopy reduces the incidence of CRC in LS patients, such surveillance still fails to prevent a substantial number of cancers [39, 41, 54–56]. Conversely, others have shown that high compliance with recommended

screening in LS patients yields cancer-specific survival rates similar to non-affected family members [55]. A recent meta-analysis found that surveillance colonoscopy was associated with a decreased incidence of CRC (OR 0.23) and decreased CRC mortality (OR 0.06) compared to no screening [44]. On average, the simple act of screening increased life expectancy by 7 years. Specifically, for people with mutations in *MLH1* or *MSH2*, the estimated risk of developing CRC over the subsequent 5 years increases from 1 in 71 for males (1 in 102 for females) in their 20s to 1 in 7 for males (1 in 12 for females) by age 50 years [57]. In light of these findings, most experts recommend surveillance colonoscopy every 1–2 years in patients diagnosed with LS. Carriers of MLH1 or MSH2 mutations should undergo screening colonoscopy starting at age 20–25 years; colonoscopy should commence at age 30 for those with MSH6 and no later than age 35 for PMS2 [58, 59].

Women with LS are at increased risk for developing endometrial and ovarian cancers, and after CRC, endometrial cancer is the most common malignancy in LS. MSH6 in particular conveys elevated risk, with a lifetime incidence of over 40% [58]. Based on these risks, female LS patients should undergo annual bimanual exams with endometrial sampling and transvaginal ultrasound starting around age 30–35 years [58]. Such patients should also be counseled on prophylactic hysterectomy and bilateral salpingo-oophorectomy (TAH/BSO) after completion of childbearing, a recommendation supported by a large case-control study of women with Lynch that found 100% risk reduction in subsequent gynecologic malignancy [60]. Strong consideration should be given to concurrent TAH/BSO in LS patients requiring colectomy. Although LS patients are at risk for other malignancies besides colorectal and gynecologic cancers, the estimated lifetime risks for these other malignancies do not exceed 3% regardless of gene mutation [61]. Transitional cell malignancies within the urinary system occur more commonly relative to the average-risk population. Annual urinalysis effectively screens for urothelial cancers. Similarly, there is an elevated incidence of upper gastrointestinal epithelial malignancy; a baseline esophagogastroduodenoscopy (EGD) with patient-tailored surveillance should be done at age 30–35 years, and repeated every 2–3 years, especially in individuals with a family history of LS-related gastric cancers.

Surgical Treatment

Since knowledge of LS-related gene defects may influence recommendations for extent of surgery, it is preferable that biopsies of clinical cancers obtained during colonoscopy undergo routine testing for MMR gene products. If LS is either genetically confirmed or there is a high index of clinical suspicion, patients should be counseled on the surgical options for treating their colon cancer. Multiple studies favor total abdominal colectomy over segmental resection in patients with LS [62–65]. The most recent US Multisociety Task Force on CRC and ASCRS Clinical Practice Guidelines both recommend total abdominal colectomy with ileorectal anastomosis in LS patients [58, 59].

Extended resection reduces the risk for developing secondary colorectal malignancy. A large registry-based cohort study found that the risk of metachronous CRCs increases to over 60% at 30 years [64]. This risk was reduced in LS patients who underwent subtotal colectomy at the index diagnosis. Notably, the observed risk for developing a metachronous colon cancer in the segmental resection group approximated the de novo risk associated with LS, suggesting there was no risk reduction of subsequent malignancy when patients undergo segmental resection only [59]. Kalady et al. found that 47% of patients meeting Amsterdam clinical criteria for HNPCC developed advanced adenomas or CRC following index segmental colectomy at a median follow-up of 69 months, compared to only 19% of those treated with total colectomy [62]. Similar results were reported in a meta-analysis of almost 1000 LS patients; metachronous cancers developed more commonly following segmental vs. total colectomy (23.5 vs. 6.8%, respectively; OR 3.7) [63]. However, no difference in overall survival between the two groups was found. Others have confirmed the lack of demonstrable survival benefit following total colectomy [56].

Factors influencing the decision for less radical resection include tumor stage, age, fecal continence status, anticipated reliability with surveillance examinations, and patient preference. There is little benefit to prophylactic colectomy in patients with incurable stage IV disease. Compared to segmental resection, total abdominal colectomy leads to significantly greater stool frequency and adversely impacts social function [66]. LS patients should be counseled on the anticipated bowel function prior to surgery. Another reasonable option is subtotal colectomy and ileosigmoid anastomosis. Patients would be expected to enjoy nearly the same risk reduction as total abdominal colectomy and would still be able to undergo surveillance via flexible sigmoidoscopy while having improved bowel function.

Patients with LS and rectal cancer may be a group who are best served with segmental resection [59]. The alternative of total proctocolectomy with or without IPAA presents a pronounced functional difference from the patient perspective versus restorative proctectomy. However, the risk of developing a second colorectal malignancy following proctectomy varies between 15% and 27% within the first decade postoperatively, even with regular endoscopic surveillance [67, 68]. In addition to patient-specific features, factors such as the necessity of pelvic radiation and the prospects for sphincter salvage based on tumor location will impact this decision.

Given the significant risk for metachronous CRC, regular colonoscopy on an annual basis is recommended after colectomy [59]. Although no clear benefit has been demonstrated in terms of survival, such intensive surveillance may detect malignancy at an earlier stage [64].

Medical Treatment

Patients with stage III MMR-deficient CRCs are treated with oxaliplatin-based adjuvant chemotherapy (e.g., FOLFOX), similar to those with sporadic tumors [69, 70]. However, single-agent 5-FU-based chemotherapy may be less efficacious in patients with LS, and no survival benefit is seen in stage II MMR-deficient patients, even in the setting of other high-risk features [71]. Interestingly, although CRCs with mutated MMR genes present more commonly with poor differentiation and mucinous features, LS patients experience better stage-matched survival and fewer recurrences compared to sporadic cancers, particularly for cancers in the proximal colon [69, 70, 72, 73]. As mentioned above, MMR-deficient cancers express high levels of tumor-related neoantigens, prompting increased TIL presence [49]. An exciting recent development is clinical application of immune-modulating drugs for fighting solid tumors. Pembrolizumab and nivolumab are specific antibodies to the programmed cell death protein 1 (PD-1); collectively, these drugs are commonly termed immune checkpoint inhibitors [17]. Along with ipilimumab (an antibody against cytotoxic T-lymphocyte antigen 4 (CTLA-4)), these immunotherapies are FDA-approved for treating metastatic CRCs with high microsatellite instability. Evidence suggests that most MMR-deficient tumors respond to immunotherapy but most MMR proficient tumors do not [17]. A confirmatory phase III trial is underway, comparing overall survival from colon cancers with deficient mismatch repair treated with adjuvant FOLFOX vs. FOLFOX plus atezolizumab (a PD-L1 antibody) [45].

Long-term aspirin use seems to reduce the risk of subsequent CRC in LS patients. The CAPP2 randomized controlled trial investigated the utility of aspirin 600 mg/day in patients with LS [40]. Investigators found a 50% reduction in cancer incidence in patients randomized to the aspirin interventional arm over a period of 4 years. Notably, despite regular endoscopic surveillance, 7% of non-aspirin study participants developed CRC during the study. Routine aspirin use is recommended by the American Gastroenterological Association, while the American College of Gastroenterology makes it a conditional recommendation until further evidence is obtained [44, 74].

POLE/POLD1-Related Hereditary Cancer

A relatively newly described syndrome is polymerase proofreading-associated polyposis (PPAP). With an autosomal dominant inheritance and high penetrance, PPAP develops due to inactivating mutations in either *POLE* or *POLD1* [75, 76]. These proteins are members of the highly conserved DNA polymerase family of genes involved with both synthesizing and proofreading DNA. *POLD1* also participates in mismatch repair, and defective polymerase proofreading in combination with deficient MMR can contribute to the phenotype [77]. Patients with *POLD1* or *POLE* mutations exhibit limited adenomatous polyposis and are at increased risk for CRC, and women with *POLD1* mutations have elevated risk for endometrial and breast cancers [78]. No recommendations for screening exist, although frequent colonoscopy and colectomy as indicated based on phenotype seem reasonable [74].

Familial Adenomatous Polyposis

Familial adenomatous polyposis (FAP) accounts for approximately 1% of CRCs. The syndrome is clinically defined by the presence of over 100 synchronous colorectal adenomas. FAP affects men and women equally and has a prevalence between 2 and 3 cases per 100,000 worldwide [74]. Along with extracolonic manifestations as described below, FAP results in a near 100% risk for developing CRC by age 40 years [79]. While there is a strong familial association, de novo cases of FAP account for 25% of the disease, and these patients typically have invasive malignancy at presentation.

Genetic Mutations

FAP is inherited in an autosomal dominant manner with near 100% penetrance. The syndrome is caused by monoallelic mutation of the *APC* gene, a tumor suppressor located on chromosome 5q21. Adenoma formation occurs when the second gene copy is rendered nonfunctional through an acquired mutation or loss. The fact that 85% of sporadic CRCs (and 100% in FAP) harbor *APC* mutations reinforces its central role in progression to malignancy.

Over 800 mutations in *APC* have been described. Inactivating mutations most often occur towards the 5′ end of exon 15 in a portion termed the mutation cluster region. Limited genotype-phenotype correlations exist predicting the course of the disease. For instance, individuals with over 1000 polyps typically exhibit mutation in the mid-portion of the gene (exons 1250–1464). Specific mutations between exons 311 and 1444 predict congenital hypertrophy of the retinal pigment (CHRPE, see below), and mutations after 1444 correlate with desmoid development [80]. Such correlations remain imperfect; although more common with changes in specific coding regions, desmoid disease may occur with almost any described *APC* mutation [81]. No reliable predictors for upper gastrointestinal adenomas are known.

Extracolonic Manifestations

Several extracolonic conditions arise in patients with *APC* mutations. As prophylactic colectomy for FAP has become

widespread, these extracolonic manifestations now pose a greater mortality risk than CRC [82]. Duodenal adenomas develop in 90% of FAP patients, although the lifetime risk for duodenal cancer is only 5–10% [74, 83, 84]. Duodenal cancer usually presents around the fifth decade of life. Depending on location, polypectomy, segmental resection, or pancreaticoduodenectomy may be indicated. Up to 12% of FAP patients develop papillary thyroid cancer, with a female preponderance [85]. Affected patients are also at increased risk for bilio-pancreatic malignancy and hepatoblastoma. CHRPE is a benign finding consisting of black or brown spots on the retina. While no treatment is necessary, the presence of CHRPE may prompt genetic evaluation, since CHRPE is present in nearly 80% of FAP patients [86].

Desmoid tumors are histologically bland-appearing fibrous tumors that arise from connective tissue throughout the body. Approximately 15% of FAP patients develop desmoids.[87] Of these, roughly half will develop intra-abdominally, typically within 5 years of an inciting event such as surgical trauma. Risk factors for desmoid formation include a family history of desmoids, female sex, prior abdominal surgery, and specific mutations with the 3′ end of *APC* (specifically, codons 1399 and 1444) [87]. Notably, desmoids can occur with practically any *APC* mutation [81]. Desmoid behavior is unpredictable; they may grow, remain stable, or even spontaneously regress. Intra-abdominal desmoids may be staged based on symptoms, size, and involvement of other organs [88]. Advanced desmoids may cause mesenteric ischemia, ureteral or gastrointestinal obstruction, compression of the vena cava, and even death. One large single-center study reported a 5-year survival of only 53% in FAP patients with advanced desmoids who required TPN and narcotics [89]. Small or incidentally discovered desmoids may be resected surgically. However, asymptomatic desmoids should be observed to reduce the risk of further progression [88]. Patients with larger desmoids are often treated with NSAIDs such as sulindac and anti-estrogen agents (e.g., tamoxifen) [90]. Antisarcoma drugs (adriamycin/dacarbazine) may be used in extreme cases [89].

Screening Recommendations

FAP patients present with polyps at a mean age of 16 years, with hundreds of polyps developing by the second and third decade of life. Endoscopic screening should start at puberty. Flexible sigmoidoscopy is reasonable until polyps first develop, and then full colonoscopy is required [74]. The vast majority of polyps in FAP are tubular adenomas less than 5 mm in size. Additionally, histological findings unique to this syndrome are microadenomas or aberrant crypt foci, comprised of dysplastic epithelium in single mucosal crypts [91]. Colonoscopy should continue every 1–2 years until after puberty, at which point colectomy is recommended. A similar surveillance program should also be offered to first-degree relatives of FAP patients in whom genetic testing has not been performed or was inconclusive. Establishment of institutional or national FAP registries and screening of at-risk relatives has significantly improved survival [82, 92].

Upper endoscopy to evaluate for gastric and proximal small bowel adenomas should start at age 25–30 years, with frequency of follow-up exams based largely on the Spigelman stage of the visualized polyps. Consideration for annual thyroid ultrasound is on a case-by-case basis. Finally, in families with a history of hepatoblastoma, alpha-fetoprotein and liver ultrasound should be performed in children until age 7 years following genetic confirmation of *APC* mutation [74]. There are no consensus screening recommendations for desmoids.

Variants of FAP

Attenuated FAP

Patients with attenuated FAP (AFAP) typically present with fewer adenomatous polyps (12–100) at later age than FAP patients, with cancer developing between age 50 and 70 years. There may be a predilection for more proximal malignancy, with relative rectal sparing [93]. Mutations in AFAP occur at either the far proximal (5′) or distal ends of the *APC* gene, producing a truncated APC protein and resulting in an attenuated phenotype.[93] Screening with full colonoscopy should commence in the late teens to early 20s and continue every 1–2 years. Although CRC risk is attenuated, upper gastrointestinal polyp formation and risk are comparable to classic FAP [94]. Patients with AFAP can be managed with colonoscopic polypectomy and may not require colectomy. If colectomy is indicated, many patients with rectal sparing are adequately treated with total abdominal colectomy and ileorectal anastomosis, with ongoing surveillance of the rectum [74, 93].

Gardner Syndrome

Largely an antiquated moniker, Gardner syndrome is recognized as a variant of FAP caused by specific *APC* mutations. In addition to polyposis, patients with Gardner may develop osteomas of the jaw or skull, supernumerary teeth, and epidermoid cystic lesions.

Surgical Treatment

Colon screening with subsequent surgery decreases and almost eliminates mortality related to CRC in FAP [74, 95]. Prophylactic surgery timing is guided by polyp burden and size, polyp histology, and symptoms. While not unheard of, CRC before age 20 years is rare, and typically surgical resection can be postponed to early adulthood.

Generally, most FAP patients undergo total proctocolectomy with ileal pouch-anal anastomosis (IPAA). This operation removes the vast majority of polyp-bearing colonic mucosa and substantially reduces subsequent cancer risk.

However, IPAA reduces fecundity in females and has the potential to impair erectile and ejaculatory function in males [96, 97]. Quality of life following IPAA is reduced, and urinary and bowel dysfunction are common complaints [98]. The alternative of total colectomy with ileorectal anastomosis preserves the pelvic nerves and normal reproductive anatomy. This may be an acceptable option in FAP patients with fewer than 20 rectal polyps or in patients with AFAP. However, patients should be cautioned that eventual proctectomy is often required. Furthermore, registry-based data suggests that initial IPAA offers improved long-term survival to FAP patients, with the relative reduction in survival seen with ileorectal anastomosis largely due to the development of metachronous rectal cancer [99]. The rectum should be cleared of polyps endoscopically, and the histology of the polyps reviewed, prior to offering a patient a rectal-sparing operation for FAP. Others have explored using mutation analysis to guide surgery [100, 101]. Based on the site of *APC* mutation, patients having a "severe" genotype had a 61–74% risk of requiring subsequent proctectomy within 20 years of initial total colectomy. Total proctocolectomy with end ileostomy eliminates the risk of CRC.

Regardless of surgical approach, lifelong post-surgical surveillance is required. Annual proctoscopy is needed for patients with ileorectal anastomosis. Adenomas may also develop following IPAA, either in the retained anal transition zone or in the pouch itself [96, 102]. Considerable debate exists over the utility of mucosectomy during IPAA. A large meta-analysis comprised of more than 4100 patients found that nocturnal seepage occurred significantly more frequently in FAP patients who underwent mucosectomy [103]. Conversely, a trend towards more dysplasia was noted in the stapled cohort. Rectal adenocarcinomas have developed after both double-stapled IPAA and mucosectomy/hand-sewn IPAA but are rare, and no firm conclusions can be drawn regarding relative efficacy. As one would do prior to total abdominal colectomy, the transition zone and distal rectum should be cleared of polyps endoscopically, and the histology of the polyps reviewed, prior to offering a patient restorative proctocolectomy using a double-stapled technique for FAP.

MUTYH-Associated Polyposis

First described in 2002, MUTYH-associated polyposis (MAP) is a polyposis syndrome inherited in an autosomal recessive manner [104]. Patients typically present with an attenuated polyposis phenotype, such that the initial clinical definition included between 20 and 99 polyps to distinguish it from the more extensive polyposis seen in FAP. The majority of polyps are tubular adenomas, although tubulovillous and serrated adenomas may also occur [105]. Although most MAP patients will have significant polyposis, some malignancies occur in otherwise normal-appearing colon. Most MAP patients develop CRC in their 40s to 50s.

While significant polyposis is a defining feature, unlike FAP and AFAP, MAP patients do not have an identified *APC* mutation. The MUTYH protein is a base excision repair gene that repairs oxidative damage to DNA by excising oxidized guanosine that mis-pairs with adenosine. Dysfunctional MUTYH results in somatic G-to-T transversions within multiple genes, including *APC* and *KRAS*, leading to the development of colorectal neoplasia. The involvement of multiple genes likely explains the significant clinical heterogeneity in terms of age of onset, polyp type, and progression to invasion. Similar to the MMR-deficient malignancies seen with LS, MAP-related cancers occur more often proximally within the colon, and they tend to have higher rates of mucinous histology and TILs [106]. Likewise, overall survival tends to be better compared to sporadic cancers.

Polyps may be managed endoscopically, although often the disease burden precludes complete clearance. The diagnosis of invasive cancer should prompt total abdominal colectomy with ileorectal anastomosis and subsequent annual rectal surveillance. Patients with MAP-related rectal cancer should be considered for total proctocolectomy.

MAP should be suspected in any patient with CRC in the setting of significant polyposis but without an identified *APC* genetic mutation, or in young patients with a family history suggestive of autosomal recessive inheritance. Unlike other polyposis syndromes, offspring of affected patients have only 1–2% of having MAP since the estimated population incidence of a mutation in *MUTYH* is 1 in 45 [107]. However, siblings of the proband have a 25% likelihood of inheriting biallelic *MUTYH* mutations and should undergo genetic counseling and consider genetic testing, as mutation status may drive screening recommendations.

Patients with biallelic loss of *MUTYH* have a 50-fold risk of developing CRC relative to the general population, progressing to 80% incidence by age 70. Conversely, monoallelic mutation confers a threefold risk [108]. Colonoscopy every 1–2 years is recommend in patients with biallelic inactivating mutations, along with periodic EGD to evaluate for duodenal adenomas. Patients with MAP develop duodenal adenomas at a later age and less frequently than in FAP, although duodenal neoplasia still occurs in roughly one third of MAP patients [109].

Serrated Polyposis Syndrome

Serrated polyposis syndrome (SPS) is the most common polyposis syndrome currently known, found in as many as 1:111 individuals in screening cohorts [110, 111]. SPS increases the risk for CRC and predominantly occurs in patients of European lineage. The overall incidence is unknown but estimated at less than 1% of the population [112, 113]. Previously referred to as hyperplastic polyposis syndrome, the definition was broadened to include other serrated lesions such as sessile serrated polyps and serrated adenomas. SPS may have

considerable phenotypic overlap with MAP; testing for MUTYH mutation is reasonable in the setting of concurrent adenomas. BRAF mutations are also commonly observed. Recently, mutations in the ubiquitin ligase RNF43 have been identified in some families with SPS [114]. However, since the underlying genetic defects in SPS have not been fully elucidated, diagnosis relies exclusively on clinical criteria.

Diagnosis

With the increasing awareness of endoscopists of the malignant potential in serrated polyps, and the concomitant increase in detection and resection, the definition of SPS has evolved. The World Health Organization 2019 definition for SPS is the presence of one of the following conditions: (1) at least 5 serrated polyps proximal to the rectum, with 2 of these being greater than 10 mm in size, or (2) over 20 serrated polyps of any size distributed throughout the large bowel, with at least 5 being proximal to the rectum [110]. Notably, this is a cumulative lifetime polyp count.

Treatment

The lifetime risk for advanced neoplasia from SPS may be as high as 50%, although precise estimates are unknown [74, 112, 115]. Complete clearance of all polyps should be performed during colonoscopy, with a surveillance interval of 1–3 years based on polyp burden. Limited data suggest that intensive colonoscopic surveillance may reduce the risk for CRC developing in patient with SPS [116]. Patients who develop cancer should undergo segmental or total colectomy after informed discussion with the patient regarding risks and anticipated bowel function. Additionally, SPS is strongly associated with smoking [117]. The importance of smoking cessation as a modifiable risk factor should be reinforced in patients meeting clinical criteria for SPS.

Hamartomatous Polyposis Syndromes

While hamartomatous polyps themselves are non-neoplastic, the various hamartomatous polyposis syndromes predispose patients to developing colorectal adenocarcinoma. In addition to increased risk for malignancy, large polyp burden may necessitate surgical intervention for symptoms of gastrointestinal bleeding, obstruction secondary to intussusception, or abdominal pain [118]. Clinical criteria for assigning each syndrome based on phenotype and family history are largely being replaced with genetic evaluation with next-generation sequencing. The hamartomatous polyposis syndrome described below is all inherited in an autosomal dominant manner.

Juvenile Polyposis

Juvenile polyposis (JPS) is inherited most commonly through germline mutation of *SMAD4* or *BMPR1A*. Both these genes function as tumor suppressors within the TGF-ß pathway [119]. Specific mutations of *SMAD4* are also associated with hereditary hemorrhagic telangiectasias. Juvenile polyps may develop in the colon, stomach, small intestine, and duodenum. Polyps develop in the first decade of life; the average age at diagnosis is 18.5 years, when patients typically present with melena or hematochezia [74].

The lifetime risk of CRC in patients with JPS is approximately 40%, although estimates vary and the incidence may approach 68% by age 60 years [74, 120]. Cancer may develop at a young age, so recommendations for screening include initial colonoscopy at age 12 years, or earlier if presenting with symptoms [74]. All polyps should be cleared during each colonoscopy, and surveillance is based on polyp burden. Surveillance should also include regular EGD, as the lifetime incidence of gastric cancer approaches 30%.

Any patient with high-grade dysplasia, invasive malignancy, or polyp burden exceeding ability to manage endoscopically should undergo colectomy. Either total abdominal colectomy with ileorectal anastomosis or total proctocolectomy is acceptable. Patients offered the former option should be reliable and committed to regular flexible sigmoidoscopy of the rectum, as roughly half will require completion proctectomy due to excessive polyp formation [121].

Peutz-Jeghers Syndrome

Unlike JPS, hamartomas seen in Peutz-Jeghers syndrome (PJS) occur most frequently in the small bowel. Though smaller in number, PJS polyps tend to grow to larger size and more often cause symptoms through obstruction or abdominal pain. The majority of PJS patients develop mucocutaneous pigmentation, often seen at the vermillion border of the lips. The findings of perioral pigmentation and two or more hamartomatous polyps should prompt genetic evaluation for *STK11* mutations. This tumor suppressor is mutated in 94% of PJS families, although approximately 25% of PJS arises from de novo mutations [122, 123].

PJS leads to increased risk for both gastrointestinal and extraintestinal cancer. The estimated lifetime risks of developing malignancy are 39% for colorectal, 29% for gastric, 13% for small bowel, 21% for ovary, 10% for cervical or uterine, 9% for testicular, 15% for lung, and as high as 36% for pancreas [74]. The lifetime risk of breast cancer varies in PJS but may approach 50% in some cohorts. Screening for gastrointestinal involvement includes upper and lower endoscopy starting by age 8 years and then repeated every 3 years. Evaluation of the small bowel by either capsule endoscopy or CT enterography is also recommended.

Small bowel obstruction due to intermittent intussusception from a hamartoma develops in roughly 50% of PJS patients [124]. When operating for an obstructing lesion, the surgeon should thoroughly evaluate the remainder of the bowel for smaller polyps. This can be aided with on-table enteroscopy through the open ends of the resected segment.

Similar to other polyposis syndromes, progression to malignancy is best treated with total colectomy with ileorectal anastomosis. The role of STK11 as a tumor suppressor and evidence for unchecked neoplastic growth in its absence has led to efforts at chemoprevention. However, several studies with selective mTOR inhibitors (e.g., everolimus) have been plagued by poor patient accrual due to the rarity of PJS [125].

Cowden Syndrome

Also termed PTEN hamartoma tumor syndrome (PHTS), Cowden syndrome (CS) is caused by mutation of *PTEN*, a tumor suppressor gene involved in regulating intracellular signaling and apoptosis. Bannayan-Riley-Ruvalcaba syndrome is a variant that is also typically caused by *PTEN* mutation. Colonic polyps are found in 95% of CS patients, ranging from few to hundreds in number and distributed throughout the colon [74]. While hamartomatous polyps are the most common, multiple synchronous polyp types are often seen at colonoscopy, including adenomas, inflammatory polyps, ganglioneuromas, lipomas, and leiomyomas.

CS patients have a lifetime risk of CRC of 9–16%, with cancer often developing before the age of 50 years [126, 127]. Those identified with this disorder should start surveillance colonoscopy at age 15 years, followed by repeat exams every 2 years thereafter [74].

Conclusion

CRC is most commonly sporadic with a small percentage of cases being inherited. The genetic pathways involved and treatment of the tumors have substantial overlap, but the surveillance and need for preventive surgery differ substantially based on risk of tumor development.

Management of Malignant Polyps

23

Dennis Yang and Mark H. Whiteford

Key Concepts

- Detailed polyp assessment is the first crucial step in determining the best therapeutic strategy.
- Endoscopic resection of low-risk T1 colorectal cancer is an effective treatment in select patients.
- En-bloc resection is crucial for adequate histopathologic assessment for curative intent.
- Transanal endoscopic surgery is another technique that permits full-thickness en-bloc resection for select malignant polyps or early cancers in the rectum.
- All polyps with predictors of deep submucosal invasion should be referred for surgery given the high risk for lymph node metastasis.

Overview

Colorectal cancer (CRC) remains a clinical problem as the third most common cancer worldwide and the second leading cause of cancer death [1]. Nearly all CRCs (>90%) are adenocarcinomas, and the majority (60–65%) arise sporadically as a consequence of somatic genetic and epigenetic mutations largely attributable to environmental risk factors [2]. A well-recognized characteristic of CRC carcinogenesis is that most cancers arise from benign precursor polyps. These polyps are growths or protuberances into the lumen above the adjacent colonic mucosa [3]. Benign polyps are lesions with dysplastic elements confined to the muscularis mucosa and have virtually negligible risk for lymph node metastasis. Conversely, malignant polyps are defined as lesions with dysplasia extending into the submucosa but not the muscularis propria and are classified as T1 lesions based on the current TMN classification [4, 5]. The key distinction between malignant polyps and their benign precursor lesions is the potential for lymph node metastasis, based on depth of submucosal invasion [6].

Colonoscopy has been shown to reduce CRC incidence and mortality by enabling the early detection and management of malignant polyps and its precursors [7–9]. Detailed lesion assessment is the first key step in directing the optimal endoscopic or surgical approach. In this chapter, we discuss the relative benefits and limitations of both endoscopic and surgical resection of malignant polyps, features associated with curative resection and assessment of lymph node metastasis, and surveillance strategies for patients with T1 colorectal cancers removed endoscopically.

Colorectal Cancer Precursor Lesions

Adenomatous polyps and serrated polyps represent the two main neoplastic subtypes that serve as direct precursors to most CRCs [3].

Adenomas

Adenomas are commonly regarded as the prototypical precursor of CRC, given that nearly 85–90% of sporadic CRCs derive from adenomas [10]. Histologically, adenomas are characterized by epithelial clusters of dysplastic glands and can be divided into tubular, tubulovillous, or villous types as per the World Health Organization (WHO) classification

system [11]. By definition, a tubulovillous and villous adenoma have at least 25% and 75% of its volume with villous features, respectively [11]. Grading of dysplasia in adenomas is currently based on the revised Vienna classification of gastrointestinal epithelial neoplasia [12]. Adenomas with low-grade dysplasia (LGD) have neoplastic changes confined to the epithelial glands. In contrast, lesions with high-grade dysplasia (HGD) are characterized by a constellation of any of the following features: complex glandular crowding and irregularity, cribriform architecture, and severe cytological atypia [12, 13]. The principal distinction between an adenoma with HGD and a malignant polyp is that, in an adenoma with HCD, the dysplastic changes are confined to the epithelium without extending into the submucosa and thereby have no metastatic potential [14]. In general, lesions ≥1 cm, with predominantly villous features and/or HGD on histology are considered "advanced adenomas" with a higher risk of malignant transformation [15].

Serrated Polyps

Serrated polyps are an encompassing designation that includes hyperplastic polyps (HPs), sessile serrated lesions (SSLs), and traditional serrated adenomas (TSAs). HPs are the most common serrated polyp. They are usually less than 5 mm in size and are predominantly located in the rectosigmoid. Endoscopically, HPs are generally oval or round in shape and have a similar color to the surrounding normal colon mucosa. These lesions are often regarded as nonneoplastic. In contrast, both SSLs and TSAs are considered precursors lesions for CRC and may account for up to 25% of sporadic CRCs [10, 16]. Histologically, according to the WHO criteria, the presence of crypt distortion (e.g., horizontal crypts, dilated crypts, serrations extending to the crypt base) is the main feature that distinguishes SSLs from HPs [11]. SSLs are usually larger than HPs, are located predominantly in the right colon, and are characterized by an overlying mucous cap and poorly defined lateral margins on endoscopic evaluation. TSAs are a rare type of villous polyp that features prominent cytoplasmic eosinophilia, elongated nuclei, and ectopic crypts [11, 14]. On gross morphology, these lesions have an erythematous "pine cone" appearance and are mostly located in the distal colon [16, 17].

Colorectal Cancer Carcinogenic Pathways

Adenoma-Carcinoma Pathway

The adenoma-carcinoma sequence, in which the adenoma is the precursor to CRC, represents the "classic" or conventional pathway to CRC. In this stepwise model, gradual cumulative genetic and epigenetic mutations drive the transformation from normal colonic epithelium to adenoma and ultimately invasive cancer [18]. Early in this sequence, alterations in the adenomatous polyposis coli (APC) tumor suppressor gene result in overactivation of the Wnt/β-catenin signaling pathway, initiating dysregulated proliferation and adenoma development [19]. Subsequent "hits" in this classical pathway involve mutations to the KRAS oncogene and loss of function mutations of the TP53 tumor suppressor gene, which ultimately contributes to the progression from HGD to carcinoma [20]. This classical model of colorectal tumorigenesis forms the basis of the chromosomal instability (CIN) pathway [18–20].

Serrated Pathway

Similar to the classic adenoma-carcinoma sequence, the serrated pathway is also characterized by the accumulation of genetic and epigenetic alterations resulting in histological progression. It is widely accepted that the first step in this pathway involves the mutation in a gene that regulates the mitogen-activated protein kinase (MAPK) pathway, such as KRAS or BRAF [21]. Activating mutations of the oncogene BRAF induces both unregulated cellular proliferation through the MAPK pathway and methylation of CpG islands (CpG island methylator phenotype [CIMP]). Many tumor suppressor genes are silenced in the CIMP pathway, which subsequently promotes the progression of serrated polyps to CRC [22, 23].

Definition of Terms: Colorectal Cancer and the Malignant Polyp

CRC is defined as the invasion of neoplastic cells beyond the muscularis mucosa. Polyps with dysplastic elements (e.g., adenomas or serrated polyps) that are confined to the muscularis mucosa and without submucosal invasion do not meet the clinically accepted definition of CRC [5]. Historically, it was not unusual for pathologists to interchangeably use the terms *intramucosal adenocarcinoma*, *intraepithelial carcinoma*, *carcinoma* in situ, and HGD to label these lesions. This practice was rather confusing as the word "adenocarcinoma" can often be easily misinterpreted as being equivalent to CRC [24]. In contrast to any other organ in the gastrointestinal tract, the colonic mucosa is biologically unique in the sense that neoplastic invasion of the lamina propria (histologic area between the epithelium and muscularis mucosa) has negligible risk of lymphatic or distant metastasis [25]. Hence, these lesions, categorized as pT is on the TNM classification, should be considered "benign" and can be adequately treated with complete endoscopic resection without additional interventions [26].

The term *malignant polyp* is used to describe a colorectal lesion with dysplastic elements that appear benign macroscopically but has invaded through the muscularis mucosa and into the submucosa and are designated pT1 lesions according to the TMN classification [4, 5]. Malignant polyps account for approximately 12% of all polyps, and their incidence may be increasing due to the implementation of more effective screening programs [27]. The optimal management of malignant polyps is complex and requires a multidisciplinary approach. The critical initial step in the evaluation and management of malignant polyps revolves around careful lesion characterization, in an effort to recognize selected lesions that may be cured with endoscopic resection versus those that will require surgery.

Lesion Assessment

All colorectal polyps must be carefully examined during endoscopy, and features such as polyp size and location, macroscopic appearance, and pit/vascular pattern should be assessed and documented, as these features direct management decisions.

Polyp Morphology and Size

Lesions are initially characterized endoscopically by their macroscopic appearance (morphology) and size, which are two important features that may help differentiate benign precursor lesions and CRC.

The Paris classification is a consensus system used to describe the gross morphology of neoplastic lesions in the gastrointestinal tract [28]. This classification system, first introduced in 2002 by a multidisciplinary group of experts, has been widely validated and accepted as the standard nomenclature for colon polyps [29]. Based on the Paris classification (Fig. 23.1), lesions measuring 2.5 mm above the surrounding mucosa layer are broadly categorized as polypoid (type 0-I), whereas those measuring less than 2.5 mm are nonpolypoid (type 0-II). Polypoid type 0-I lesions can be pedunculated (0-Ip), subpedunculated (0-Isp), or sessile (0-Is). In general terms, pedunculated polyps are lesions that are attached to the underlying colonic mucosa by a stalk, while sessile polyps grow in a more flattened pattern across the mucosa thereby with less separation between the neoplastic epithelium from the underlying colonic mucosa. Nonpolypoid type 0-II can be further subdivided into those that are superficially elevated (0-IIa), flat (0-IIb), or depressed (0-IIc). Excavated lesions are designated as type 0-III. Lastly, polyps are considered mixed-type lesions if they have a combination of the above features (e.g., 0-IIa + IIc, 0-Is+IIa, 0-Is+IIc). It should be noted that the "0" is usually omitted in clinical practice—for example, an endoscopist is likely to label a polyp "type IIa" instead of "type 0-IIa."

The risk of invasion has been shown to be proportional to lesion size and the degree of polyp depression. In a prospective study of 1000 consecutive colonoscopies with 321 adenomas, polypoid lesions (Paris 0-I) ≤ 5 mm in size had essentially a 0% risk of harboring invasive cancer as compared to 90% in excavated lesions (Paris 0-III) ≥ 15 mm in size [30]. Similarly, in a prospective, multicenter observational study of 479 consecutive patients referred for endo-

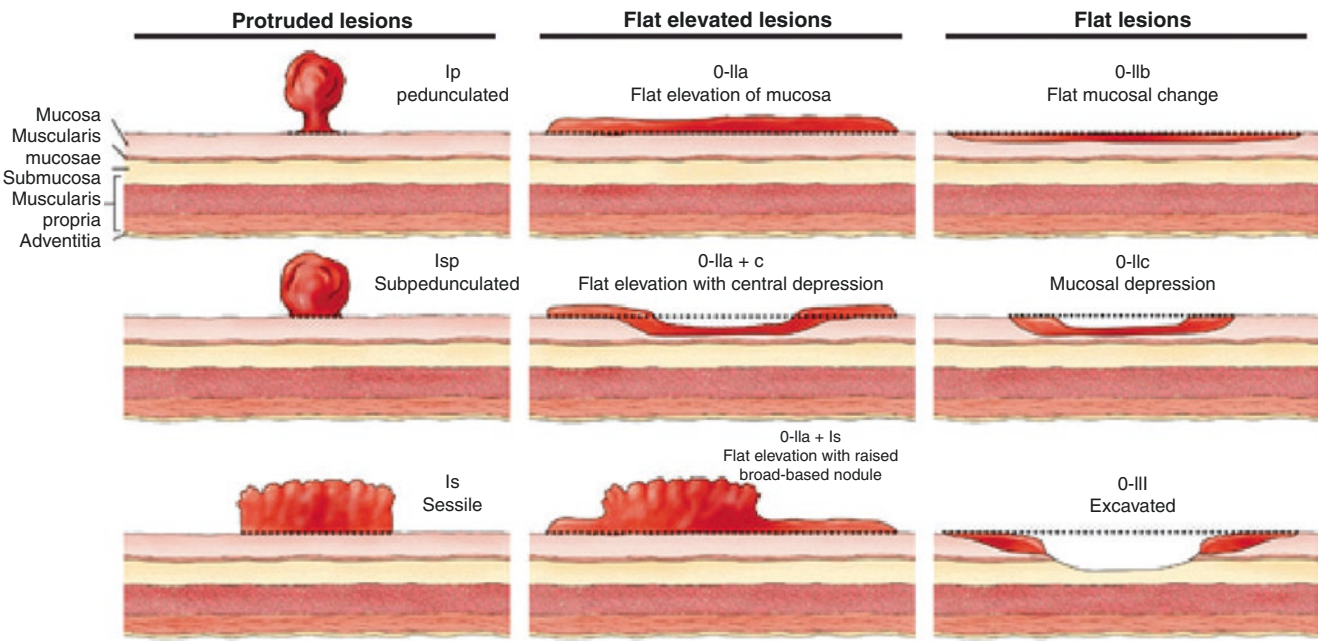

Fig. 23.1 Paris classification of polyps. (Reused with permission Holt and Bourke [95]. Copyright © 2012 Elsevier)

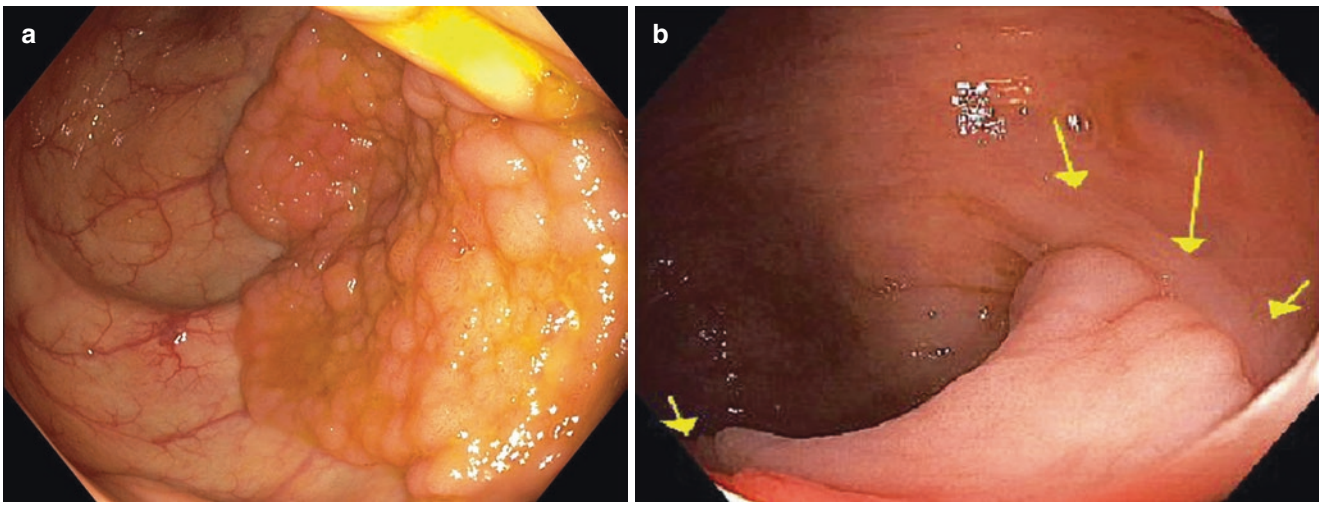

Fig. 23.2 Lateral spreading tumor with granular surface (LST-G) (**a**). Lateral spreading tumor non-granular type (LST-NG) highlighted by arrows (**b**)

scopic resection of sessile colon polyps ≥20 mm, Moss et al. identified lesions with depression (Paris 0-IIa + IIc) to be a risk factor for submucosal invasion [26]. Depressed lesions, particularly those with ulcerations or gross wall deformity should raise the suspicion of a deeply invasive cancer that may not be amenable for endoscopic resection.

Superficial nonpolypoid lesions measuring more than 10 mm in diameter that extend laterally rather than vertically are also referred as laterally spreading tumors (LSTs). The incidence of LST on routine colonoscopy is approximately 9% [31]. LSTs are broadly subclassified into the granular (LST-G) or non-granular type (LST-NG) (Fig. 23.2) [30]. LST-G is characterized by a nodular appearance that can be homogenous or mixed.

Similar to Paris classification, LST morphology is also prognostic for the risk of invasion. Homogenous LST-Gs have a low risk of local invasion (<2%) as compared to LST-Gs with mixed-size nodules (as high as 30% for those measuring more than 30 mm in size) [32]. Conversely, LST-NGs have a smooth surface and can be either flat or pseudo-depressed. The risk of submucosal invasion is even higher in LST-NGs with pseudo-depression, increasing from 12.5% for LST-NGs < 20 mm to 83% in those >30 mm in size [33]. In addition to polyp morphology and size, location is another important factor for risk of submucosal invasion. In a prospective study of 2277 LSTs in 2106 patients referred for endoscopic resection, Burgess et al. identified LST-NG or LST-G mixed-type lesions located in the rectosigmoid colon as having the highest risk for malignancy [34].

Polyp Surface Pit and Vascular Pattern

The shape of the opening of the crypts in the epithelium, or commonly referred to as pit pattern, has been shown to be associated with histologic prediction. Staining the surface of the colon with special dyes (e.g., indigo carmine) during conventional chromoendoscopy (CE) facilitates the evaluation of these pits. However, the main drawbacks include the cumbersome preparation and instillation of dyes, additional procedural time, and the lack of availability of some of these agents in many centers. Many newer generation endoscopes are equipped to enhance imaging by digitally manipulating and filtering the light source, e.g., narrow band imaging. This form of optical digital CE has the advantage of being more readily accessible and convenient to use, as opposed to conventional dye-based CE.

Kudo and colleagues first highlighted the feasibility of examining and classifying pit patterns to distinguish non-neoplastic from neoplastic polyps via magnifying endoscopy [35]. This scheme classifies pit patterns into seven types based on the pit appearance and structure (Fig. 23.3). Type I pits appear as round pits and are characteristic of normal colon mucosa. Type II includes stellate or papillary pits, which often correspond to hyperplasia. Type III-s pits appear as tubular or round pits smaller than in type I, whereas type III-L includes tubular or round pits larger than those in type I. Type IV pits have a dendritic or gyurs-like pattern. Type III to type IV pit patterns are often characteristic of adenomatous polyps, which can be resected endoscopically. Lastly, type Vi includes irregularly sized and arranged pit patterns, while type Vn describes lesions with an amorphous, nonstructured pit pattern. Both type Vi and Vn are indicative of either superficial or deep submucosal invasion, respectively, with only a select number of these cases amenable to endoscopic resection and the rest requiring surgery [36–38].

As noted previously, narrowband imaging (NBI) is a form of digital CE that facilitates detailed inspection of the capillary mucosal pattern by filtering white light into spe-

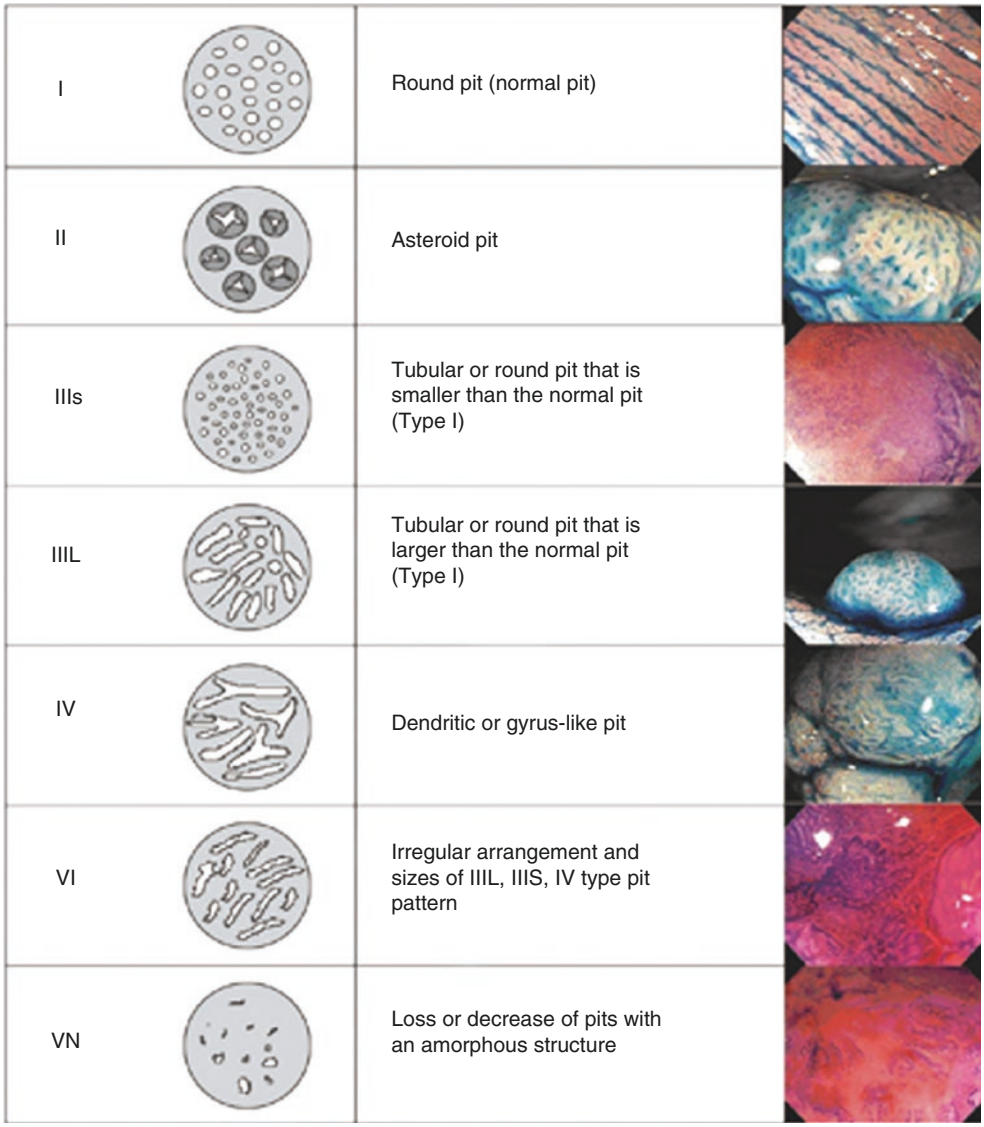

Fig. 23.3 Kudo pit pattern classification. (Reused with permission Tanaka et al. [96]. Copyright © 2006 Elsevier)

cific wavelengths that enhance the superficial microvasculature structures [39]. The Sano classification was the first published NBI magnifying endoscopic classification in 2006 [40] with several validation studies subsequently corroborating its usefulness in both qualitative and quantitative diagnosis of colorectal lesions [41–43]. In addition to Sano, there has been multiple other classification systems introduced in Japan over the years [44]. In an effort to develop a simpler classification system that could be adopted worldwide, particularly in non-Asian countries, the Colon Tumor NBI Interest Group (CTNIG) headed by both Eastern and Western expert endoscopists introduced the Narrow-Band Imaging International Colorectal Endoscopic (NICE) classification system in 2009 [45]. The NICE classification categorizes lesions into three types (1–3, and) based on color, vessels, and surface pattern (Fig. 23.4). Type I lesions, typically hyperplastic or serrated lesions, are characterized by having same or lighter color than the background, none or isolated lacy vessels, and dark or white spots of uniform size. Adenomatous polyps are classified as type II and feature browner color when compared to the background with brown vessels surrounding oval, tubular branched white structures. Lastly, type III lesions show a dark brown background, disrupted or missing vessel pattern, and amorphous or absent surface pattern, which most often corresponds to lesions with deep submucosal invasion [45]. The NICE classification system has been validated as an important tool for neoplasia classification and depth assessment [45, 46]. In a multicenter prospective study of 1634 consecutive patients with 2123 lesions >10 mm in size, the NICE classification identified those with deep invasion with 96.4% specificity [46].

NBI International colorectal endoscopic (NICE) Classification*

	Type 1	Type 2	Type 3
Color	Same or lighter than background	Browner relative to background (verify color arises from vessels)	Brown to dark brown relative to background; sometimes patchy whiter areas
Vessels	None, or isolated lcy vessels coursing across the lesion	Brown vessels surrounding white structures**	Has area(s) of disrupted or missing vessels
Surface Pattern	Dark or white spots of uniform size, or homogeneous absence of pattern	Oval, tubular or branched white structure surrounded by brown vessels**	Amorphous or absent surface pattern
Most likely pathology	**Hyperplastic**	**Adenoma*** **	**Deep submucosal invasive cancer**
Examples			

* Can be applied using colonscopes with or without optical (zoom) magnification
** These structures (regular or irregular) may represent the pits and the epithelium of the crypt opening.
*** Type 2 consists of vienna classification type 3, 4 and superficial 5 (all adenomas with either low or high grade dysplasia, or with superficial submucosal carcinoma). The presence of high grade dysplasia or superficia submucosal carcinoma may be suggested by an irregular vessel or surface pattern, and is often associated with atypical morphology (e.g., depressed area).

Depth of Invasion

The depth of invasion is the most important feature when evaluating resectability and risk for lymph node metastasis. As previously alluded, polyps with dysplastic cells confined to the muscularis mucosa are benign lesions that can be cured endoscopically. Conversely, CRC is defined clinically by the invasion of neoplastic cells through the muscularis mucosa into the submucosa. The depth of submucosal invasion and other histological features often determine the risk of lymph node metastasis and thereby the optimal treatment strategy.

Haggitt Classification of Pedunculated Polyps

In 1985, Haggitt and colleagues introduced a classification system for protruded polyps based on the depth of invasion

[47]. According to this system, lesions are classified as levels 0–4 (Fig. 23.5). Level 0 corresponds to neoplastic cells limited to the mucosa without breaching the muscularis mucosa. It should be noted that the terms "carcinoma in situ" or "intramucosal carcinoma," which were used for level 0 lesions, should no longer be used as these lesions are by definition benign given the negligible risk for metastasis due to the absence of lymphatics in the mucosa layer. Levels 1–3 pertain specifically to pedunculated polyps. Level 1 corresponds to a pedunculated polyp in which cancer cells invade into the submucosa, but these changes are restricted to the head of the pedunculated polyp. Levels 2 and 3 indicate cancer cells invading into neck of the polyp (junction between the head and the stalk) and any region of the stalk, respectively. Lastly, level 4 indicates when cancer cells have invaded into the submucosa of the bowel wall below the stalk of the polyp.

Kudo and Kikuchi Classification of Sessile Polyps

Both Kudo et al. and Kikuchi et al. introduced the concept of classifying sessile polyps into three levels based on their degree of malignant submucosal invasion (SMI): Sm1, invasion into the upper third of the submucosa; Sm2, invasion into the middle third; and Sm3, invasion into the lower third (Fig. 23.6) [48, 49]. This classification system has direct clinical implications, as the risk of lymphatic spread is directly proportional with the depth of submucosal invasion, with the highest risk being in those lesions extending into the deepest third of the submucosa (Sm3) [50]. The main drawback of this system for routine clinical practice is the need of a significant portion of the submucosa within the resected specimen in order to define the deepest border of the submucosa. Most polypectomy specimens are limited to

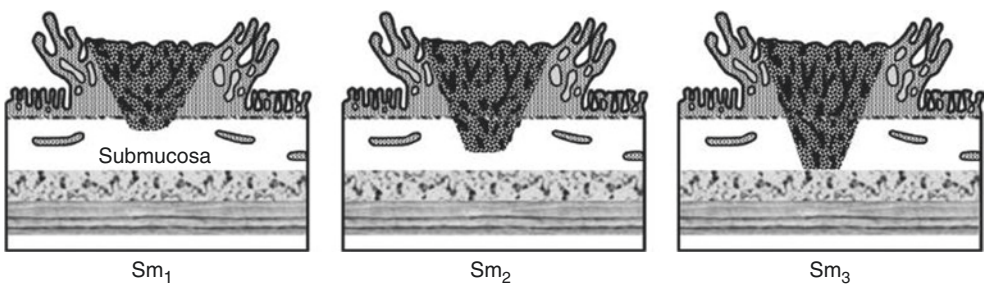

Fig. 23.6 Classification of submucosal invasion (SM) of malignant polyps. (Reused with permission Mohamed and Schofield [98]. Copyright © 2014 Elsevier)

the middle or deep submucosal layer and do not extend down to the muscularis propria, a landmark required to determine SM1, SM2, and SM3 invasion. As such, this classification system has been further modified as to assess risk of metastasis simply based on the depth of SMI from the muscularis mucosa [51].

Depth of Invasion and Risk of Lymph Node Metastases

Kitajima et al. standardized histopathological evaluation of SMI in CRC and determined that in pedunculated lesions, the rate of lymph node metastasis was 0% for Haggitt level 1 and in level 2 or 3 when SM depth was <3000 μm. For all non-pedunculated lesions, the risk of lymph node spread was 0% if SMI was <1000 μM, 3.9% if SMI was <2000 μM, and 17.1% if SMI was ≥2000 μM [52].

Histopathological Factors Influence the Risk of Lymph Node Metastasis in Early Colorectal Cancer

In addition to depth of invasion, several histopathological features have been associated with an increased risk of lymph node metastasis. In a study of 292 early invasive CRCs with surgical resection, Ueno et al. identified potential parameters associated with nodal involvement [52]. Unfavorable tumor grade (poorly differentiated adenocarcinoma and mucinous adenocarcinoma vs well- and moderately differentiated adenocarcinoma), lymphovascular invasion (evidence of cancer involvement of lymphatic and/or venous vessels), and tumor budding (single or cluster cancer cells) were all qualitative parameters associated with lymph node metastasis and unfavorable prognosis with endoscopic resection [52]. Indeed, in a subsequent systematic review and meta-analysis including 23 studies and 4510 patients, the main factors associated with lymph node spread included depth of SMI > 1000 μm (OR 3.87; 95% CI: 1.50–10.00, $P = 0.005$), unfavorable tumor grade (OR 5.60; 95% CI: 2.90–10.82, $P < 0.0001$), lymphovascular invasion (OR 4.81; 95% CI: 3.14–7.37, $P < 0.0001$), and tumor budding (OR 7.74; 95% CI: 4.47–13.39, $P < 0.001$) [53].

Endoscopic Resection of Malignant Polyps

The adequacy of endoscopic resection is dictated by the lesion's risk for lymph node metastasis, given that endoscopic resection does not remove or sample the lymph node drainage basin. Overall, endoscopic resection is the preferred treatment for benign precursor lesions (those without malignant invasion into the submucosa) given the negligible risk for lymph node metastasis and sparing the patient the significant cost, morbidity, and mortality associated with surgery [54, 55]. With advances in endoscopic resection techniques, select malignant polyps can also be adequately removed endoscopically, provided that SMI is <1000 μm and there are no unfavorable histopathological factors [53].

Endoscopic Mucosal Resection (EMR) Technique

In conventional terms, EMR in the GI tract refers to the technique of submucosal injection underneath the target lesion (lift) followed by snare resection. The purpose of the submucosal lift is to separate the target lesion from the underlying muscularis propria as to facilitate endoscopic resection. Submucosal injection also enhances polypectomy by making the tissue easier to resect with a snare; decreases bleeding and perforation risk by increasing the distance between mucosa and muscularis propria layers; and improves the chances of complete resection. Normal saline has been commonly used as the submucosal injection fluid given its safety and low cost. However, more recently, the use of viscous solutions in randomized trials has demonstrated a longer-lasting lift when compared to normal saline [56]. A contrast agent (indigo carmine or methylene blue) is usually added to the injection fluid. This blue-dyed injection fluid allows staining of the submucosa which permits differentiation of the layers of the colonic wall during endoscopic resection and early recognition of any deep injury to the nonstaining muscle wall layer. As liquid is injected into the bowel wall, the loose connective tissue of the submucosa can be separated, and the thin mucosal layer lifted up off of the muscularis propria. The "non-lifting sign," first described by Uno in 1994, refers to the phenomenon whereby a mucosal cancer has invaded into the submucosa and prevents the mucosal layer from being detached and elevated [56]. Non-lifting sign can also be observed when the submucosal layer has been scarred by previous submucosal tattoos, biopsy, or resection attempts.

It is critical to remember that the first endoscopic resection has the highest likelihood for successful complete polyp removal. The location of the injections for submucosal lift is performed strategically as to direct the target lesion toward the lumen and away from any folds. Deflection of the endoscope tip is performed during submucosal injection (known as dynamic injection) in order to help shape the submucosal mound favorably for EMR. Lesions should be removed in as few pieces as safely possible.

Following submucosal lifting, resection during EMR is performed with a snare. There are many sizes and shapes of snares, which usually range between 15 mm and 20 mm in

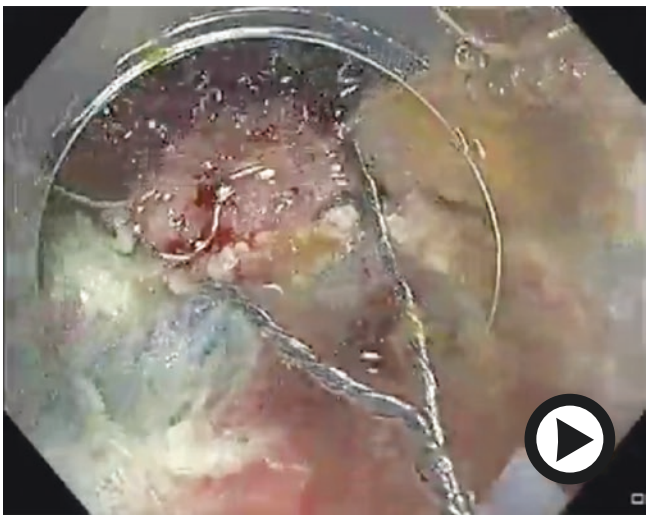

Fig. 23.7 Endoscopic mucosal resection (EMR) of a semi-circumferential lateral spreading tumor granular mixed-type (LST-G mixed) in the ascending colon. https://doi.org/10.1007/000-33d

diameter. Larger and stiffer snares are generally used to remove larger flat lesions. Given the size of the snares, en-bloc resection (one piece) can often be achieved for lesions measuring ≤20 mm, whereas piecemeal resection is required for larger lesions. Accurate snare placement should involve ensuring at least a 1 mm margin of healthy tissue at the perimeter of the polyp. During piecemeal EMR, successive pieces are removed in an orderly fashion, avoiding leaving "islands" of neoplastic tissue within the resection plane. As each section of the lesion is resected, the submucosal resection site should be washed and inspected for bleeding or muscle injury. Finally, prophylactic hemostasis and completeness of polyp removal can be achieved by ablating any visible submucosal vessels or islands of residual polyp with a coagulation forceps (Fig. 23.7).

Outcomes of EMR of Colorectal Polyps

EMR has been shown to be both effective and safe for the management of benign precursor colorectal polyps. In a prospective study of 1134 consecutive patients with mean lesion size of 36.4 mm, EMR was associated with complete resection in >90% of the cases [58]. Delayed bleeding is the most common adverse event, which has been historically reported in up to 7% of patients; albeit recent data suggest that prophylactic clip closure of the EMR resection site may reduce the risk in selected cases [59].

The main limitation of EMR in the management of colorectal polyps is the inability to resect lesions larger than 20 mm in en-bloc fashion. Piecemeal EMR increases the risk of recurrence, with varying rates ranging from 7% to 25% [58, 60]. The factors responsible for polyp recurrence after piecemeal EMR have not been completely elucidated, but incomplete resection at the lateral margins appears to be at the heart of the problem. While recurrence of benign polyps after piecemeal EMR can often be adequately treated endoscopically and new strategies have been introduced to reduce the risk of residual tissue [57, 58, 61], piecemeal EMR of a malignant polyp is considered non-curative. Piecemeal EMR significantly hinders histopathological evaluation, as the fragmented tissue specimens compromise specimen orientation and interpretability of the resection margins. Hence, as per the National Comprehensive Cancer Network practice guidelines, patients with endoscopically curable malignant polyps (limited SMI and favorable histopathological factors) who undergo piecemeal EMR inevitably still require surgery due to the high risk of understaging the lesion owing to the compromised pathological interpretation [62].

Endoscopic Submucosal Dissection Technique

Endoscopic submucosal dissection (ESD) was initially developed in Japan for the treatment of early gastric cancer [63]. The main advantage of ESD over conventional EMR is that it theoretically permits the en-bloc resection of any lesion, irrespective of size. Given its efficacy and safety among expert endoscopists in Japan, ESD has been expanded to include lesions in other parts of the GI tract, including the colon.

Delineation of the target lesion borders is often performed by placing cautery marks lateral to the margins of the polyp. Markings serve as a visual guide during dissection to ensure a negative pathological margin. Following this step, similar to EMR, submucosal injection is performed as to lift the polyp and to create a cushion between the lesion and the underlying muscularis propria. A viscous lifting solution is routinely used during ESD as the longer-lasting mucosal lift has been associated with increased procedural efficiency and safety [64, 65]. Upon completion of an adequate submucosal lift, a circumferential mucosal incision is traditionally performed to penetrate the muscularis mucosa and allow visual identification of the dye-stained submucosal space. After this initial incision, the exposed submucosal tissue is further dissected by repetitive injections and cutting with the ESD knife along the incision margins.

From a technical standpoint, ESD is a complex flexible endoscopic surgical procedure performed through an endoscope, hence, often described as "single-hand surgery with no help from assistants to provide traction." Maintaining adequate visualization of the dissection plane during ESD is often regarded the rate-limiting and most challenging aspect of the procedure. Providing adequate countertraction to expose the dissection field is key, and multiple techniques and novel platforms have been introduced, with promising

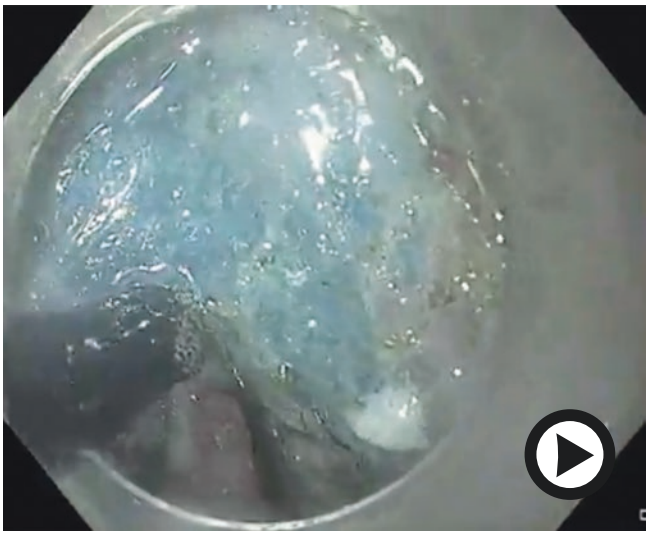

Fig. 23.8 Endoscopic submucosal dissection (ESD) of a large lateral spreading tumor granular type (LST-G) in the rectum using the "pocket-creation" technique. https://doi.org/10.1007/000-33c

results [67, 68]. In addition, one of the challenges during colorectal ESD is the rapid dissipation of the injected fluid from the mucosal incision line. As such, in 2016, the concept of the "pocket-creation" method was introduced (Fig. 23.8) [66]. Unlike conventional ESD in which a circumferential mucosal incision is performed around the polyp initially, with the pocket-creation technique only a small mucosal incision is initially performed. The endoscope is then inserted into this small opening and submucosal dissection/tunneling performed deep to the lesion, which results in less dissipation of the injectate. Following completion of the submucosal dissection, the initial mucosal incision is subsequently extended along the remaining margins of the lesion. In a retrospective study of 887 colorectal lesions treated with ESD, when compared to conventional ESD, the pocket-creation method was associated with higher en-bloc resection rate (100% vs 96%; $P < 0.001$), complete resection rate (91% vs 85%; $P = 0.03$), and shorter procedural time [69].

Outcomes of ESD for Colorectal Polyps

Early case series on colorectal ESD from Asia reported reasonable en-bloc resection rates of approximately 80% but were plagued by the frequency of serious adverse events, including perforation occurring in up to 10% in some studies [70]. However, with the development of dedicated ESD devices as well as improved proficiency in the technique, subsequent large studies from Asia have reported en-bloc and curative resection rates over 90–98%, with perforations occurring between 2.5% and 5% of the cases and <1% requiring surgical intervention [71, 72].

Although ESD has been rapidly embraced in Asia, the transition of ESD to the Western Hemisphere has been slower, particularly due to the technical complexity of the procedure, its steep learning curve, and the relative limited training opportunities in the West [73]. As such, initial studies have demonstrated lower complete resection and higher complication rates when compared to studies originating from Asia. In a systematic review and meta-analysis on clinical outcomes of ESD in 18,764 colorectal lesions, Fuccio and colleagues demonstrated that complete (R0) resection rate was significantly lower in Western vs Asian countries (71.3% vs 85.6%; $P < 0.001$) with a higher rate of both delayed bleeding (4.2% vs 2.4%; $P < 0.001$) and perforation (8.6% vs 4.5%; $P < 0.001$) [73, 74]. In a recent multicenter study from North America, rectal ESD ($n = 171$) was associated with an en-bloc and R0 resection rate of 82.5% and 74.9%, respectively and was curative in 81.8% of malignant polyps with favorable histologic features [75].

For benign and malignant polyps located within the rectum, transanal endoscopic surgery (TES) is a desirable option over flexible EMR and ESD. While ESD of large polyps is largely performed piecemeal and limited to the submucosal plane, TES can be performed in either the submucosal or full-thickness plane and is usually performed en-bloc with low rates of specimen fragmentation (<10%), positive margins (66–93%), and polyp recurrence (5–11%) [76–80]. TES is also feasible for endoscopically challenging polyps such as circumferential lesions and lesions which extend down into the anal canal. The limiting factor for TES is that the instruments are typically not flexible and it may be difficult to reach the proximal rectum [77].

Endoscopic Approach to Malignant Polyps

The first critical step in the management of malignant polyps is detailed lesion assessment as to potentially differentiate those amenable for endoscopic resection and those with features suggestive of advanced disease that will require surgery. As previously described, endoscopic features suggestive of deep SMI may include depressed lesions (Paris 0-IIc), those with surface ulceration/excavation (Paris 0-III) with abnormal/disrupted surface pit/vascular pattern (Kudo classification Type V/Vn and NICE type III). When a lesion with suspected deep SMI is identified, biopsies should be obtained from the portion of the lesion with such features and the patient referred for surgical resection. The site of the lesion should be inked with a tattoo for reference identification during surgery [81]. To improve polyp location at time of surgery, tattoo should be placed in multiple quadrants just distal to the polyp, photographed, and clearly documented in the colonoscopy report. The exception to the previous statement includes pedunculated polyps (Paris Ip) that may have endo-

scopic features of deep SMI limited to the head (Haggitt level 0–2). In these cases, en-bloc resection at the level of the stalk is associated with favorable prognosis [82].

All colorectal polyps without features of deep SMI, including malignant polyps with superficial SMI and favorable histological characteristics, are potential candidates for endoscopic resection. As mentioned previously, en-bloc endoscopic resection is mandatory for the removal of malignant polyps, as assessment of depth of SMI and resection margin status cannot be reliable obtained with a fragmented specimen. Malignant polyps that are 2 cm or smaller can often be removed en-bloc with EMR. For lesions >2 cm in size, ESD is usually required. Following endoscopic resection, the resected specimen should be pinned on a cork board or similar material as to maintain its in situ architecture. Placing the resected specimen in formalin without pinning can result in curling of the edges, which can make differentiation between the lateral and deep resection margins challenging and render the measurement of depth of SMI inaccurate [24, 83]. Endoscopic resection of a malignant polyp is considered curative if the following criteria are met on histopathological assessment: (1) all resection margins are negative, (2) SMI < 1000 μm, (3) well to moderately differentiated tumor grade, and (4) absence of lymphovascular invasion and/or tumor budding [84]. If endoscopic tattoo was not performed at the index colonoscopy, a repeat colonoscopy is necessary within 1–2 weeks and placement of a tattoo to facilitate endoscopic surveillance or intraoperative localization at the time of surgical resection.

Malignant polyps and early cancers located in the rectum are well suited for transanal endoscopic surgery (TES). As with benign polyps, TES can remove the lesion en-bloc. It is also possible to remove rectal lesions in full-thickness fashion where appropriate. This provides a "total biopsy" which permits optimal pathologic evaluation for SM level of invasion, tumor budding, and other high-risk features. Patients then can be better risk stratified and counseled regarding need for repeat endoscopic procedure, surveillance, or radical surgery [85, 86]. The downside of full-thickness resection is the additional morbidity, long-term functional derangements (especially for distal lesions), and the scarring that occurs outside of the rectal wall, which can make subsequent proctectomy more challenging.

Prior to attempting endoscopic resection of a potentially malignant polyp, it is advisable to obtain a carcinoembryonic antigen (CEA) level for surveillance if the lesion is proven to be malignant. Following the endoscopic resection of a malignant polyp, it is often advisable to obtain a baseline cross-sectional imaging (chest and abdominopelvic computed tomography) to exclude the possibility of metastatic disease. While there is no consensus on the timing, experts advise delaying endoscopic ultrasound or cross-sectional imaging at least 3–4 weeks after the endoscopic procedure as to allow the bowel wall to heal and any reactive inflammatory lymphadenopathy to subside [24]. This will avoid the problem of reactive lymphadenopathy being classified radiographically as metastatic spread, which could lead to overtreatment of the patient.

Predicting the Risk of Residual Mural Cancer or Lymph Node Metastasis Following Endoscopic Resection of Malignant Polyp

Assessing the risk of occult lymph node metastasis in T1 colorectal cancers is an imperfect science. There is no single histologic feature that can accurately predict this risk, yet clinicians need some estimate of risk to counsel patients regarding the decision to elect repeat endoscopic intervention, surveillance with watchful waiting, or radical surgical resection. In order to have an informed discussion, it is necessary to estimate both the risk of occult residual cancer and the risk of perioperative surgical morbidity and functional outcomes following surgery. As mentioned previously, prognostic indicators for increased risk of residual cancer include positive resection margin (less than 1 mm, or indeterminant), submucosal invasion less than 1 mm, lymphovascular invasion, tumor budding, and poorly differentiated histology. Multiple unfavorable features are also known to have an additive risk [85, 87].

It is not uncommon for pathology reports to omit many of these features as they have not been routinely included in guidelines for synoptic reports [88]. Ideally, the pathology slides should be reviewed at a multidisciplinary tumor board by dedicated gastrointestinal pathologists to identify and tally the number of high-risk features to better stratify the risk of recurrence. This can then be used to counsel the patient and guide management decisions.

The ACPGBI position statement for management of the malignant polyp provides a useful risk stratification tool (Table 23.1). High-risk histologic features are weighted and then added together to calculate a risk score and estimated risk of residual disease [4]. Over a 3-year period, the tool was utilized to guide the MDTs of a regional cancer network in the UK in the management of 173 patients after endoscopic resection of malignant colorectal polyps. Thirty-seven patients (21.4%) underwent primary surgical resection with a residual disease rate of 43%, while 136 patients managed with surveillance had a 4.4% recurrence [89].

Recurrence Following Endoscopic Resection

Given its higher en-bloc and curative resection rate when compared to EMR, ESD is often advocated as the preferred endoscopic approach for malignant polyps with superficial

Table 23.1 Criteria are based on histological description of endoscopically resected malignant polyp weighted for prognostic significance of each risk factor. Where more than one risk factor is present, the degree of risk is added together to give a total risk score

Histologic criteria		Degree of risk	
Resection margin <1 mm		4	
Resection margin 1–2 mm		1	
Pedunculated: Haggitt level 4		4	
Sessile: Kikuchi 2		2	
Sessile: Kikuchi 3		4	
Poor differentiation		3	
Mucinous tumor		1	
Tumor budding		1	
Lymphovascular invasion		2	
Total score	*Grade of risk*	*Estimated risk of residual cancer*	*Recommended course of action*
0	Very low	<3%	Routine follow-up
1	Low	<5%	Assess other factors, close follow-up
2	Medium	5–10%	Discuss risk/benefit of surgery vs follow-up
3	High	8–15%	Discuss risks, err toward surgery
≥4	Very high	> 20%	Recommend surgery unless patient unfit

SMI (T1 CRC), particularly when larger than 2 cm in size [90]. Several studies have reported on the local recurrence and prognosis following ESD of malignant polyps. In a retrospective study evaluating clinical outcomes of ESD in 310 consecutive colorectal neoplasms, of which 53 were T1 CRCs, disease-free survival was 100%, and no distant metastasis was observed, whereas all local recurrences (2%) occurred in patients with piecemeal resection at a median follow-up of 3 years [91]. Similarly, Yoda and colleagues demonstrated that endoscopic resection of malignant polyps with favorable histological features is associated with excellent oncological outcomes, with 5-year disease-free survival and recurrence of 98% and 0.8%, respectively [92]. Based on these data, patients who undergo endoscopic resection of malignant polyps with favorable histologic criteria should be informed that the risk of residual or recurrent disease, particularly after en-bloc resection, is minimal, but not zero.

Surveillance After Endoscopic Resection

The post-polypectomy surveillance guidelines published in the USA and Europe have been mainly based on the aggregate data on the rate of metachronous advanced neoplasms and CRC death [93, 94]. In the case of endoscopic resection of malignant polyps, the risk of recurrence and/or metastatic disease has been mainly reported to occur within 3–5 years [91–93]. The European Society of Gastrointestinal Endoscopy (ESGE) recommends surveillance colonoscopy at 6 months following piecemeal endoscopic resection of all colorectal polyps larger than 10 mm; however, no definitive recommendation is given specifically for timing of surveillance post-resection of malignant polyps. Since local recurrence is rare following en-bloc resection, the Japan Gastroenterological Endoscopy Society (JGES) suggest that follow-up colonoscopy should be performed within 3 years after resection [84]. While experts suggest that tumor markers, such as carcinoembryonic antigen (CEA) and chest/abdominopelvic computed tomography, should be periodically done for surveillance, there is no consensus on the actual method or the timing of surveillance.

Conclusion

Endoscopic resection of low-risk T1 colorectal cancer is an effective treatment in select patients. Detailed lesion assessment is crucial in determining the best therapeutic strategy. Selected lesions with superficial SMI can be adequately managed with en-bloc endoscopic curative resection with either EMR or ESD. For malignant polyps or early cancers in the rectum, TES is another alternative, which can also provide full-thickness en-bloc resection where appropriate. All lesions with predictors of deep SMI should be referred to surgery given the high risk for lymph node metastasis.

Colorectal Cancer: Preoperative Evaluation and Staging

24

Amanda V. Hayman and Carol-Ann Vasilevsky

Key Concepts

- The method chosen to screen a patient for colorectal cancer (CRC) should be individualized based on patient comorbidities and life expectancy, access, cost, baseline risk, compliance, and tolerance for invasive procedures due to differing costs, sensitivities, and cadences of the various options.
- Defining the anatomic location where the sigmoid colon transitions to the rectum is increasingly determined by cross-sectional imaging due to its reproducibility and is less dependent on endoscopic localization alone, as body habitus and gender can influence the location of the peritoneal reflection.
- Proper tumor localization and staging is essential to establishing treatment recommendations; understanding the pitfalls of each staging modality is important to avoid under- or overtreatment.
- Magnetic resonance imaging (MRI) using a rectal cancer protocol is now standard of care for locally advanced rectal tumors. Endorectal ultrasound (ERUS) is being used less commonly as it is more operator dependent, less reproducible, and invasive for the patient; however, ERUS remains an important staging modality for early stage rectal tumors when determining eligibility for local excision.
- A combination of histologic and radiographic factors should be used to risk stratify CRC; higher-risk tumors should be considered for more aggressive neoadjuvant treatments; however, patient frailty or comorbidities may limit these treatment options and should be individualized.
- Preoperative optimization and preparation of the colorectal cancer patient is essential to maximizing postoperative and oncologic outcomes; a variety of tools, including guidelines and checklists, are available to assist the surgical team in this endeavor.

Diagnosis of Colorectal Cancer

A diagnostic workup for colorectal cancer may follow a positive result from one of the various screening tests available or follow investigation of symptoms, which may be acute or subacute. A positive noninvasive screening test or unexplained iron-deficiency anemia typically prompts colonoscopy, which then detects malignancy. Alternatively, a patient may present with abdominal pain or distension and seek emergent care. Cross-sectional imaging may then demonstrate an intraluminal lesion in the colon or rectum, resulting in further workup.

Screening and Diagnostic Modalities

The ideal screening test for any disease should be easily available, inexpensive, and noninvasive, with high sensitivity and specificity. Because CRC is often asymptomatic, screening tests are universally recommended for patients starting at either age 45 [1] or 50 [2] and ending between ages 75 and 86, based on the patient's life expectancy and health status (see Chap. 22). Once symptoms occur, the disease is typically in an advanced state with poorer survival rates.

There are a myriad of options for CRC screening; the choice for a specific patient should be individualized based on a constellation of factors, including personal and family history of CRC or polyps, family history of inherited CRC

Table 24.1 Summary of the pros and cons of the most commonly used CRC screening modalities

	Pros	Cons
FOBT (fecal occult blood testing)	Inexpensive Noninvasive Reduces CRC mortality by 15–33% Convenient Widely available	Low specificity and sensitivity Requires annual testing Requires dietary/medication restrictions Inaccurate in setting of benign GI bleeding (peptic ulcers, hemorrhoids, diverticulosis) Requires daily testing for 3 days Cannot differentiate between polyp and cancer Positive test requires colonoscopy
FIT	Inexpensive Noninvasive No dietary/medication modification required Higher specificity than FOBT (less chance of false positive for UGIB) Comparable sensitivity to colonoscopy Recommended by USPSTF	Requires annual testing Cannot differentiate between polyp and cancer Positive test requires colonoscopy
DNA-FIT	Every 3 years Covered by Medicare 92% sensitive for all CRC (less sensitive for stage IV)	Expensive, insurance may not cover Minimal long-term data Positive test requires colonoscopy Higher false-positive rates Less sensitivity for adenomas
Colonoscopy	Can differentiate between polyps and cancer Preventative (removes adenomas before they progress to cancer) Diagnostic and therapeutic Highest specificity/sensitivity Longer time interval between tests (up to 10 years)	Requires bowel preparation Invasive with risk of serious complication Typically requires sedation Variable based on endoscopist skill May not be widely available Expensive

syndromes, personal history of inflammatory bowel disease (IBD), medical comorbidities, age/life expectancy, tolerance for risk, anxiety, access to healthcare resources, compliance with follow-up, and insurance coverage/cost.

It can be a confusing discussion for the physician to choose the appropriate screening modality for his or her patients. Understanding the benefits and drawbacks is essential for the patient and physician to make the correct choice. Table 24.1 may assist the healthcare team involved in this decision-making. We cover the available diagnostic and screening modalities for CRC below.

Fecal Sampling

The least invasive and most widely available screening test for asymptomatic, average-risk persons is fecal sampling for occult blood or tumor DNA. This method may be palatable for some patients as it avoids mechanical bowel preparation and is more practical in geographic areas with poor access to endoscopy. These tests do not replace endoscopy, and it should be noted that any positive test usually prompts colonoscopy. However, this initial triage test can conserve colonoscopy for a smaller population. The three fecal-based tests available are discussed below:

- *FOBT* (fecal occult blood test): a guaiac-based test detects presence of heme (nonprotein portion of hemoglobin) and detects blood for all sources (including animal). Patients are instructed to put a smear of their stool on a different stool card 3 days in a row and then mail the cards in. Testing is recommended on an annual basis. This is the oldest stool-based test available and is quite inexpensive. It requires dietary and medication modification for several days prior to the test, including avoiding red meat, raw produce, antacids, vitamin C, nonsteroidal anti-inflammatory agents, loperamide, and iron supplements. Menstruation is a relative contraindication. Relatively low specificity and pretest dietary and medication restrictions have made it less attractive than newer stool tests [3]
- *FIT* (fecal immunochemical test): a.k.a. "safety-chemical" method detects antibodies to the human protein globin portion of hemoglobin found in red blood cells. This results in less cross-reactivity to nonhuman blood and improved specificity over FOBT [3]. It also requires only a single card and thus better compliance. However, it is still a test that is recommended to be performed annually.
- *Multitarget stool DNA-FIT* (Cologuard®) test: combines the FIT test with an additional test that detects genetic mutations found in cancer cells ((KRAS, NDRG4, BMP3, β-actin). It has a 13% false-positive and 8% false-negative rate. It is recommended to be performed every 3 years. It was approved for use in 2014. However, it is relatively expensive ($649 out-of-pocket) compared to other stool assays and may not be covered by insurance. Further, it

cannot differentiate between advanced polyps and adenocarcinoma [4, 5]

Flexible Sigmoidoscopy

Flexible sigmoidoscopy can examine the distal portion of the colon and can be performed in an office setting with minimal preparation and without sedation. Flexible sigmoidoscopy is typically more easily tolerated than rigid proctoscopy and can extend beyond 25 cm. It has been suggested as a screening tool in younger adults since there is a higher incidence of left-sided cancers in this population and was used historically in conjunction with barium enema. It is, however, insufficient in older individuals due to a shift of polyps and cancers to the more proximal colon. As such, it has been combined with FIT or FOBT which theoretically enhances detection.

Computed Tomography (CT) Colonography

CT colonography (CTC or "virtual colonoscopy") is another option available for screening. The technique involves obtaining multiple thin-slice CT images after carbon dioxide insufflation of the colon via a rectal tube, typically in two positions (supine and lateral). The images are reconstructed to give both two and three dimensional views of the colon mucosa. The advantage of CTC is that it avoids the need for sedation and may be preferable for patients with comorbidities who cannot undergo optical colonoscopy or who have a tortuous colon. It does, however, require a full cathartic bowel preparation prior to the procedure, and any suspicious findings usually prompt subsequent optical colonoscopy. Patients are exposed to radiation and may have a risk of contrast nephropathy. It has comparable sensitivity to colonoscopy for polyps greater than 1 cm but is less effective for detecting smaller lesions as they are difficult to differentiate from stool [4]. Since it involves the instillation of air or carbon dioxide into the rectum, it may be associated with abdominal cramping and may rarely result in perforation. It may also identify incidental abdominal findings that may require subsequent additional investigation. Lastly, this test is typically not covered by Medicare. It can be difficult to obtain insurance approval, despite receiving an "A" grade from the US Preventive Services Task Force.

CTC is the procedure of choice in the setting of incomplete colonoscopy due to technical limitations, or an obstructing lesion, and provides better imaging resolution than more traditional fluoroscopic tests (i.e., contrast enema). However, in the setting of a known malignancy, the costs and risks of CTC should be considered in light of how treatment decisions would be altered by CTC findings. If a patient has been diagnosed with CRC and has an endoscopically obstructing tumor of the proximal colon that does not allow for completion colonoscopy, it is unlikely that a CTC will provide any findings that would drastically change management, as the colon proximal to the tumor will likely be resected. For patients with endoscopically obstructing tumors of the distal colon, CTC may be helpful to rule out synchronous tumors preoperatively. However, it is also reasonable to forgo CTC, as these patients will receive staging via CT scan which, although not as sensitive as CT colonography, should at least be able to detect any synchronous large lesions. Furthermore, even if CTC does detect a small proximal lesion, it cannot be biopsied in the setting of a distal untraversable lesion. Therefore, in these settings, the patient's clinical situation needs to be carefully considered regarding the benefit of any further assessment for synchronous lesions. If the patient is to undergo any neoadjuvant treatment, this will hopefully allow completion colonoscopy after tumor shrinkage and prior to surgical resection.

Colonoscopy

Colonoscopy is the most sensitive and specific test for colorectal cancer and polyps, being both diagnostic (i.e., detects polyps and cancers), therapeutic (can remove polyps), and preventive (can prevent polyp progression to cancer). It can also detect other abnormalities, such as inflammatory bowel disease or diverticulosis. However, it is the most invasive option, requiring full bowel preparation, which is associated with nausea, vomiting, abdominal pain, and dehydration, and is generally distasteful. It also carries periprocedural risks, including colonic perforation (0.1%), gastrointestinal bleeding (especially after biopsy or polypectomy), missing a lesion (false negative), or incomplete procedure (either knowingly or unknowingly, which occurs about 5–10% of the time) [5]. Also, the quality of the procedure varies based on the performing physician's technical expertise, which can lead to false negatives. Lastly, most rural areas have lower volume providers and less access to endoscopy overall, often resulting in unacceptably long travel times for patients.

If during colonoscopy a neoplasm is encountered, the endoscopist should then consider the potential benefits of biopsy and tumor localization. For patients with obvious adenomatous neoplasms of the intraperitoneal colon which will clearly require colectomy, it could be argued that biopsy results will be unlikely to change subsequent management and may incur unnecessary cost to the patient, can exacerbate bleeding, carries a risk of perforation, and can have false-negative results that only serve to confuse the patient. However, biopsy may be helpful in detecting Lynch syndrome preoperatively (which may alter treatment decisions)

and help guide chemotherapeutic choices if the patient is found to have incurable distant metastatic disease on preoperative staging and is to be treated nonoperatively. Moreover, insurance companies may refuse to cover the cost of staging tests without a histologic cancer diagnosis. If the etiology of the lesion is in question, i.e., possible lymphoma or ischemic ulcer, then biopsy is warranted. If the tumor is small and unlikely to be appreciated from the serosal side intraoperatively, the distal extent of the tumor should be marked with tattoo to assist with intraoperative localization (see Chaps. 23 and 25).

If a rectal tumor is encountered, biopsy should be performed routinely, and molecular testing including immunohistochemistry for mismatch repair proteins (IHC for MMR) should be performed. Rectal cancer patients are often treated with neoadjuvant radiotherapy and chemotherapy, which may alter the tumor so that molecular analysis is not possible postoperatively. In addition, some medical and radiation oncologists will be reluctant to initiate neoadjuvant therapy in a patient without histologic confirmation of adenocarcinoma. The distal extent of the tumor should be marked with tattoo to ensure complete resection following neoadjuvant therapy.

Delineating Colon Versus Rectum

Where the colon ends and the rectum begins is hotly debated. The various potential modalities used to make this distinction include intraoperative visualization, endoscopy, and cross-sectional imaging. A reproducible definition is important for numerous reasons, including eligibility for clinical trials, localization for serial surveillance of rectal cancer, determining treatment plans (i.e., upfront surgery versus neoadjuvant chemoradiation), and for prognostic estimates. The clinical implications are also critical, since rectal tumors demonstrate clinical features that differ from colon tumors, such as risk of peritoneal disease, lymphatic drainage, threatened radial and/or distal margins, consideration of sphincter preservation, and need for protecting ileostomy.

According to the National Comprehensive Cancer Network (NCCN) Clinical Practice Guidelines in Oncology, the rectum is defined as beginning at a virtual line drawn from the sacral promontory and symphysis pubis on magnetic resonance imaging (MRI) of the pelvis, ending at the upper border of the anorectal ring [6, 7]. The rectum is arbitrarily divided into three parts, based on measurement on rigid proctoscopy: low (0–6 cm from the anal verge); mid (7–11 cm), and high (12–15 cm) (Fig. 24.1) [8].

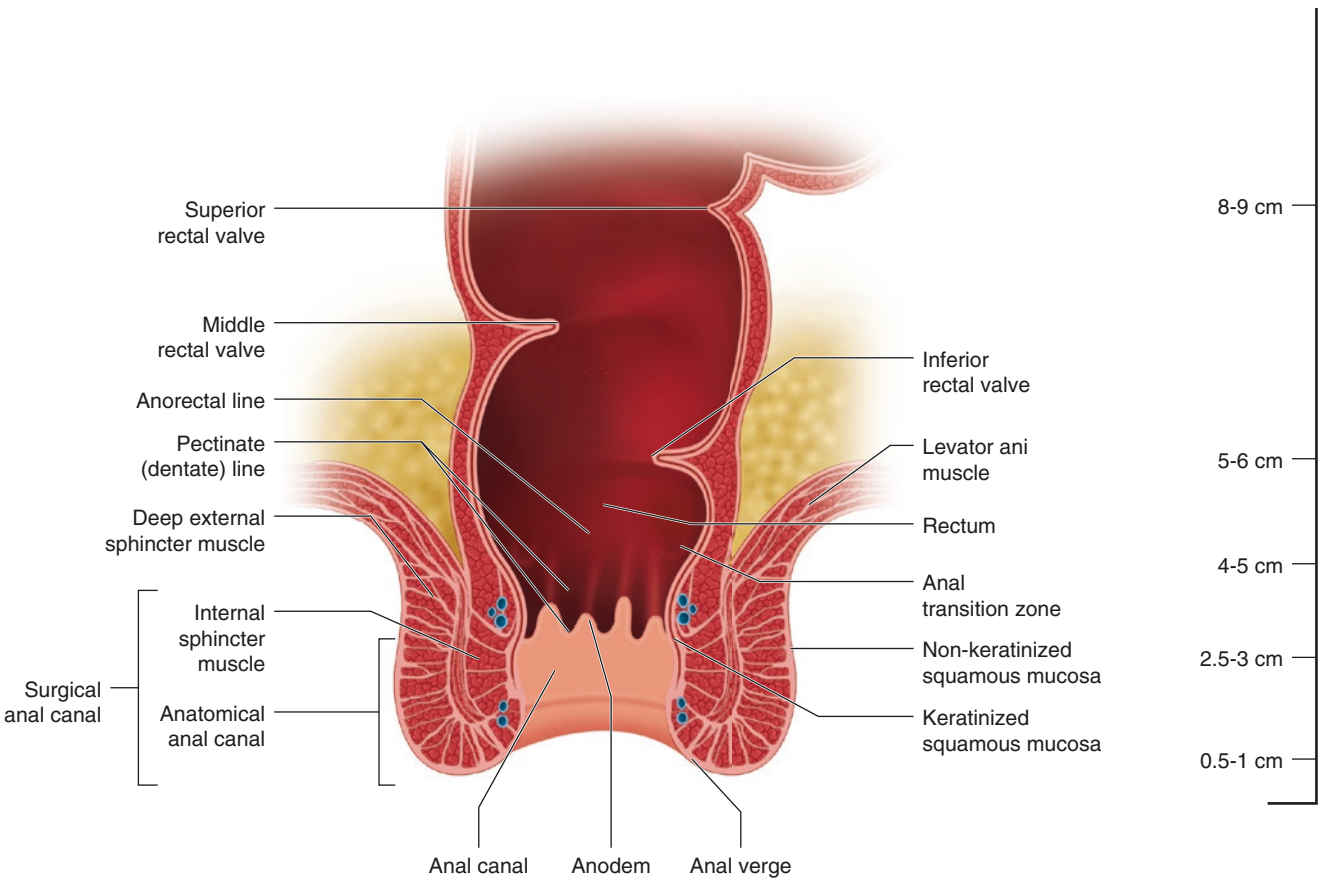

Fig. 24.1 Delineation of the low, mid, and upper rectum with relevant landmarks

Table 24.2 Commonly used criteria for delineating colon from rectum

Intraoperative/ Surgical Criteria	Cross-sectional imaging (CT/MRI)	Endoscopic
- where the teniae splay - where the epiploica terminate at the peritoneal reflection (varies by gender) the sacral promontory	- a delineating line between the sacral promontory and the pubic symphysis - the sigmoid "takeoff" from the rectum (i.e., end of the mesorectum), seen as an acute angulation	- distance from the anal verge on rigid proctoscopy (typically 12 or 15 cm) - beyond the third rectal valve

Initial National Cancer Institute consensus guidelines [7] used 12 cm via rigid proctoscopy in the left lateral decubitus position as the commonly accepted cutoff for the rectosigmoid junction. However, an international Delphi consensus concluded that the "sigmoid takeoff" should be utilized, as seen on cross-sectional imaging, marking a shift from a single clinician's physical evaluation to a radiographic one [9]. One of the drivers behind this transition is the growing use of MRI in staging newly diagnosed rectal cancers, buoyed by the growth of programs such as the National Accreditation Program for Rectal Cancer (NAPRC) [10], newer staging guidelines, and criteria for clinical trial eligibility, all of which favor, or even require, MRI for initial staging. The purported benefit of using MRI versus endoscopic evaluation for staging is that imaging is more reproducible and thus more easily interpreted and comparable over time in multidisciplinary discussions such as tumor boards. However, there is still clear variation in all these definitions and a wide variety of clinical implications for each modality, which will be discussed later on in the chapter. In Table 24.2, we compile the most commonly used criteria for delineating the colon from the rectum.

Adding to this complexity is a newer algorithm for treating locally advanced colon cancer with upfront chemotherapy, as seen in the recently published FOxTROT trial [11]. This is also an option for bulky upper rectal cancers and is in line with NCCN guidelines [7]. Although in daily practice it can be challenging to definitiviely differentiate a colon from a rectal location of the tumor, every attempt should be made to do so as the clinical behavior and treatment recommendations differ.

Staging and Workup of Colon and Rectal Cancer

Once the diagnosis of colorectal cancer has been established, the extent of locoregional and distant spread should be determined. Many of the staging examinations are similar for colon and rectal cancers. However, the locoregional staging of rectal cancer does involve additional evaluation. Appropriate staging is especially important for rectal cancer as it drives treatment decisions in order to minimize under- or overtreating the tumor, both of which have future implications with respect to prognosis and quality of life (see Table 24.3).

TNM Staging

Both colon and rectal cancers are staged according to the American Joint Committee on Cancer (AJCC) TNM staging system, eighth edition [12], which is based on the depth of invasion of the tumor (T stage), the extent of lymph node involvement (N stage), and the presence of distant metastases (M stage) (see Table 24.4). For rectal cancer, staging requires consideration of both the initial clinical stage upon which treatment decisions are made and the final pathologic stage which may be the most important prognosticator (Table 24.5) [13]. The prefix "c" for clinical is added to denote an *estimate* of stage based typically upon radiographic imaging, and "p" is added to denote histologic staging postoperatively, while the prefix "yp" is used to denote histologic staging following neoadjuvant treatment [12].

History

Initial workup should include a complete tumor-specific history, such as duration of symptoms, abdominal or pelvic pain, rectal bleeding and its characterization whether mixed in with stool, bright red or maroon in color, tenesmus, incontinence, change in bowel habits (new onset constipation, diarrhea, frequent thin stools), and weight loss. Patients may also present with fatigue, shortness of breath, and reduced endurance during exertion due to iron-deficiency anemia. Urinary problems, baseline fecal continence, and sexual function should also be ascertained with regard to rectal cancers. In addition, family history should be elicited to rule out the possibility of a hereditary or familial syndrome which

Table 24.3 Diagnostic workup of primary rectal cancer

Parameter	Method of choice
Location (distance from anal verge)	Digital rectal exam (DRE) Rigid sigmoidoscopy
Visualization of colon	Colonoscopy Virtual colonography
Morphological verification	Biopsy
cT stage	
-Early	ERUS, MRI
-Intermediate/advanced	MRI, preferred over ERUS
-Sphincter infiltration	MRI, DRE, ERUS
cN stage	MRI preferred, CT, ERUS
M stage	CT chest and abdomen, PET/CT if extensive EMVI for other sites

Table 24.4 American Joint Committee on Cancer (AJCC) TNM Staging Classification for Colorectal Cancer 8th ed, 2017

T-PRIMARY TUMOR	
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ invasion of lamina propria
T1	Tumor invades submucosa
T2	Tumor invades muscularis propria
T3	Tumor invades subserosa or into non-peritonealized pericolic or perirectal tissue
T4	Tumor directly invades other organs or structure and/or perforates visceral peritoneum
T4a	Tumor perforates visceral peritoneum
T4b	Tumor directly invades other organs or structures
N -REGIONAL NODES	
Nx	Regional nodes cannot be assessed
N0	No regional lymph nodes identified
N1	Metastasis in one to three lymph nodes (tumor in lymph nodes measuring ≥0.2 mm) or any number of tumor deposits are present, and all identifiable lymph nodes are negative
N1a	Metastasis in one regional node
N1b	Metastasis in two to three regional lymph nodes
N1c	No regional lymph nodes are positive, but there are tumor deposits, i.e., satellites in the subserosa or in non-peritonealized pericolic or perirectal soft tissue without lymph node metastasis
N2	Metastasis in four or more regional lymph nodes
N2a	Metastasis in four to six regional lymph nodes
N2b	Metastasis in seven or more regional lymph nodes
M -DISTANT METASTASIS	
M0	No distant metastasis
M1	Distant metastasis
M1a	Metastasis confined to one organ-liver, lung, ovary, non-regional lymph nodes without peritoneal metastasis
M1b	Metastasis in more than one organ
M1c	Metastasis to the peritoneum with or without other organ involvement
T categories Although these categories have not changed, and T4 was divided into T4a and T4b in the previous edition, further clarification that tumors with perforation in which tumor cells are continuous with the serosal surface through inflammation are considered to be T4a. In the lower rectum, in the absence of peritoneal covering, tumors that invade or directly adhere to adjacent organs or structures are considered T4b.	
N categories There is a discussion regarding isolated tumor cells in lymph nodes and micrometastases. Isolated cells consist of up to 20 cells within subcapsular or marginal sinus of a lymph node should be designated N0 (or NOi+), but their presence does not change the state to stage III. Micrometastases are clusters of 20 or more cells or metastases measuring >0.2 mm and <2 mm in diameter. Lymph nodes with micrometastases are considered positive and designated N1. Outcomes in tumors with nodal micrometastases ranging from 0.2 to 2 mm are similar to those with metastases >2 mm; thus the designation of N1mi is unnecessary. The interpretation of discrete tumor nodules found within the lymph drainage area of the primary rectal carcinoma is clarified. Nodules that contain no identifiable lymph tissue or vascular/neural structures should be considered tumor deposits and designated N1c. Tumor deposits within a vessel wall should be considered lymphovascular invasion with the site-specific designations of L+ for lymphatic or small vein invasion and V+ for deposits in endothelial cell-lined spaces with associated red blood cells or smooth muscle cells. If tumor nodules are found around neural structures, they are classified as perineural invasion. N1c changes the disease to stage III even in the absence of nodal metastases. The number of deposits has no influence on the designation and is not added to the number of positive nodes.	
M categories M1c which denotes peritoneal metastases has been added	

Key changes to AJCC staging of colorectal cancer [12]

would prompt genetic counseling and testing. Comorbidities must be ascertained in order to establish suitability for surgical procedures or chemotherapy. The patient may warrant a cardiology or pulmonary assessment, nutritional consult, and, if appropriate, a geriatric evaluation including frailty screening [14] prior to recommendation of treatment. Past surgical history should also be queried since this may affect choice of future surgical approach.

Physical Examination

On physical examination, the abdomen should be assessed for previous scars, as well as palpable masses, hepatomegaly, or abdominal distention, especially in the presence of suspected obstruction. If the patient has a thin body habitus and a large intra-abdominal luminal mass, it may be possible to palpate the mass on abdominal exam. In the presence of a high-grade obstruction, the patient may present with abdom-

TNM Staging System for Colorectal Cancer 8th ed., 2017

inal distention and pain. For distal rectal tumors, perhaps the most important diagnostic test is a thorough digital rectal exam (DRE). If the lesion is palpable, the surgeon should determine and document: percentage of luminal circumference involved; quadrant(s) involved; distance between the distal margin of the tumor and the superior aspect of the anorectal ring; tactile characteristics (firm versus soft, mobile versus tethered versus fixed, etc.), and involvement of other structures (anal sphincter muscles, posterior vaginal wall, levator muscles, prostate). In addition, DRE allows the evaluation of sphincter bulk and tone, which is important should restorative proctectomy be considered. DRE is limited in that it can only be used to assess distal tumors that are within range of the examining finger and may be also limited by patient body habitus.

Proctoscopy

Proctoscopy should be performed by the operating surgeon to determine the exact location of any tumor reported to be in the rectosigmoid by the endoscopist at index colonoscopy, prior to initiation of treatment. This examination is critical, as determination of tumor location at index colonoscopy is often inaccurate [15]. This is especially true for tumors described as being in the "sigmoid" or "rectosigmoid" which are subsequently found to be in the mid or distal rectum [15]. For rectal cancers, it is important to clearly delineate tumor location relative to anatomic landmarks in order to determine if sphincter-sparing surgery would be an option and to mark the distal extent of the tumor with tattoo (see above). It is also useful as a surveillance tool to assess tumor response to neoadjuvant therapy. Proctoscopy can be performed in clinic without sedation, with only an enema preparation in most patients. Rigid proctoscopy requires less equipment, but one cannot see beyond 25 cm, and it can be challenging to see lateral lesions. Furthermore, it can be quite uncomfortable for some patients and technically difficult in patients with a larger body habitus. Video flexible proctosigmoidoscopy is better tolerated by the patient and allows for photo documentation of tumor morphology and location; however, it is still subject to the vagaries of exact delineation of distance as previously mentioned .

Colonoscopy

Colonoscopy is required to fully evaluate the colon after the diagnosis of a colorectal malignancy or unresectable polyp has been made to exclude synchronous cancers which may occur in 3–5% of patients with primary rectal cancer as well as synchronous polyps which occur in as many as 30% [16]. In general, sufficient biopsies of the tumor should be obtained to confirm both the diagnosis of cancer, as well as to obtain tissue for immunohistochemistry to ascertain biomarkers which may guide chemotherapeutic options and prognosis.

Occasionally, there are conditions that may preclude a complete examination of the colon preoperatively, such as the presence of an obstructing lesion or perforation. In some cases, a water-soluble contrast enema could be considered in patients who present with acutely obstructing tumors of the left colon or rectum, in order to rule out distal synchronous large lesions and help prep the distal colon should intraoperative colonoscopy be required. CT with rectal contrast is generally preferred over water-soluble enema due to three-dimensional perspective, but typically the patient has already received a CT in the emergency room, so the risks of a repeated scan must be weighed against the benefits. Evaluation of the proximal colon may occasionally be obtained via CT colonography in cases of partial obstruction or deferred until the postoperative period or after reversal of a diverting ileostomy. If a patient presents with a completely obstructing colon or rectal cancer and either diverting loop colostomy or Hartmann's resection are performed, completion colonoscopy can be performed prior to resection or Hartmann reversal via both limbs of the stoma or via the colostomy and rectal stump to ensure that a synchronous tumor or polyp will not be ignored at the time of reanastomosis. Another feasible option in the face of an obstructing lesion is the placement of an endoscopic stent, which allows the opportunity for biopsy and can serve as a bridge to surgery following resolution of the obstruction, as well as facilitate pre-treatment colonoscopy (See Chap. 25).

Tumor Localization

Endoscopic tattooing is recommended for all colonic lesions for surgical localization. Endoscopic measurements either via landmarks or centimeters from the anal verge are notoriously inaccurate. With the exception of the cecum, which has distinct, reproducible anatomic landmarks (ileocecal valve,

appendiceal orifice), the standard recommendation is submucosal tattooing with India ink distal to the tumor in at least two quadrants.

However, because referring endoscopists may differ in their routine practice, it is imperative that the surgeon communicate with the endoscopist regarding if and how a tumor was marked with tattoo. This is especially important in the setting of a malignant polyp that has been completely removed endoscopically and is later found to have invasive carcinoma, typically to the endoscopist's surprise. In this situation, the endoscopist should repeat the colonoscopy as soon as possible in order to detect the polypectomy scar and tattoo just distal to that site. This can be quite challenging in the setting of multiple polypectomies and may require multiple tattoos, which poses treatment dilemmas for the operative surgeon [17, 18]. It is always favored to have the index endoscopist perform the repeat colonoscopy for tattooing as that individual will have the greatest chance of accurately localizing the polypectomy site in question. These cases are often best managed by a multidisciplinary discussion with the surgeon and the endoscopist. Fortunately, even when the polypectomy site may not be visible to the naked eye on endoscopy, once the surgical resection specimen has been fixed, it can often be detected pathologically, confirming resection of the appropriate segment.

As noted above, rectal tumors must be accurately localized prior to initiation of neoadjuvant treatment since assessment of distal resection margins after treatment is often difficult due to downstaging of the tumor. A few caveats should be mentioned. Tattooing with India ink for rectal cancer has been found by some investigators to be inaccurate with error rates ranging from 2% to 21% [19]. It should be remembered that submucosal tattoos that are placed preoperatively are often difficult to visualize from the abdomen because of the thick mesorectum. Some authors have suggested that submucosal rectal wall tattoos be placed in the operating room at the time of resection to accurately mark the distal resection margin [20], although this may not be possible in the setting of complete clinical response, which is why placement of tattoo at the time of diagnosis is favored. Unlike for intraperitoneal colon cancers, tattoo of extraperitoneal rectal cancers will primarily be visible during intraoperative endoscopy, and a flexible colonoscope/sigmoidoscope or rigid proctoscope should be available for localization during resection. Several case reports have also raised the issue of potential tumor implantation by improper endoscopic tattooing directly through the tumor, which obviously should be avoided [21]. In addition, tattooing may induce altered appearance of the rectal wall on MR or reactive lymphadenopathy, with possible resultant overstaging on MRI [22]. Thus, if a rectal tumor was not tattooed at diagnosis, it is optimal to obtain staging MRI and CT prior to marking the tumor endoscopically with ink. If tattoo is placed transmurally, it can render resection more difficult because the dye can obscure normal anatomic planes [23]. As such, preoperative clipping has been suggested as a feasible alternative; however, clips carry the risk of falling off [19].

Blood Work

Blood work including complete blood count, basic chemistry, and carcinoembryonic antigen (CEA) should be obtained. CEA is used as a prognosticator whereby levels <5 ng/ml have been found to have better prognoses stage for stage as opposed to CEA ≥5 ng/ml [24]. Moreover, normalization of previously elevated CEA levels in patients who were treated with neoadjuvant treatment has been associated with complete pathologic response [25]. CEA levels that fail to normalize post-resection should raise the suspicion of metastatic or residual disease. CEA should be routinely measured during surveillance of patients posttreatment since elevation of previously normal levels may signal the development of recurrent or metastatic disease. Routine testing for transaminases, bilirubin, and/or alkaline phosphatase, unless indicated for other reasons, is not necessary preoperatively as they have been found to be neither sensitive nor specific for the diagnosis of liver metastases and are no longer routinely recommended by NCCN for staging or surveillance [6], although their use is still advocated by the European Society of Medical Oncology [26].

Imaging

Computed Tomography (CT) Scan

Initial staging includes CT scan of chest, abdomen, and pelvis in order to detect the presence of synchronous metastatic disease which may be present in 30% of patients at presentation. CT scan of the chest is used to determine the presence of lung metastases and to set a baseline for any preexisting suspected benign lesions [7]. Its overall accuracy in detecting lung metastases is 84% with a sensitivity and specificity of 73% and 74%, respectively [27]. CT will also detect indeterminate pulmonary lesions in 4–42% of patients; however, upon further evaluation, only 1% are eventually confirmed as metastases [28]. Abdominal CT will indicate the presence of liver metastases, which may occur in 20–34% of patients [7]. CT is the most common imaging modality used to stage metastatic disease with an estimated sensitivity of 85%, positive predictive value of 96%, and false-positive rate of 4% [29]. For liver lesions measuring <10 mm, MRI outperforms CT because of enhanced soft tissue resolution [30]. CT may also demonstrate tumor-related complications such as perforation, obstruction, and invasion of adjacent organs and should be done with both oral and IV contrast whenever possible. If a patient has an iodine allergy, they can be prepped with steroids and diphenhydramine. In the case of renal insuffi-

ciency, an alternative is to obtain a non-contrast CT of the chest with a gadolinium-enhanced MRI of the abdomen and pelvis. Another alternative is positron emission tomography (PET) with 2-[18F] fluoro-2-deoxy-D-glucose (FDG) with fused CT imaging (PET-CT), as discussed below [13].

In general, CT cannot accurately predict metastatic spread to mesocolic or mesorectal lymph nodes. With regard to rectal tumors, CT cannot routinely determine depth of invasion or mesorectal fascial involvement, primarily because CT is unable to distinguish between tumor extension and peritumoral fibrosis. In addition, assessment of tumor involvement of adjacent organs or the pelvic sidewall is often inaccurate. The primary value of CT is its ability to detect distant metastases.

PET-CT

PET-CT is not generally recommended for initial staging of colorectal cancers but may be used to assess equivocal findings on CT scan, to rule out extrahepatic disease with established hepatic metastases when radical surgery is being planned, to confirm features associated with a high risk of metastases such as EMVI (extramural vascular invasion) on MRI or high CEA levels, and in patients with a contraindication to intravenous contrast as previously mentioned [7]. FDG (fludeoxyglucose) accumulates in malignant tumors as well as in inflammatory tissue and adenomas, thus is less sensitive with a potential for false positives [13, 31], such as in necrosis following radiation therapy. False negatives have also been reported in mucinous tumors [13], because of the relatively low cell/tumor volume ratio or any lesion <10 mm.

Rectal Cancer-Specific Staging Modalities

Appropriate staging is essential for rectal cancer, since many current treatment algorithms are driven by estimates of tumor stage. Accurate staging is paramount when considering neoadjuvant therapy, chance of future sphincter preservation, and eligibility for clinical trials, including the choice of definitive chemoradiotherapy ("watch and wait") for complete clinical responders (see Chap. 28). Following clinical staging, patients should be discussed at a multidisciplinary tumor board consisting of surgeons, medical oncologists, radiation oncologists, pathologists, and radiologists so that the most efficacious recommendations can be made for each individual patient.

Endorectal Ultrasound

Endorectal ultrasound (ERUS) and MRI are the main modalities used for local staging of a rectal cancer. ERUS involves the insertion of a water-filled balloon into the patient's rectum allowing a full circumferential view of the lumen. The five layers of the rectal wall are defined. These include (1) the area between the balloon and the mucosa, (2) mucosa and muscularis mucosa, (3) submucosa, (4) muscularis propria, and (5) the area between the muscularis propria and perirectal fat. Thus, theoretically, this modality is highly useful in determining T stage since it is able to depict invasion of the rectal wall layers (Fig. 24.2). It is technically challenging due to the necessity of constantly having to adjust the angle of the probe in relation to the rectal wall due to the presence of clot or stool that may prevent its apposition to the rectal mucosa. In addition, bulky tumors may constrict the lumen and not allow for adequate balloon distention. As such, there is a reported variation in the accuracy of ERUS in predicting

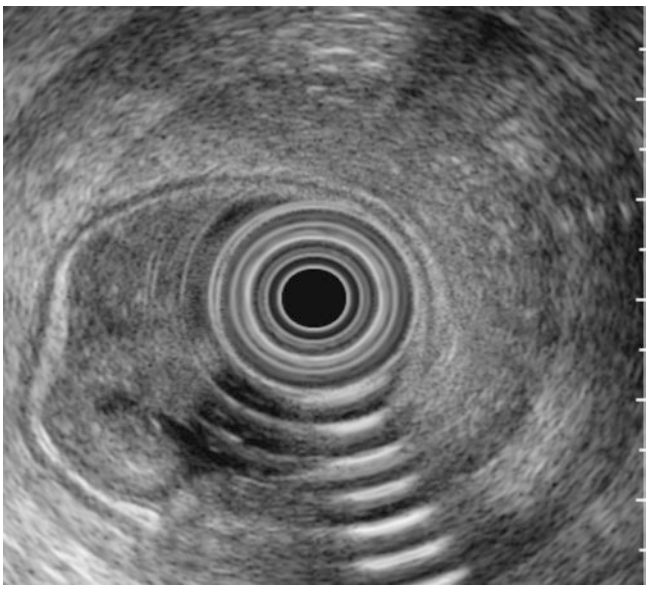

Fig. 24.2 Endorectal ultrasound of T1 tumor. (Courtesy of Lehel Somogyi, MD)

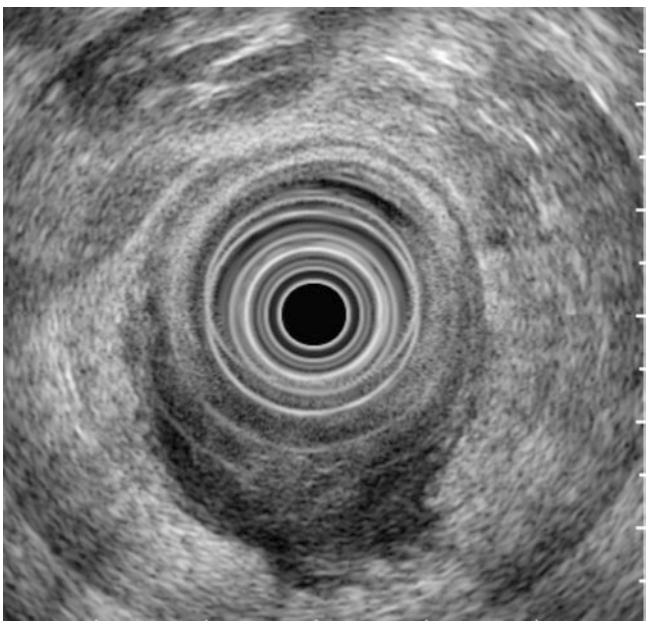

Fig. 24.3 Endorectal ultrasound of T3 tumor. (Courtesy of Lehel Somogyi, MD)

T stage ranging between 63% and 96% [32]. Although an earlier published meta-analysis of 42 studies of 5000 patients who underwent ERUS for rectal cancer staging found a pooled sensitivity of 81–96% and specificity of 91–98% for T stage [33], more recent data have shown a decline in T stage accuracy ranging from 55% to 82% (Fig. 24.3) [30].

Limitations of ERUS are that it is operator dependent; has difficulty differentiating between peritumoral inflammation versus desmoplastic reaction, especially after biopsy; and thus has difficulty in differentiating between a T2 tumor that invades the muscularis propria from an early T3 with microscopic infiltration of the perirectal fat, and some patients may require a cathartic bowel preparation if enemas cannot clear the rectum of stool [32]. Its advantage is that it may be able to differentiate T1 from T2 tumors. ERUS has an accuracy of 73% for T1 lesions with a sensitivity of 71% and specificity of 100% [34]. ERUS may also be able to stratify T1 tumors. Sessile T1 lesions have been subdivided on the basis of the depth of submucosal invasion into sm1 (slight submucosal invasion), sm2 (intermediate between sm1 and sm3), and sm3 (invasion into lamina propria) [35]. Since its main use is in the differentiation between T1 and T2 tumors, ERUS should be performed if local excision is being contemplated, where local excision is considered appropriate for low risk T1 cancers, but not favored for T2 cancers (see Chap. 27). However, it may be difficult to during ERUS to visualize the mesorectal fascia except at the level of the vagina or seminal vesicles, and thus it is suboptimal for determination of the predicted circumferential resection margin (CRM) when performing standard mesorectal excision, which may be the most important component of staging for locally advanced tumors [36]. As current multimodality treatment of rectal cancer mandates precise evaluation of the mesorectal fascia, the major limitation of ERUS is its inability to accurately define it.

In assessment of nodal status, ERUS has been found to have an accuracy of 75% (Fig. 24.4). The main limitation in assessing lymph nodes is the lack of criteria available to discriminate between malignant and inflammatory nodes. The 5 mm size criterion used to define a malignant node has a poor predictive value when compared to histology [37].

Rectal Cancer-Specific Pelvic MRI

High-resolution MRI is the recommended imaging modality for accurate locoregional staging of rectal cancer. The standard rectal cancer MRI protocol includes thin-slice, high spatial resolution T2-weighted images in order to encompass the rectal tumor and the surrounding perirectal tissues and mesorectum [30] obtaining images in three planes of view: oblique axial perpendicular to the tumor; sagittal determined by the longitudinal axis; and oblique coronal plane parallel to the anal canal (Fig. 24.5a, b). The routine use of an endorectal coil or endorectal contrast is not advised as its use may stretch the rectum thus hindering accurate interpretation of mural invasion. Although the addition of intravenous gadolinium contrast does not uniformly improve diagnostic accuracy, several studies have demonstrated that the addition of gadolinium resulted in the alteration of 24% of treatments due to downstaging of T stage which obviated the need for neoadjuvant treatment [38]. In addition, it may improve detection of extramural vascular invasion (EMVI) [23]. MRI provides information on tumor size, location, relation to the sphincters and peritoneal reflection, evidence of EMVI, and, most importantly, on the predicted circumferential resection margin (CRM). The CRM is the lateral or radial resection margin and is defined as the closest distance of the tumor to

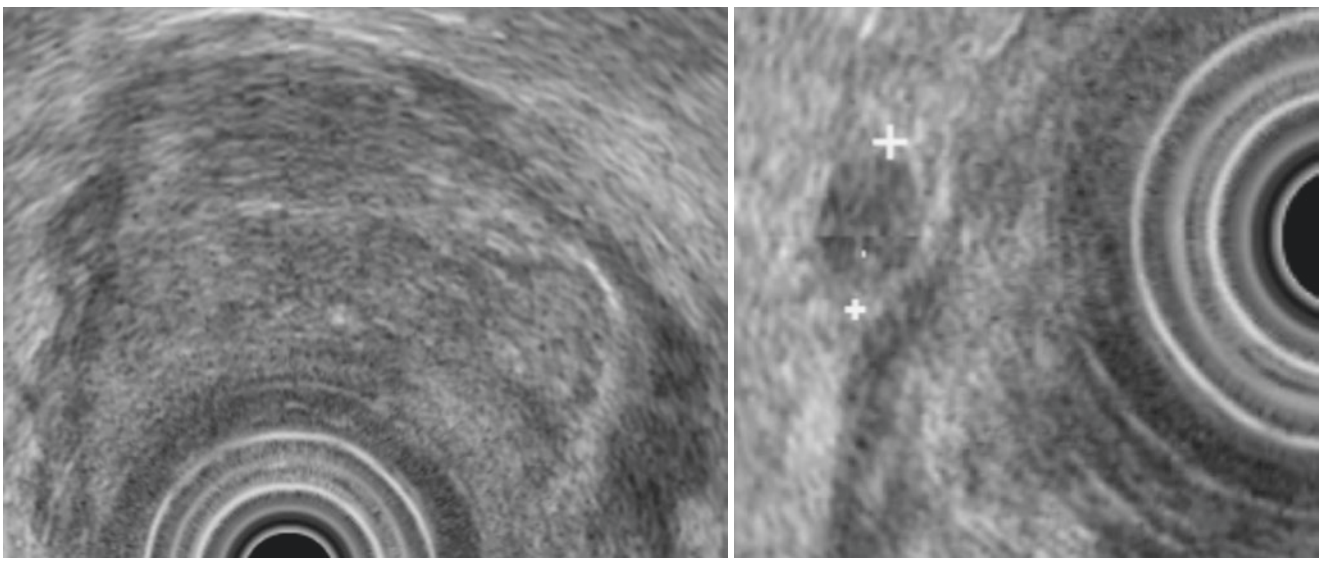

Fig. 24.4 Endorectal ultrasound of T3N1 tumor. (Courtesy of Lehel Somogyi, MD)

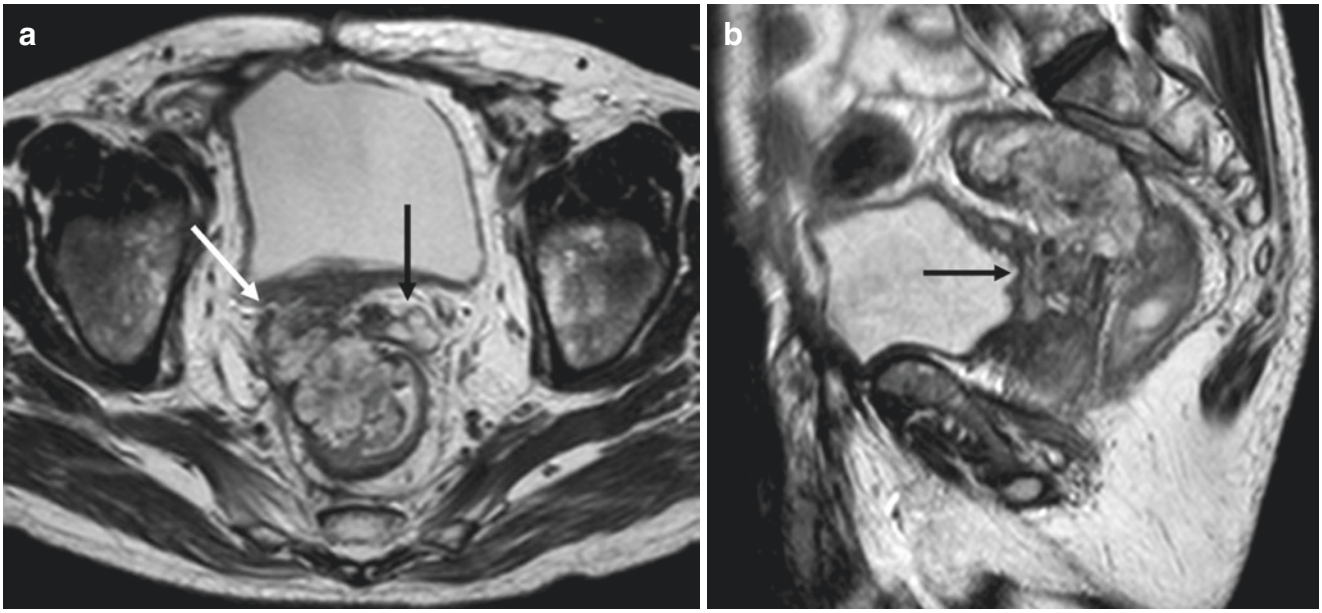

Fig. 24.5 MRI of a T4 tumor. (**a**). Axial and (**b**). sagittal T2 images show a bright, therefore mucinous, rectal cancer with direct invasion of the right seminal vesicle (white arrow); black arrow shows the normal left seminal vesicle which is fluid filled. (Courtesy of Vincent Pelsser, MD)

the mesorectal fascia. The CRM is considered to be positive when the tumor extends within 1 mm or less of the mesorectal fascia (Fig. 24.6a–e). With neoadjuvant treatment, tumor retraction from the CRM is regarded as an good prognostic feature (Fig. 24.7a–c) [36]. Local recurrence rates are higher with positive CRM. MRI is superior to ERUS for assessing the CRM because of its ability to identify the mesorectal fascia. MRI was found to have sensitivity for CRM involvement of 77%, while specificity was 94% [39]. CRM assessment by high-resolution MRI was the only preoperative variable that significantly predicted local recurrence, disease-free, and overall survival in one study [40]. A negative CRM is associated with a 67% 5 year survival versus 47% with a positive CRM.

The accuracy of T stage has been found to improve with increasing T stage (Fig. 24.8a, b). However, as is the case with ERUS, there is variability in the ability to discriminate between a T2 and an early T3 lesion, often misinterpreted so as to overstage the tumor [30]. Characterization of T3 and T4 lesions has overall accuracy of nearly 100% (Fig. 24.9). High-quality MRI also allows for subclassification of T3 lesions (Fig. 24.10). Although not mentioned in the AJCC staging eighth edition or any TNM version, the European Society for Medical Oncology (ESMO) subclassifies T3 lesions based on depth of invasion from the muscularis propria to the outer edge of the tumor into T3a (<1 mm), T3b (1–5 mm), T3c (6–15 mm), and T3d (>15 mm) [26]. This subclassification has major potential clinical applications since there are differences in recurrence and survival rates within the T3 category [41]. Moreover, this subclassification has the ability to better risk stratify tumors, into need for neoadjuvant treatment (for more advanced T3 lesion) versus upfront resection with proctectomy alone (for early T3 lesions), a practice that is more common in Europe than in North America. The Canadian Quicksilver Trial, a prospective nonrandomized trial looking at the safety and feasibility of using MRI criteria to identify patients with good prognostic rectal cancer features, found that MRI criteria were able to select patients who could undergo primary rectal cancer surgery instead of initial chemoradiotherapy and achieve a low rate of CRM positivity of 4.9% compared to 10% in historical controls [42].

MRI is used primarily used to evaluate the relationship of the tumor to the mesorectal fascia or other structures in close proximity (i.e., any threatened radial margin), as well as to the peritoneal reflection, as this will predict oncologic prognosis [40]. Small T3 tumors of the upper rectum that are confined to the rectum and mesorectum alone may be amenable to upfront resection, whereas in the converse situation (a bulky upper rectal tumor that abuts the mesorectal fascia), neoadjuvant radiotherapy is more likely to have a clinical impact (Fig. 24.11a–c). These nuances should guide neoadjuvant treatment decisions more than an arbitrary anatomic delineation.

Low rectal cancers (defined as extending from the anal verge to 6 cm) are classified by MRI as extending to or below the origin of the levators on the pelvic sidewall. An estimated one-third of rectal cancers are low [43]; these tumors are associated with relatively poor outcomes despite radical operative procedures. This has prompted the creation of a MRI-based staging system based on the relationship of the

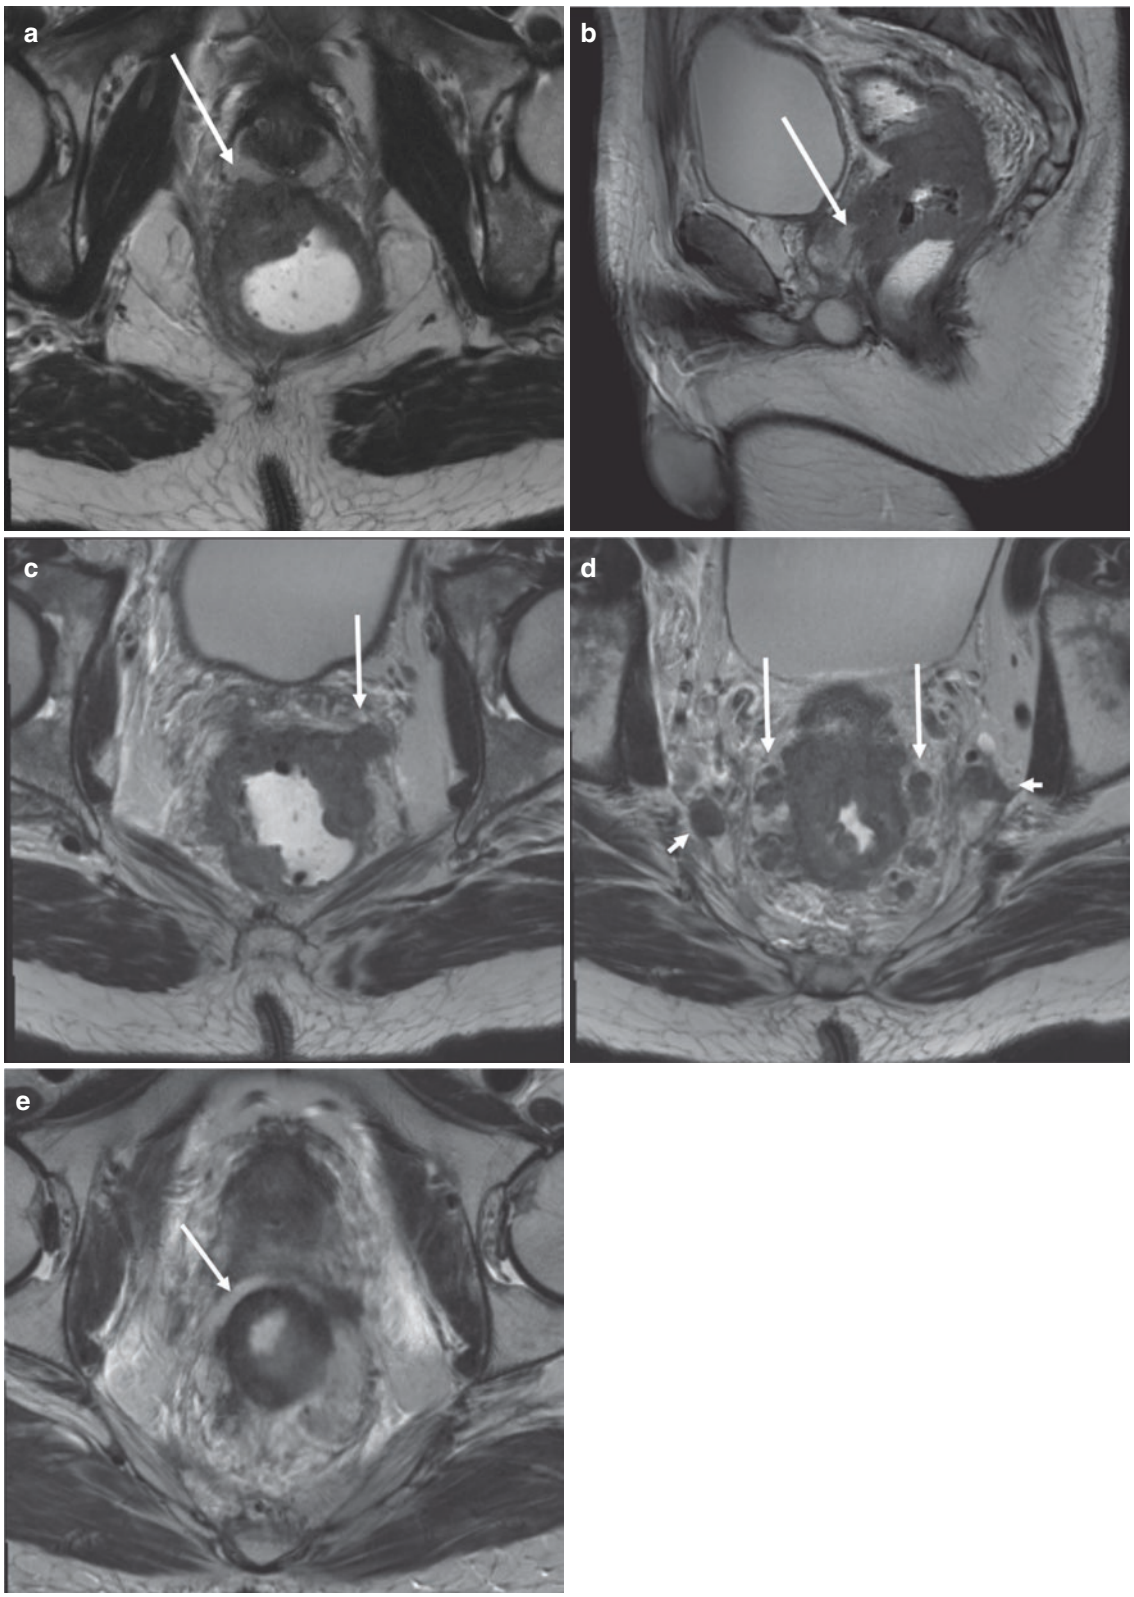

Fig. 24.6 MRI of a T4 tumor with CRM involvement and subsequent treatment regression. (**a**) Axial and (**b**) sagittal T2 images show an anterior T4 rectal cancer with direct invasion of the peripheral zone of the prostate (white arrow). The primary tumor has intermediate signal on the T2 sequence. (**c**) Axial T2 image shows extramural extension of the rectal cancer with transgression the mesorectal fascia (CRM +) (white arrow). (**d**) Axial T2 image shows multiple irregular mesorectal lymph nodes of abnormal signal (N2 – more than three nodes) (long white arrows) and pelvic sidewall adenopathy (short white arrows). (**e**) Axial T2 image after treatment shows good response of the tumor to therapy with profound T2 dark signal of the tumor from fibrosis (tumor regression grade 2) (white arrow). Note the significantly darker signal of the contracted tumor site after treatment as opposed to the intermediate signal prior to therapy as seen on image (**a**). (Courtesy of Vincent Pelsser, MD)

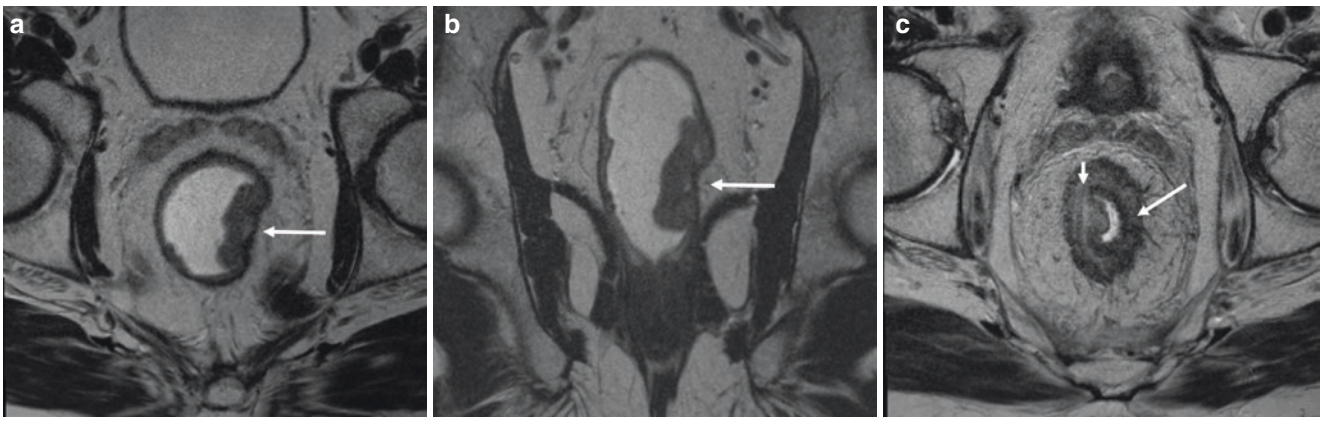

Fig. 24.7 MRI of T1/2 tumor with posttreatment regression. (**a**) Axial and (**b**) coronal T2 images show a rectal tumor not extending beyond the outer muscular layer (T1-T2 tumor) (white arrow). (**c**) Axial T2 image after treatment shows good response of the tumor to therapy with profound T2 dark signal of the tumor from fibrosis (tumor regression grade 2) (long white arrow); submucosal T2 bright signal is present circumferentially from radiotherapy edema (short white arrow). (Courtesy of Vincent Pelsser, MD)

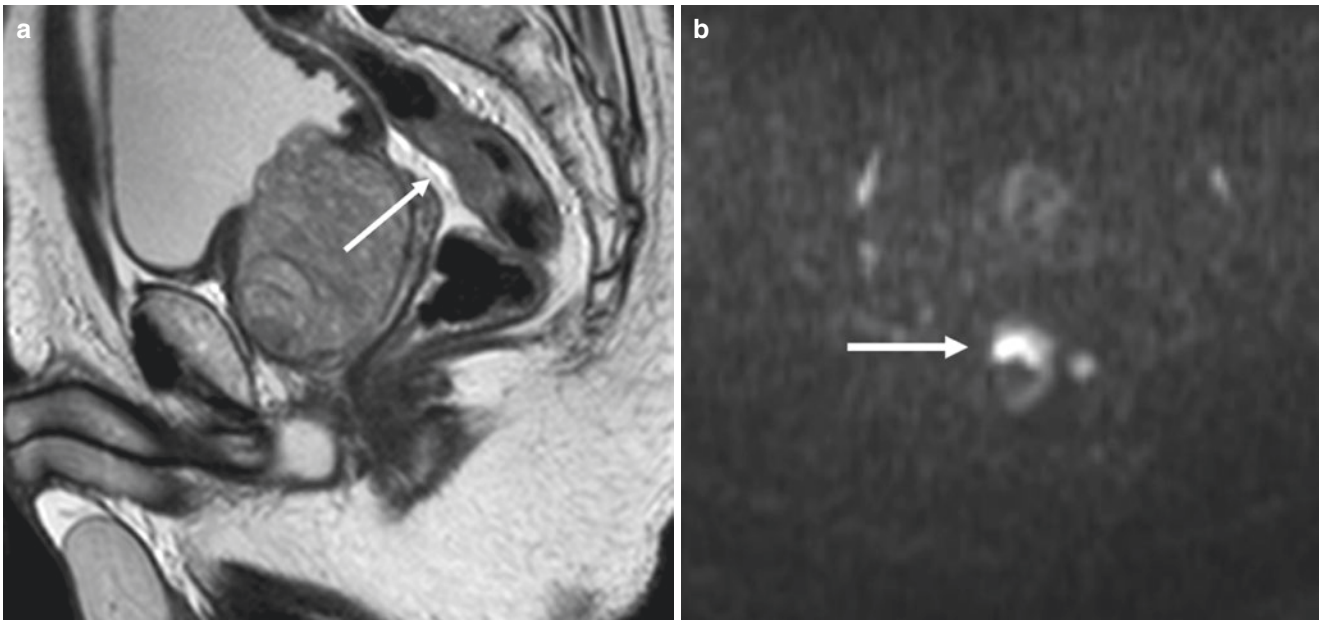

Fig. 24.8 MRI of T1/2 tumor with with diffusion-weighted imaging. (**a**) Sagittal T2 image shows a muscle contained (T1-T2 tumor) focal rectal cancer (white arrow). (**b**) with positive bright signal on axial diffusion imaging (white arrow). (Courtesy of Vincent Pelsser, MD)

tumor to the intersphincteric space and levators. More superficial tumors (T1 and 2) that have not invaded the intersphincteric plane are more likely to be resected with clear CRM and thus require a less radical procedure as compared to T3 and T4 tumors that have invaded the intersphincteric space or levators. These tumors have an 18-fold increased incidence of CRM involvement and often require extralevator abdominal perineal resection (ELAPE) or exenteration to achieve clear margins.

The soft tissue contrast seen on MRI makes it an ideal modality to identify mesorectal nodes (Fig. 24.12). Morphological appearance of nodes has been found to be a better discriminant of nodal involvement than size due to capsule disruption from tumor infiltration, resulting in necrosis within the node [30]. Using the criteria of irregular border and mixed signal intensity, MRI-detected lymph node has been reported to have a sensitivity of 85% and specificity of 97%. A meta-analysis of 21 studies on the use of MRI for rectal cancer, however, reported a sensitivity of 77% and specificity of 71% for MRI-predicted lymph node involvement [39].

Rectal cancers assessed by MRI have been grouped into: [30]

- The *"Good"*: T1-T3a/b, N0, No EMVI, CRM clear; predicted local recurrence risk <10%
- The *"Bad"*: T3c/d-T4 or N1/2, CRM clear, predicted local recurrence risk 10–20%
- The *"Ugly"*: threatened (<1 mm) or involved CRM, EMVI present, low rectal cancer with involved intersphincteric plane or levators; local recurrence risk >20%

MRI enables assessment of the pelvic side wall lymph nodes (PSWLN), which is reported to be one of the reasons for local recurrence, despite optimal surgery in the plane of the mesorectum [according the principles of "total mesorectal excision" (TME)] especially in distal third cancers, which spread along the internal iliac artery and then to the lateral pelvic side wall [44]. Distal rectal cancers have been reported to be associated with a 15% incidence of PSWLN compared to 8% incidence in higher tumors [45].

Fig. 24.9 MRI of T3bN1 tumor. Axial T2 image shows a low rectal cancer with focal extension beyond the outer muscular layer (T3b) (long white arrow); positive mesorectal adenopathy (N1: three or fewer nodes) is present posteriorly (short white arrow). (Courtesy of Vincent Pelsser, MD)

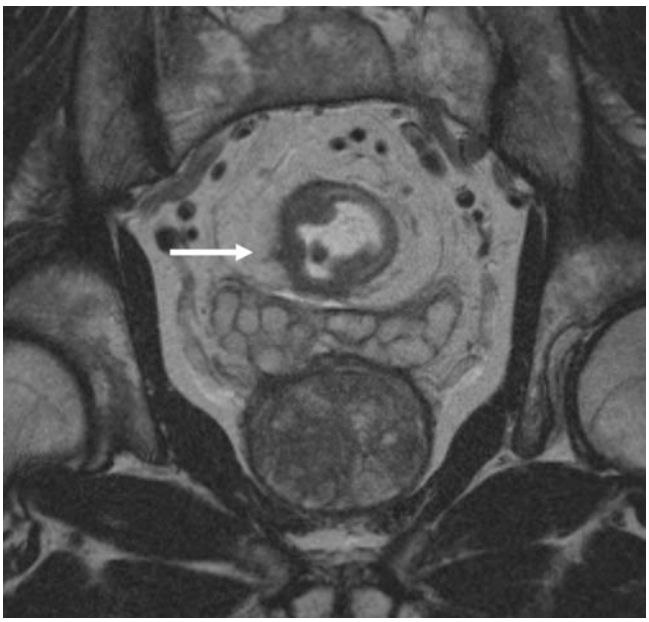

Fig. 24.10 MRI of T3b tumor. Axial T2 image shows a rectal cancer with focal extension beyond the outer muscular layer (T3b) (white arrow). (Courtesy of Vincent Pelsser, MD)

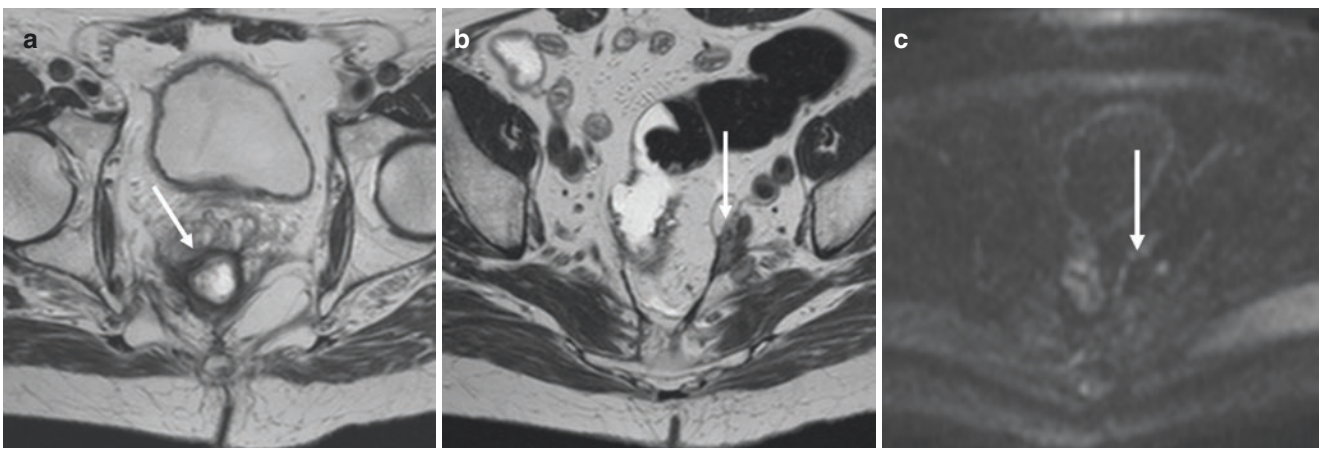

Fig. 24.11 MRI of T3b tumor with posttreatment regression. (**a**) Axial T2 image shows a rectal cancer with focal extension beyond the outer muscular layer (T3b) (white arrow). (**b**) Axial T2 image after treatment of a tumor shows T2 dark signal at the original tumor site from fibrosis (tumor regression grade 2) (white arrow). (**c**) The same patient had a left-sided T2 intermediate small mass (**b**) along the pelvis sidewall (white arrow); diffusion imaging (**c**) was negative showing dark signal (white arrow) indicating absence of tumor in this location, which was subsequently confirmed by PET scan (images not shown) and stability over time. (Courtesy of Vincent Pelsser, MD)

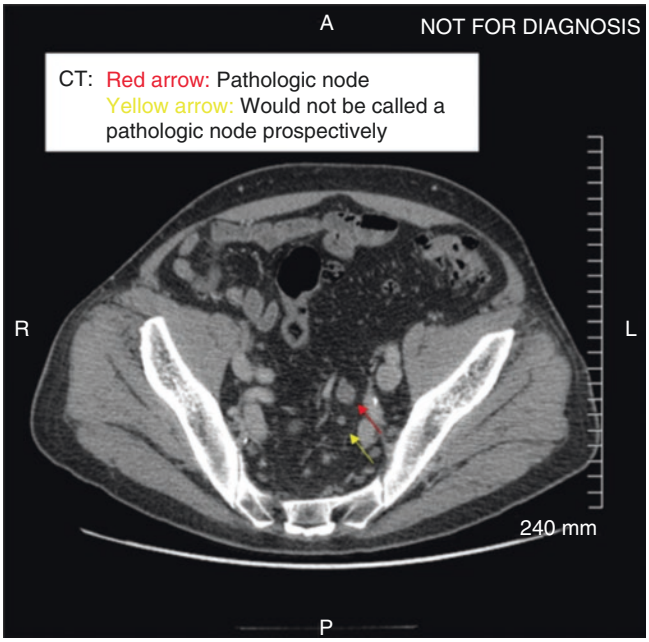

Fig. 24.12 Diffusion-weighted MRI showing a positive and negative mesorectal lymph node

Table 24.6 Performance of MRI at restaging (yMRI)

	Sensitivity	Specificity
yT	50.4%	91.2%
yN	76.5%	59.8%
yMRF	76.3%	85.9%

Table 24.7 Tumor regression grade (TRG) scale

mrTRG1	Complete response. No evidence of treated tumor
mTRG2	Good response. Dense fibrosis without obvious residual tumor
mTRG3	Moderate response:>50% fibrosis or mucin along with intermediate intensity tumor
mTRG4	Slight response: small areas of fibrosis/mucin with mostly tumor
mTRG5	No response: no change in appearance or bulk from original tumor

The value of restaging MRI following neoadjuvant therapy is controversial. For evaluation of the effects of neoadjuvant treatment on the tumor, MRI with diffusion-weighted and T2-weighted sequences has been suggested as an imaging modality to reliably predict regression response with increased sensitivity of 84% compared to 50% with T2 -weighted sequences alone for evaluation of T stage. In terms of nodal response, T2-weighted MRI is better to denote complete disappearance of nodes [46]. However, the performance of MRI for restaging is lower than for the primary staging (see Table 24.6).

Response of the tumor on MRI after neoadjuvant therapy can be graded by comparing pre- and posttreatment MRIs using the MR tumor regression grade (mrTRG) scale (Table 24.7), in which the relative amounts of viable tumor, fibrosis, necrosis, and inflammation are compared and classified. Some studies have demonstrated that MRI can predict complete pathologic response with high accuracy; however, results have not been uniformly reproduced (see Chap. 28).

Preoperative Evaluation

Prior to considering restorative proctectomy, baseline fecal, urinary, and sexual function should be documented and the risk of postoperative dysfunction discussed. As the vast majority of patients undergoing proctectomy for rectal cancer will undergo creation of temporary or permanent intestinal stoma, the patient should be seen by an enterostomal therapist for preoperative marking of an appropriate stoma site and education. For any patient of child-bearing age, the opportunities for sperm-banking or egg donation should be discussed prior to any radiation treatment or operation (if no neoadjuvant radiotherapy). If interested, they should be expeditiously referred to reproductive endocrinologist and infertility (REI) specialist. Patients with extensive comorbidities should be appropriately risk-stratified and optimized perioperatively. Two online resources available via the American College of Surgeons include the ACS NSQIP risk calculator and the "Strong for Surgery" checklist [47, 48].

Optimizing and standardizing preoperative care given to rectal cancer patients have been found to be associated with better-quality pathologic specimens and decreased 30-day morbidity [49]. A best practice preoperative checklist was developed by the American Society of Colon and Rectal Surgeons which outlines the measures necessary to optimize patient care and improve outcomes in patients with rectal cancer (Table 24.8) [50]. Garfinkle et al. looked at compli-

Table 24.8 ASCRS preoperative evaluation checklist

Formal pathology review was performed that confirmed invasive carcinoma
In the unobstructed patient, a complete colonic evaluation was performed
The tumor location within the rectum (distance from anal verge, tumor length, anterior, posterior, left, right), as well as relationship to levators and anorectal ring was documented
An assessment of family history, preoperative stool continence and sexual function were documented
Clinical staging of the primary tumor (MRI +/− ERUS) was performed
Clinical staging for distant metastases (chest, abdomen, pelvis) was performed
Preoperative or perioperative CEA level was measured
Consideration of neoadjuvant treatment for > T2 or node positive disease has been documented
Among those who received neoadjuvant treatment, the tumor was restaged, and location was reconfirmed just prior to operation
A multidisciplinary discussion of care, preferably during a formal tumor board conference, was documented
If a stoma is considered, the site was preoperatively marked

ance with the preoperative checklist and found that compliance with the checklist was associated with improved histologic and 30-day postoperative outcomes [50, 51]. In an effort to standardize and improve the quality of rectal cancer care, the American College of Surgeons Commission on Cancer has developed the National Accreditation Program for Rectal Cancer (NAPRC) which evaluated process and procedure measures for patients who underwent proctectomy. The process measures included clinical staging completion, treatment starting fewer than 60 days from diagnosis, CEA level drawn before treatment, tumor regression, and grading and margin assessment. The performance measures included negative proximal, distal, and circumferential margins and > or equal to 12 lymph nodes harvested during resection [52].

Prognostic Factors Associated with Overall and Disease-Free Survival

A combination of pathologic, clinical, and tumor-specific characteristics allows for a better prediction of oncologic outcome. A recent study of rectal cancer patients after surgical resection with curative intent found that patient age, tumor regression grade, pathologic stage, extranodal tumor deposits, and positive margins had the greatest impact on overall and disease-free survival [53]. The presence of tumor deposits was the strongest independent predictor of poorer outcome. Patients who achieved complete pathologic response after neoadjuvant treatment enjoyed significant improvement in overall and disease-free survival. A more complete discussion of the various prognostic factors follows below.

Pathologic Features: Pre-Resection

Although it is clear that a well-performed surgical resection (i.e., negative circumferential margins, complete mesorectal or mesocolic excision) is the most important prognostic indicator for nonmetastatic colorectal cancers, tumor biologic behavior also influences the risk of recurrence and distant metastasis and can influence choice and duration of adjuvant chemotherapy.

Poor pathologic features include lymphovascular invasion, perineural invasion, tumor budding, lymph node positivity and ratio, microsatellite stability, poorly differentiated tumors, and adverse histologic type. These features can be very influential when determining the risk of local recurrence and/or lymphatic spread and are especially helpful for stratifying risk when considering oncologic resection of locally excised malignant polyps [54].

Lymphovascular Invasion (LVI)

LVI is a marker for possible lymph node involvement and is identified when tumor cells are found around lymphatic channels, suggesting the tumor is in transit to regional lymph nodes. When this feature is present in resected stage I or II colorectal cancers, adjuvant chemotherapy should be considered. Additionally, when found in malignant polyp specimens, this would strengthen the recommendation for radical resection.

Perineural Invasion (PNI)

PNI refers to cancer involving the space surrounding a nerve. While PNI has been associated with poor prognosis and a high risk of recurrence, a recent single center study found that prognosis was better in patients with PNI negative cancers. PNI was found to be a significant risk factor for recurrence [55]. PNI has been found to be an independent prognosticator over LVI and lymph node involvement in patients treated with neoadjuvant treatment. It is hypothesized that tumor in the perineural space around the rectum may be more radioresistant than tumor in lymphovascular spaces [56].

Tumor Budding

Tumor budding is a pathologic feature that is being increasingly used to stratify the risk of lymphatic spread and is especially clinically relevant for malignant polyps. (See Chap. 23.) Defined as the presence of tumor cells or clusters within the stroma of the tumor (intratumoral budding) or at the tumor edge (peritumoral budding), it is thought to represent epithelial-mesenchymal transition and is associated with worse prognosis. Tumor cell density indicates the relative proportion of tumor cells to other constituents of the tumor area. A lower tumor cell density has been found to be associated with poorer prognosis and is a strong predictor of lymph node metastasis, lymphovascular invasion, local recurrence, and poor disease-free survival. High tumor budding has been found to be associated with an infiltrative growth pattern and lymphovascular invasion [57]. Clinically, it is similar to LVI/PNI, suggesting that a more aggressive treatment approach should be employed for these tumors [58, 59].

Mismatch Repair (MMR) Deficient or Microsatellite Instability-High (MSI) Status

It is now routine for all colorectal cancers to be evaluated for genotypic evidence of Lynch syndrome, performing immunohistochemistry on biopsy specimens if possible, or resected specimen at minimum, looking for absent expression of MMR proteins and/or evaluation for MSI-high status (see Chap. 22). Any MMR-deficient (with normal BRAF) or MSI-high tumor should prompt consideration of genetic counseling and/or germline mutational analysis to assess for Lynch syndrome. This may have immediate surgical implications (i.e., determining the extent of resection), as well as neoadjuvant or adju-

vant treatment considerations (i.e., MSI-high tumors are less responsive to 5U-based therapy). In addition, it will help risk stratify at-risk relatives. The recent approval of immunotherapy (PD1 inhibitors) for metastatic, unresectable, or borderline resectable MSI-high tumors can have major treatment implications for patients. Overall, MSI-high tumors carry a better prognosis than MSI-low tumors, likely because they are considered to be less aggressive overall, potentially due to an improved host immune response to the tumor. This is despite the fact that these tumors are often poorly differentiated and that 5-fluorouracil (5-FU)-based chemotherapy is less effective. (See Chap. 30.) However, it is likely that the lack of efficacy of 5-FU is due to the fact that these tumors have such a better prognosis at baseline that chemotherapy is less able to show a significant effect [60].

Tumor Grade

Tumor grade is a stage-independent prognostic factor, with undifferentiated or poorly differentiated tumors being associated with poorer prognosis than moderately or well-differentiated tumors. This is considered to be a marker for more aggressive tumors.

Histologic Type

Histologic types that are associated with worse prognoses include mucinous, signet ring (>50% of the tumor contains intracytoplasmic mucin), and adenosquamous. This is thought to be due to the relative chemoresistance of these predominantly acellular tumors.

Pathologic Factors: Post-Resection

Lymph Node Positivity and Ratio

Guidelines have acknowledged that the minimum acceptable number of lymph nodes for accurate staging is 12. An association between lymph node harvest (LNH) and survival has been demonstrated, and it has been suggested that patients in stage II disease with a lower LNH have a worse prognosis [61]. The number of retrieved lymph nodes often falls short of the recommended 12. Factors that may be responsible include patient age, body mass index, tumor location, neoadjuvant therapy, surgical technique, and the pathologists' assessment. LNH is often intrinsically less with age (possibly due to a weaker immune response to the tumor) and tumor location in the rectum. Furthermore, the number of lymph nodes retrieved following neoadjuvant treatment is often less than what is retrieved after surgery alone, likely due to the effect of radiation on the lymphatic system [62]. Retrieval of fewer nodes may, in fact, be a marker of higher tumor response and better prognosis following neoadjuvant treatment [63]. LNH is enhanced in MSI-H tumors due to the immune response linked to the lymphocytic infiltrate.

The importance of lymph node ratio (LNR), the ratio of metastatic nodes to the total number of nodes harvested, has been highlighted as a prognostic tool with a lower LNR associated with a better prognosis. Increasing LNR has been found to be an independent predictor of decreased overall and disease-free survival [64]. In fact, the IDEA trial demonstrated that for patients with adequate LNH and low lymph node positivity (1 or 2), a reduced duration of 3 versus 6 months of FOLFOX chemotherapy had equivalent oncologic outcomes with less morbidity [65].

Extranodal Tumor Deposits

Extranodal tumor deposits are irregular discrete tumor deposits found in the pericolonic or perirectal fat or in adjacent mesentery away from the leading edge of the tumor within the lymphatic drainage area of the primary tumor, but not associated with a lymph node. Most are thought to be due to LVI or PNI but are not counted as lymph nodes replaced by tumor. The presence of extranodal tumor deposits is associated with relatively poor survival. Tumors with comparable T stage and without satellite nodules have been found to have higher 5-year survival rates compared to the same T stage with nodules (2% vs 37% $p < 0.0001$) [66]. Moreover, the presence of tumor deposits has been associated with decreased survival following neoadjuvant therapy [67].

Mesorectal Grade

The quality of mesorectal excision has been shown to be an independent factor of local and overall recurrence. Perforation of the rectum during surgery is also associated with poor prognosis and should be recorded as pT4 [68, 69]. It has also been suggested that mesorectal grade correlates inversely with size of the tumor, i.e., perforation during surgery or incomplete excision may occur more often during excision of large, bulky, locally advanced tumors with extensive fibrosis.

Tumor Regression Score

As neoadjuvant therapy has become the standard of care for many rectal cancers, the size of viable tumor remaining is a measure of the effectiveness of therapy, with the absence of

Table 24.9 Tumor regression score

Tumor regression score	Description
0	Complete response
1	Near-complete response
2	Partial response
3	Poor or no response

viable tumor and minimal residual disease being associated with better outcome [70]. Complete pathologic response following treatment is associated with a favorable prognosis [25]. A tumor regression score is used to assess the response of the tumor and not the nodes (Table 24.9) [70].

Clinical or Imaging-Based Factors

Age

Younger age (<45) at presentation has been associated with poor prognosis overall, possibly due to the presence of adverse prognostic features and advanced tumor stage at diagnosis. However, after controlling for disease stage, patient, and treatment factors, prognosis may be more favorable in younger patients since these patients can be treated more aggressively [71]. Also, advanced age is often associated with frailty which may limit the ability to tolerate chemotherapy or chemoradiotherapy.

Older patients also have worse baseline bowel dysfunction and continence. Therefore, older patients with rectal cancer are often not good candidates for restorative proctectomy with low colorectal or coloanal anastomosis, nor do older patients tolerate temporary diverting ileostomy well due to the reduced drive to drink fluids with age and increased risk of dehydration. Therefore, frail patients with rectal cancer but without a threatened CRM should be considered for upfront nonrestorative proctectomy, Hartmann resection, or abdominoperineal resection, depending on location of the tumor relative to the pelvic floor. If there is concern for a threatened radial margin, another option is neoadjuvant short-course radiotherapy (4–5 Gy for 5 days, for a total of 20–25 Gy) followed by resection. Neoadjuvant short-course radiotherapy is better tolerated than long-course chemoradiotherapy and has shown equivalent oncologic outcomes [72].

Extramural Vascular Invasion (EMVI)

EMVI is a strong predictor of poor prognosis which, as previously mentioned, can be predicted on prestaging MRI. EMVI is defined as the presence of tumor cells in the microvasculature beyond the muscularis propria and is more prevalent in locally advanced T3/T4 lesions, although it may be present with early stage tumors as well [30]. Histologically confirmed EMVI has been associated with a higher risk of local recurrence and poorer survival regardless of nodal status or depth of mural invasion. The incidence of EMVI ranges from 9% to 61% [73]. Brown has described MRI-directed EMVI grading system which is able to predict histologic EMVI with a high specificity ranging between 88% and 96% but with low sensitivity of 29–62% due to the inability to accurately visualize small caliber vessels. MRI evaluation of EMVI has been suggested by some authors to be more accurate than histologic assessment [74]. MRI-detected EMVI predicts both risk of recurrence, as well as synchronous metastases [34, 75]. MRI-detected EMVI was also associated with a fourfold risk of developing metachronous metastases within 1 year of diagnosis [76]. Thus the presence of EMVI on MRI may signify tumor embolization into the systemic circulation. Therefore, even for T1 or T2 tumors, patients with MRI-detected EMVI should be considered for chemotherapy to improve distant control [73].

Circumferential Radial Margin (CRM) Status

In addition to locally advanced tumors (T3/T4), other factors predictive of CRM involvement include tumor <4 cm from the anal verge, anterior quadrant invasion, and EMVI [77]. The presence of all four features predicts a risk of incomplete resection as high as 60%. These patients may benefit from total neoadjuvant therapy with radiotherapy and multidrug systemic chemotherapy prior to resection.

The NCCN recommends neoadjuvant treatment for all clinical stage II (cT3/T4; N0) and clinical stage III (any cT; N1/2) rectal cancers [78], but this includes a heterogeneous group of patients, some of whom may be overtreated. As a result, the UK and ESMO have shifted their treatment decision-making from being based purely on TNM to one that is guided by MRI findings. This allows personalized rectal cancer management based on selective MRI criteria in order to minimize the risks of over- and undertreatment, based on the risk of local recurrence [30].

An involved CRM increases the risk of local recurrence and mortality with both colon and rectal tumors. Although more commonly associated with a discussion on rectal cancer, the radial margin of the colon is formed by its mesenteric attachment point along with the cut edge of nonserosalized or retroperitoneal segments at the time of colon resection. Radial margin positivity is associated with multivisceral resection and conversion from laparoscopic to open resection and is a stage-independent outcome predictor strongly associated with recurrence and shorter survival [79]. Even with complete mesocolic excision, a radial margin <1 mm was found to be an independent predictor of survival and recurrence [80]. Russell et al. used a cancer-predictive mode [81] that included older age, male sex, African-American race, as well as advanced AJCC stage especially T stage, signet ring his-

tology, and poor/undifferentiated grade were associated with a positive circumferential margin.

If involved CRM is suspected preoperatively, careful surgical planning for extended resection and possible consideration for neoadjuvant multidrug chemotherapy are warranted. With respect to rectal cancer, tumor involvement of the CRM is the most critical factor in predicting local recurrence. For locally advanced rectal cancers, neoadjuvant therapy may result in downstaging, but if the CRM is still positive, the risk of local recurrence is increased. CRM is both an indicator of quality surgery and the success of neoadjuvant therapy. The AJCC manual also suggests that the surgeon mark the specimen on the non-peritonealized margins of resection with ink, especially in the area with the deepest involvement of tumor, to allow the pathologist to evaluate the radial margin and thus the completeness of resection [12]. This should be done routinely for all cases where colon or rectal neoplasia (cancer or polyp possibly containing cancer) is resected.

Tumor Location

It has been suggested that primary tumor location is a prognostic feature in colorectal cancer. With respect to colon cancer, tumors located distal to the splenic flexure compared to right-sided tumors have been associated with better prognosis independent of stage [82, 83]. However, it has also been suggested that tumor location may be a proxy for tumor biology in that proximal tumors, being commonly associated with β-RAF or KRAS mutations, are associated with poorer prognosis. However, the relationship between tumor sidedness and prognosis is not straightforward and may be dependent on stage and histologic characteristics especially in stage III disease [84].

With respect to rectal cancer, low tumors are associated with a relatively poorer prognosis, partially due to the rigid, narrow configuration of the pelvis and the technical challenges this poses intraoperatively. The consequence is a lower rate of complete mesorectal excision and higher rate of radial and distant margin positivity, as tumor location moves more distally.

Conclusion

Once a diagnosis of colorectal cancer has been made, it is essential that proper localization and staging be done to assure that the patient will be assigned to the correct treatment protocol as determined by multidisciplinary tumor boards. Doing so will enable the patient to receive optimal management in order to effect the goals of long-term disease-free and overall survival.

Colon Cancer Surgical Treatment: Principles of Colectomy

25

Evie H. Carchman and Matthew F. Kalady

Key Concepts

- Surgical resection of the primary tumor remains the cornerstone of treatment for stage I–III colon cancer and plays a role in treating surgically resectable stage IV disease.
- Extent of colectomy is based on the anatomic location of the tumor.
- Goals of resection are to achieve negative circumferential margins and to remove the mesentery at greatest risk for lymphatic spread.
- Examination of lymph nodes allows for accurate cancer staging, which is imperative for selection of patients for adjuvant therapy.

Introduction

Colorectal cancer is among the most common cancers in the United States, with an estimated 145,600 new cases and 51,020 associated deaths in 2019 (1). The 5-year survival rate is 64.4%, based on data from 2009 to 2015. The most accurate predictor of outcomes, based on the globally recognized TNM system for classification of malignant tumors, is pathologic stage. Preoperative clinical staging with imaging can determine the extent of local disease and detect distant metastases, which may affect the treatment plan and sequence of treatments. Surgical resection of the primary tumor remains the cornerstone of treatment for stage I–III colon cancer and plays a role in treating surgically resectable stage IV disease. A clear understanding of anatomy, as well as the appropriate extent of resection, guides the surgical approach and has an important bearing on oncologic outcomes.

Preoperative Tumor Localization

When planning a colectomy, it is essential to determine the precise location of the tumor. Typically, the diagnosis of neoplasia is made after identification and biopsy of the tumor on colonoscopy, with note of the location of the tumor made on the report. However, mislocalization of the tumor, based on preoperative colonoscopy alone, occurs in 11–21% of cases and can result in a different surgical procedure than originally planned in 11% of cases (2–5). This number may be even higher when cecal and rectal tumors are excluded, due to the lack of definitive landmarks in the distal ascending, transverse and left colon, and variations in patient anatomy. It should also be noted that localization based on "centimeters from the anal verge" should never be relied upon, as this is often a highly inaccurate measurement when performed during the course of flexible colonoscopy. This is especially important for tumors in the rectosigmoid, where misclassification of tumor location can lead to inappropriate treatment. Many experienced colorectal surgeons will repeat flexible sigmoidoscopy on any patient referred to them with a neoplasm anywhere in the left colon, to avoid the mistake of taking a patient with a rectal cancer directly to the operating room for resection.

Preoperative computed tomography (CT) may demonstrate the exact location of the tumor. However, often the tumor is too small to see definitively on CT, and thus other localization methods should be considered. When a tumor is encountered at colonoscopy, endoscopic tattoo placement should be considered. Tattooing of the tumor facilitates localization of the tumor intraoperatively, especially in cases where palpation of the tumor is not possible such as during minimally invasive colectomy. Effective tattooing has been

S. R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, https://doi.org/10.1007/978-3-030-66049-9_25

shown to reduce operating times and ensure that the correct segment of colon is resected (6).

For most colonoscopically placed tattoos, India ink is used. The goal is to inject into the submucosal plane. Full-thickness injection results in inadvertent spraying of tattoo ink throughout the abdomen, which can make localization difficult. One technique to more accurately and reliably confine the injection to the submucosa is to first inject 0.5–1.0 mL of saline into the submucosa to create a bleb and then insert the India ink into the saline bleb (0.75–1.0 mL). It is helpful to repeat this procedure in three or more quadrants to avoid mesenteric injection only. It is also important to not inject directly into the tumor but rather the opposite wall or just distal to the tumor. One should note the placement of the tattoo relative to the tumor in the colonoscopy procedure note. It is preferable to inject tattoo only distal to the tumor, rather than both proximal and distal, as occasionally only one tattoo site can be identified intraoperatively. In addition, usually it is the distal extent of the lesion that is most critical for the surgeon when performing resection. An example of a laparoscopic view of a colonoscopic tattoo is shown in Fig. 25.1.

Even with tattoo placement, the location of the tumor and the tattoo can be sometimes difficult to discern, e.g., the tattoo ink is dispersed throughout the abdomen, or the surgeon is unable to visualize the tattoo marks due to mesenteric quadrant location placement, inadequate tattoo amount, obesity, or adhesions. Thus, when the tumor cannot be definitively identified on preoperative imaging, the patient and surgeon should always be prepared for the possibility of intraoperative colonoscopy for localization. Intraoperative colonoscopy should ideally be performed using carbon dioxide as the insufflation gas to limit bowel dilatation.

Another method of tumor localization is to place a metallic clip adjacent to the tumor at the time of colonoscopy. Plain radiographs in the supine position can be performed immediately post-colonoscopy. The colon is often still filled with gas and the location of the clip relative to the outline of the colon discernible. Alternatively, staging CT of the abdomen and pelvis can be performed shortly after colonoscopy and clip placement. If the clip remains in situ, then the anatomic location of the tumor should be readily visible on CT. This method may be especially important when tattoo ink is unavailable at the time of colonoscopy.

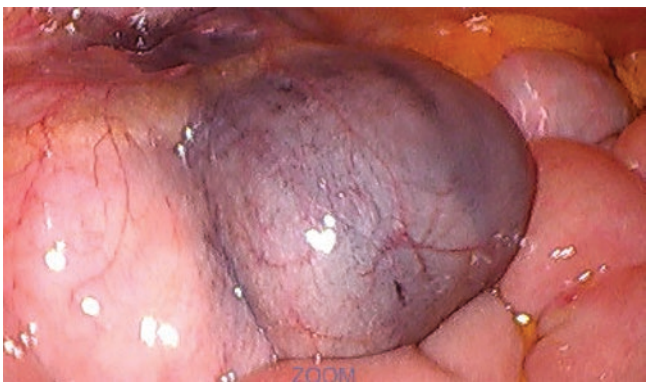

Fig. 25.1 Intraoperative localization of a hepatic flexure tumor by identification of tattoo

General Surgical Principles

Extent of Resection

In addition to removing the tumor itself, at least a 5-cm margin should be obtained both proximally and distally, and the feeding vessel should be taken at its origin. With high ligation of the vessel, it is unlikely not to obtain 5-cm margins due to resultant ischemia of the colon both proximally and distally. Adhering to 5-centimeter margins has been shown to minimize anastomotic recurrences (7). Proximal ligation of feeding vessels to the tumor should be performed to maximize lymphadenectomy. Colectomy specimens should have the non-peritonealized margins marked with ink to assess for completeness of resection, preferably by the surgeon, as is routine for proctectomy specimens for rectal cancer.

For the treatment of sigmoid colon cancer, the level of ligation of inferior mesenteric artery is controversial (high ligation versus low ligation). There is increased lymph node yield with high ligation over low ligation. However, studies have shown no functional or oncologic differences between high and low ligation (8–10). Unfortunately, there is not a universally agreed upon nomenclature regarding the inferior mesenteric artery (IMA) and its branches nor what is exactly meant by "high" versus "low" ligation. Many experienced surgeons consider the IMA to arise at the aorta and terminate when it branches into the superior hemorrhoidal artery and the left colic artery, which means that the average length of the IMA is only a few centimeters. Other surgeons consider the IMA to include what others would label the superior hemorrhoidal artery, claiming that the IMA becomes the superior hemorrhoidal artery when it crosses the common iliac artery. This latter designation is problematic as it ignores the principle of naming arteries based on their branch points and because it is difficult to ascertain exactly where an artery "crosses" another anatomically, especially after mobilization of the mesosigmoid.

No-Touch Technique

The no-touch technique was developed due to concern about dislodging tumor cells into the circulation during tumor manipulation. This technique showed initial promise in terms of prognosis (11). However, follow-up trials failed to recapitulate these results (12). For this technique, the vascular pedicle is ligated prior to mobilization of the colon. Garcia-Olmo et al. looked at blood samples to determine whether release of circulating tumor cells (CTCs) occurred during surgery and found no evidence of detachment with tumor manipulation (13). A recent randomized controlled trial of conventional colectomy versus no-touch for colon cancer resection found no difference in disease-free survival, overall survival, or recurrence-free survival in stages II and III colon cancer patients (14).

Lymphadenectomy

When considering the surgical treatment of colon cancer, a lymphadenectomy is considered adequate when feeding vessels are taken at their origin and at least 12 lymph nodes have been harvested and examined histologically. Examination of lymph nodes allows for accurate cancer staging. Adequate surgical staging is imperative for selection of patients for adjuvant therapy. The number of harvested lymph nodes and the ratio of involved versus harvested nodes can be used as markers of adequacy of surgical resection and are associated with patient outcomes (15). There is no doubt that lymph node excision is important to oncologic staging and outcomes; however, the extent of lymph node resection is debated. Even more controversial is the role of extended lymphadenectomy for synchronous extra-regional lymph node metastasis, such as para-aortic lymph node metastasis in colorectal cancer. One study demonstrated a benefit for highly selected patients, but this is not standard practice for most colorectal surgeons (16).

Mesocolic Excision

The aim of the mesocolic resection is to remove the tumor, its associated lymphovascular supply (including central vascular ligation), and mesocolon in an intact envelope of visceral peritoneum. There are no randomized controlled trials comparing complete mesocolic excision (CME) to "standard" colon surgery. The rationale for CME comes from the improvement in rectal cancer patient survival since the introduction of "total mesorectal excision." Initial retrospective studies have shown promising oncologic outcomes. Bertelsen et al. reported 5-year outcomes for right-sided colon cancer with CME versus standard resections and found a significant reduction in 5-year recurrence (9.7% versus 17.9%, respectively). Another difference was the number of lymph nodes harvested between the two groups (median 38 versus 21, respectively) (17). The main benefit of a CME is the increased lymph node yield (18, 19). Previous opinion on lymph node yield during lymphadenectomy was that it was mainly for prognostication; however, recent studies bring into question its ability to improve patient outcomes (survival) (20, 21). By performing a central ligation of the vessels, CME also obtains central and apical lymph nodes and thus captures "skip lesions," which can occur in 5% of cases on average (22–24). Completion of CME with an intact peritoneal lining has been demonstrated to improve survival by 15% (25). The other theoretical advantage of CME is that it standardizes surgical resection. Drawbacks include the technical difficulty of performing CME compared to a standard colectomy, leading to longer operative times. Further, given the increased dissection of critical vascular structures (superior mesenteric artery (SMA) and superior mesenteric vein (SMV)), there is a potential for damage and significant complications (26, 27). The most feared complication during CME is damage to the SMV, the main outflow to the small intestines, shown to occur in about 1.6% of right hemicolectomies (26). Several studies have shown that laparoscopic CME is feasible and safe (28–30). No functional differences have been noted between patients who have undergone CME versus conventional colon surgery (31). Critically evaluating different surgical techniques is challenging, as there is no precise definition of exactly what occurs during "conventional" surgery. It may be that some surgeons have been adhering to the basic principles of CME long before the introduction of the term. Ultimately, the major benefit of CME may be refocusing surgeons of the basic principles of colectomy for cancer–central ligation of vessels, removing the mesentery at greatest risk for metastatic lymph node spread in its envelope, and achieving negative circumferential negative margins–just as "TME" did for rectal cancer.

Adjacent Tissue or Organ Invasion

Larger colon cancers may invade adjacent structures/organs. The structures/organs most commonly involved are the abdominal wall, bladder, duodenum, omentum, ovaries, peritoneum, retroperitoneum, small bowel, stomach, ureters, and uterus. Surgical planning should include en bloc resection to achieve negative circumferential margins. Adhesions from the tumor to other structures are malignant in about 40% of cases. If there is an uncertainty if there is direct invasion or rather merely abutment, proceeding with en bloc resection is favored. Without en bloc resection, patients are at higher risk of recurrence and decreased survival (32).

For abdominal wall invasion, en bloc resection and then reconstruction of the abdominal wall are recommended. For other organ involvement, complete surgical resection should be attempted if feasible and reconstruction of critical structures (ureters, iliac, etc.) if it can be performed. There can be local invasion to the tail of the pancreas and spleen that necessitates distal pancreatectomy and splenectomy. For pancreatic or duodenal invasion, there are case reports of en bloc pancreaticoduodenectomy (33).

Neoadjuvant systemic therapy can be considered for locally advanced colon cancers. Data from the FOxTROT Collaborative Group showed significant tumor downstaging, less apical node involvement, and fewer positive margins, thus, favoring preoperative treatment in patients with locally advanced, resectable colon cancer (34). Neoadjuvant chemotherapy was noted to be well tolerated and safe, with no increase in perioperative morbidity and a trend toward fewer serious postoperative complications. Evidence of disease regression was noted in 59% of patients, including some pathologic complete responses. The Collaborative Group also noted a decrease in incomplete resection rate (abstract at GI ASCO). The National Comprehensive Cancer Network also recommends consideration of neoadjuvant therapy in clinical T4b colon cancer, as this may improve survival (35).

Neoadjuvant chemoradiotherapy can be considered for sigmoid tumors invading the bladder or other pelvic organs, provided that the radiation dose to surrounding small bowel can be limited. Neoadjuvant chemoradiotherapy has also been administered to select patients with more proximal colon tumors invading other vital structures such as duodenum and pancreas, although data are limited to case reports and small series, and thus no definitive conclusions can be made regarding relative efficacy.

Surgical Procedures Based on Anatomic Location

Cecum and Ascending Colon Cancer

For lesions of the cecum or ascending colon, a right hemicolectomy with ileocolic anastomosis is recommended. The anatomic boundaries of the resection include approximately 10-cm proximal to the ileocecal valve and the proximal transverse colon (Fig. 25.2).

Technical Aspects

Regardless of approach, most patients are positioned supine on the operating table, unless intraoperative colonoscopy is anticipated, whereas the patient should be in split leg position. It is helpful to tuck at least the patient's left arm to allow multiple individuals to stand on the left side, especially for laparoscopic cases. For a medial to lateral technique, regardless of approach (laparoscopic, robotic, or open), the operating surgeon stands on the left side of the table. For an open approach, a vertical midline or transverse/oblique incision is made, using a self-retaining retractor of choice. The abdomen should be thoroughly inspected, especially the liver, for evidence of metastatic disease. The tumor is assessed for resectability, taking into account invasion of disease into the duodenum or pancreas. The small bowel is retracted into the left half of the abdomen, facilitated by tilting the table right side up. The surgeon then identifies the ileocolic artery and performs a high ligation adjacent to the duodenum, after ensuring that the duodenum is dissected free and protected (Fig. 25.3). The mesentery is then dissected off the retroperitoneum through this window. The right colic artery, if present, and the right branch of the middle colic artery and vein are identified and ligated at their origins. The remaining mesentery to the transverse colon, including the marginal artery, is taken. The remaining mesentery next to the planned transection point of the terminal ileum is also taken. The right colon is dissected off the white line of Toldt to release the remaining lateral attachments. The lesser sac is often opened to mobilize the transverse colon and complete the mobilization of the hepatic flexure. The terminal ileum and proximal transverse colon are then divided, the specimen handed off the table, and the anastomosis constructed per surgeon preference. There are a variety of ways to perform the anastomosis (intracorporeal or extracorporeal, hand-sewn or stapled, side-to-side or end-to-side or end-to-end) with no one technique showing superiority over another. Closure of the mesenteric defect is controversial, as the defect is large and unlikely to cause obstruction. The omentum of the hepatic flexure and transverse colon that is being resected is typically taken with the specimen. Reliable data indicate that mobilization along anatomic planes is important and improves prognosis (36).

In a lateral to medial approach, the surgeon first transects the white line of Toldt, usually starting at the cecum and moving toward the hepatic flexure. Then the colon and mesocolon are mobilized off the retroperitoneum and duodenum. The hepatic flexure is freed from the liver superiorly and from the duodenum posteriorly. The ileocolic, right colic, and right branch of the middle colic vessels are then ligated at their origins. The remaining part of the procedure is similar to the procedure described above for a medial to lateral approach.

Hepatic Flexure Colon Cancer

For lesions in the hepatic flexure, a right hemicolectomy may be adequate if it is in the proximal hepatic flexure, but depending on location, an extended right hemicolectomy may be required. For an extended right hemicolectomy, the anatomic boundaries of resection are the terminal ileum to distal transverse colon.

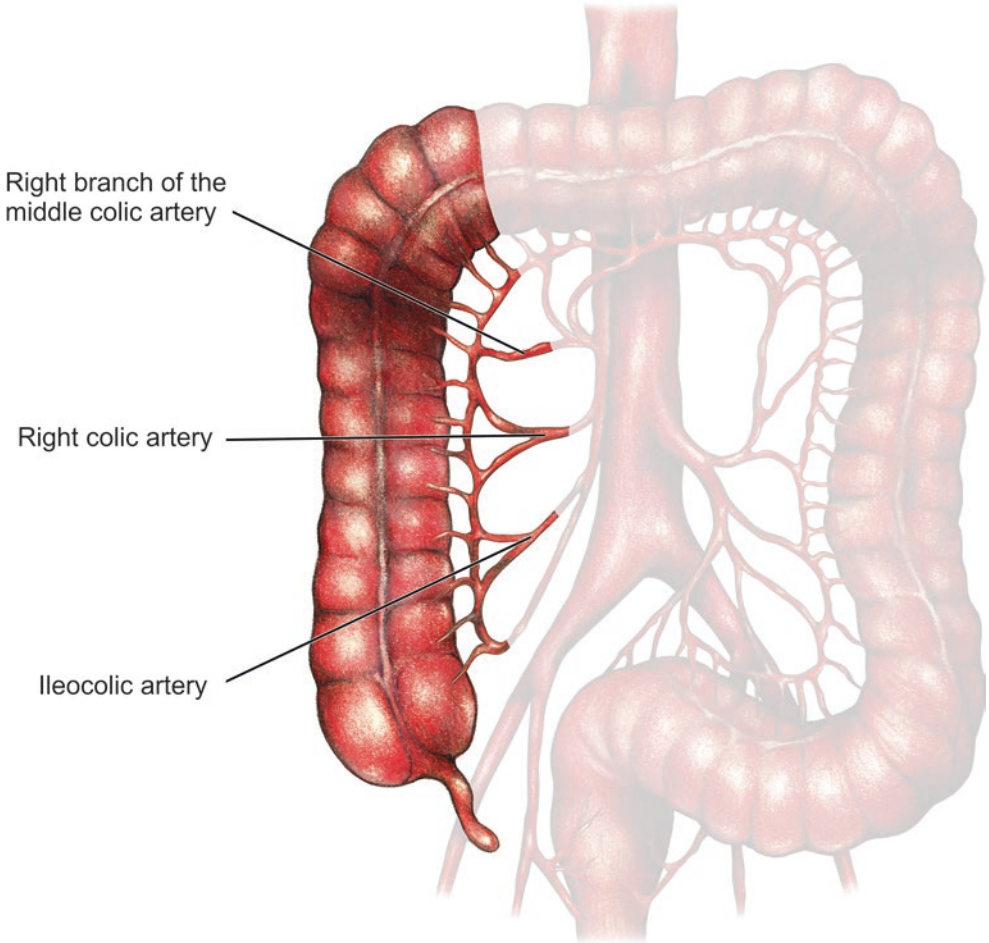

Fig. 25.2 Right hemicolectomy

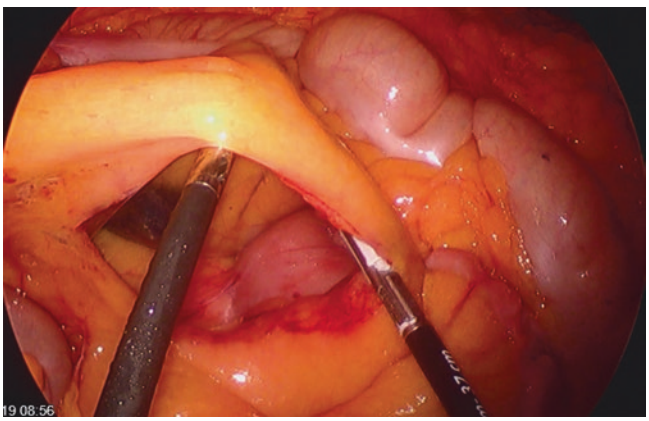

Fig. 25.3 Medial to lateral dissection of the right colon, identifying and protecting the duodenum

Technical Aspects

Please refer to cecal and right colon cancer resection (above) for a description of right hemicolectomy. In an extended right hemicolectomy, the procedure is performed similar to a right hemicolectomy, but the vascular division may include the main middle colic arterial trunk provided that there is adequate retrograde flow from the IMA to perfuse the splenic flexure (Fig. 25.4). The lesser sac is opened along its entire length, not just near the hepatic flexure and proximal transverse colon. This allows visualization and access to the blood supply. The splenic flexure may need to be mobilized to create a tension-free anastomosis. The colon and the mesentery are then resected according to the divided blood supply distribution. An ileocolic anastomosis is then created.

Removal of the spleen, either intentional or not, is associated with high morbidity and increased mortality (37). Inadvertent splenectomies are usually a consequence of capsular tear due to inadequate exposure and aggressive retraction. The incidence of required splenectomy during splenic flexure mobilization is less than 1% (38). Varty et al. conducted a case control study that compared cancers requiring splenectomy to cancers that did not. The authors found no influence on long-term survival but increased rates of postoperative sepsis (39).

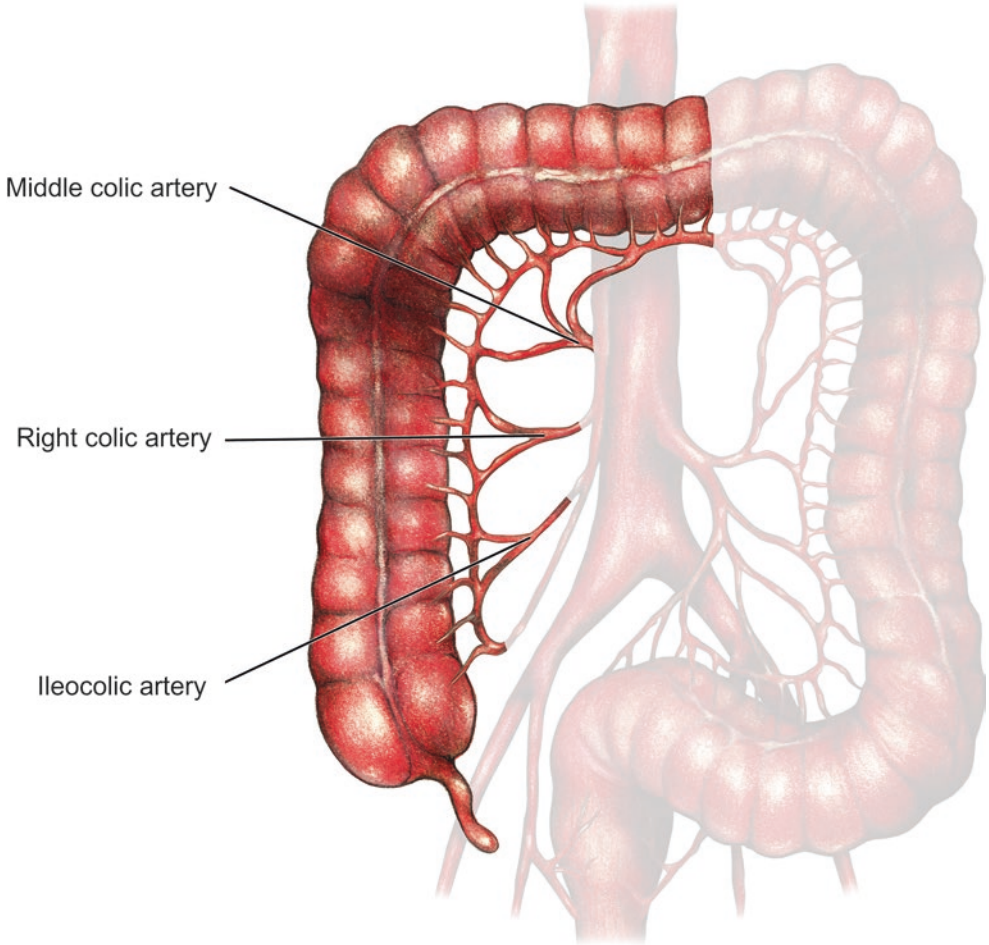

Fig. 25.4 Extended right hemicolectomy

Transverse Colon Cancer

It is often challenging to decide which surgical procedure to utilize for cancer of the transverse colon, as the blood supply comes from the middle colic, along with the right and left colic vessels. The best procedure is the one that removes the regional lymphatic drainage which is based on the arterial supply and corresponding mesentery. The decision is influenced by the location of the tumor within the transverse colon and the anatomy in that individual. The more common options include an extended right colectomy, extended left colectomy, or a subtotal colectomy. Segmental transverse colectomy is also sometimes utilized.

Technical Aspects

Proximal transverse colon cancers are typically managed with an extended right colectomy, which is described above. Lesions in the mid to distal aspect of the transverse colon may be offered an extended right colectomy, extended left colectomy, or segment transverse colectomy. An extended left colectomy requires ligation of the middle colic artery main branch in addition to the left colic artery as described below (Fig. 25.5). In the case of a mid-transverse colon cancer, a transverse colectomy may be considered. The principles of high ligation of the middle colic artery and drainage of regional lymphatics remain the cornerstone of care. In this case, the anastomosis is an ascending to descending colon anastomosis which requires mobilization of both segments and can be challenging or awkward technically. Segmental transverse colectomy is most appropriate for patients with a tumor in the mid-transverse colon with a redundant colon where mobility is not an issue. An end-to-end colo-colonic anastomosis is usually performed due to the risk of tension on a side-to-side anastomosis caused by the two sides of the colon mesentery retracting back toward their original position. There is also the concern regarding the adequacy of the lymphadenectomy that occurs with a segmental resection of the transverse colon. For these reasons, many surgeons treat mid-transverse colon lesions with an extended right colectomy which is easier for mobilization of the small bowel for an ileocolic anastomosis. A limited segmental transverse colectomy can be offered for palliative reasons or in frail patients that may not tolerate an extended resection.

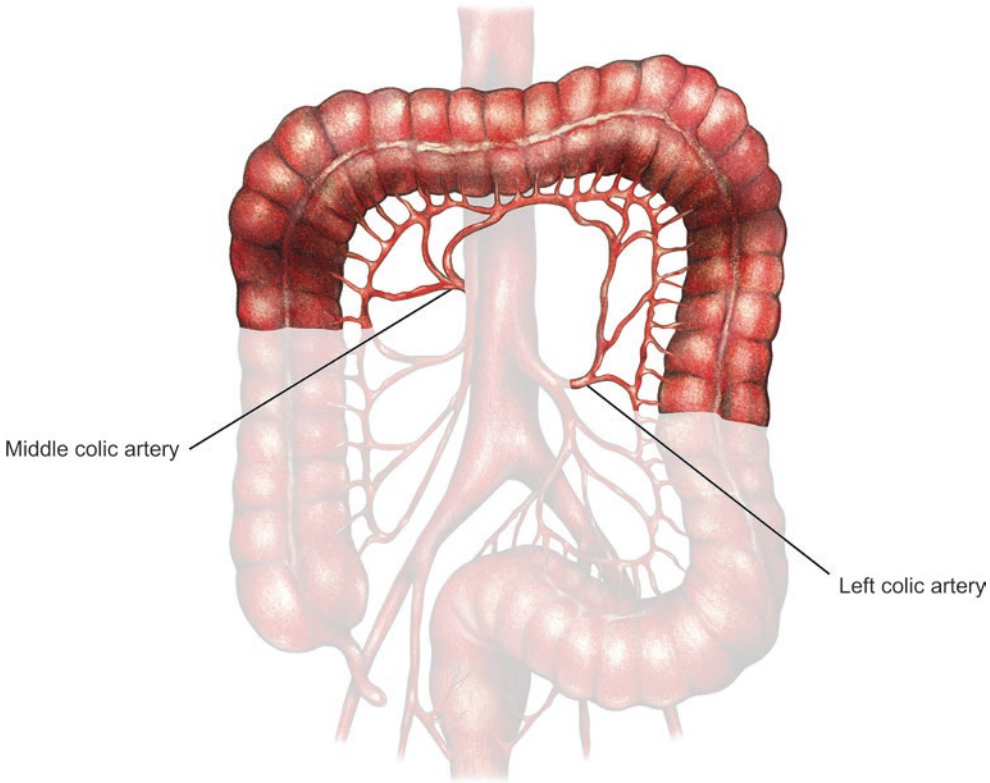

Fig. 25.5 Extended left hemicolectomy

Splenic Flexure and Descending Colon Cancer

Tumors of the splenic flexure and proximal descending colon are usually treated by a left colectomy. This procedure involves high ligation of the left colic artery and left branch of the middle colic artery (Fig. 25.6). The resultant mesenteric resection includes the areas drained by the distal half of the transverse colon and the descending colon. The resulting anastomosis is typically transverse colon to sigmoid colon. The root of the IMA and superior hemorrhoidal artery is preserved to maintain arterial flow to the remaining sigmoid colon. If colorectal anastomosis is performed, then the root of the IMA can be divided.

Technical Aspects

The patient should be positioned in split leg or low lithotomy position to facilitate stapled end-to-end anastomosis and/or leak testing of the anastomosis endoscopically. The small bowel should be positioned on the patient's right side so that exposure is gained to the base of the mesentery. Either before or after mobilization of the colon to its embryologic midline position, attention is directed to the mesentery. The inferior mesenteric vein is divided adjacent to the ligament of Treitz. A decision is made as to whether the sigmoid will be preserved, and then the IMA is divided at the aorta (sigmoid to be removed), or the left colic artery is ligated at its origin while preserving the root of the IMA and superior hemorrhoidal artery (sigmoid to be preserved). During these resections, the splenic flexure is completely mobilized, and the left side of the omentum is typically taken with the specimen. The proximal and distal colon transection lines are determined by the resected blood supply and the margin on the tumor. For some proximal splenic flexure lesions, an extended left colectomy with division of the main middle colic artery trunk divided is indicated.

For tumors located in the distal descending colon, a more formal left colectomy includes resection of the sigmoid colon and a colorectal anastomosis (Fig. 25.7). The IMA is isolated at its origin, making sure to identify and preserve the left ureter. The IMA is then ligated at its origin, and the inferior mesenteric vein (IMV) is taken near the ligament of Treitz at the inferior border of the pancreas. The mesentery is lifted off of the retroperitoneum, and the entire left colon from the distal transverse colon to the top of the rectum is removed. It is important to note that attempts at anastomosis can be difficult due to reach and tension. To facilitate reach, the IMV should be ligated proximally. The transverse colon should be mobilized and omentum released from the stomach. A retroileal anastomosis may be needed to allow reach of the colon to the rectum for anastomosis in select patients.

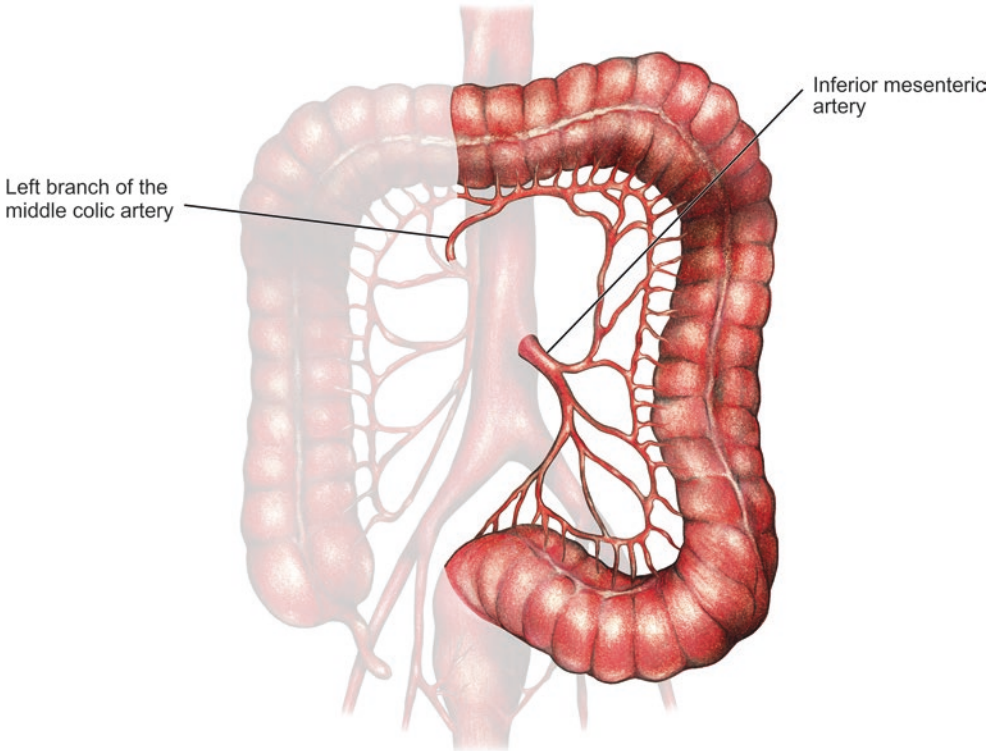

Fig. 25.7 Formal left hemicolectomy for descending colon tumor

Sigmoid Colon Cancer

Sigmoid colon cancer is treated with either a sigmoid colectomy or a left colectomy, depending on the location of the tumor in the sigmoid colon. More proximal lesions are best served with left colectomy (as outlined above) to ensure adequate lymph node harvest. Tumors in the mid to distal sigmoid colon are adequately treated with anterior resection of the rectosigmoid/sigmoid colectomy. There has not been a proven oncologic benefit for formal left colectomy for distal sigmoid colon tumors.

Technical Aspects

An anterior resection is performed for tumors of the mid and distal sigmoid colon. The patient is placed in low lithotomy position. For a medial to lateral approach, the peritoneum is incised along the root of the sigmoid mesocolon, from IMA origin to just distal to the sacral promontory. Dissection just deep to the arc of the superior hemorrhoidal vessels allows for identification and preservation of the hypogastric nerves, left ureter, and gonadal vessels. At this point, a decision is made as to whether to divide the IMA at the aorta or preserve the left colic artery and instead divide the superior hemorrhoidal artery at its origin (Fig. 25.8). As discussed previously, several studies have demonstrated that there is no survival advantage of "high" ligation of the IMA although lack of precise anatomic definitions makes it difficult to draw definitive conclusions (8, 40, 41). During mobilization of the sigmoid colon and the ligation of the vessels, the left ureter should be identified and preserved. Most injuries of the ureter occur at the level of the iliac artery. One then completes the dissection of the sigmoid and descending colon and its mesentery off of the retroperitoneum. The distal aspect of resection is the upper rectum, and the proximal aspect of resection is typically the junction of the descending and sigmoid colon, assuring appropriate margins and pulsatile arterial flow to the proximal colon conduit. One then determines if the descending colon will reach without tension to the rectal stump. If there is any tension, additional maneuvers to create length for the colon conduit include high ligation of the inferior mesenteric vein at the inferior border of the pancreas and complete splenic flexure mobilization. Some surgeons will routinely mobilize the splenic flexure, while some do so selectively. The anastomosis is then created, typically in an end-to-end fashion with an endoscopic stapler. As per routine, endoscopic inspection and pneumatic anastomotic leak testing, preferably with carbon dioxide as the instilled gas, should be performed.

Special Circumstances

Obstructing or Perforated Colon Cancer: Principles of Surgical Resection

About 15% of patients with colon cancer will present with acute obstruction or perforation. Management varies based on location of the tumor and the clinical presentation.

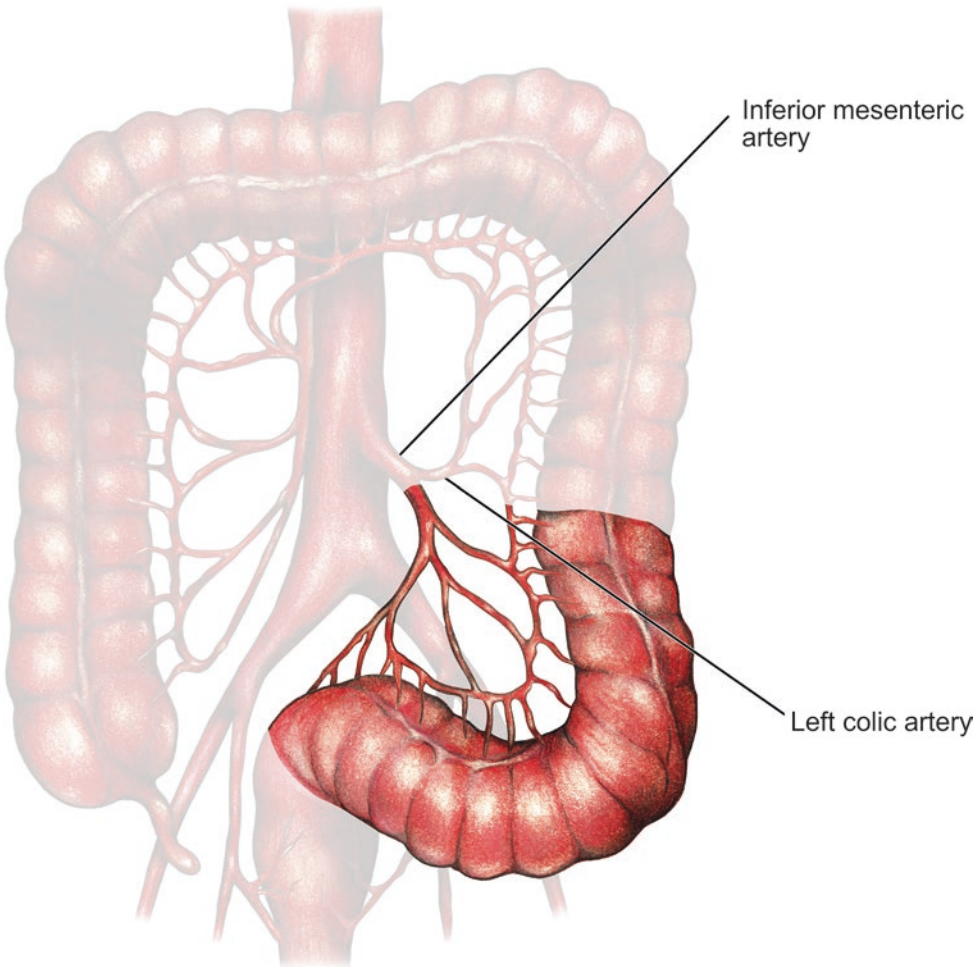

Fig. 25.8 Sigmoid colectomy

Patients who present with acute obstruction due to suspected colon malignancy typically undergo CT of the abdomen and pelvis ordered by the emergency room physician. Unless the patient has undergone recent colonoscopy, urgent water-soluble contrast enema should be considered as the next step in evaluation. Water-soluble contrast enema will typically confirm the diagnosis, evaluate for synchronous distal lesions, and prep the distal colon for possible intraoperative colonoscopy. For obstructing right colon tumors, right colectomy should be considered. The dilated colon proximal to the obstruction is removed during right colectomy, and if the ileocecal valve is competent, the ileum is usually of reasonable caliber, and the patient can thus be considered for primary anastomosis if doing well otherwise. If the ileum is dilated and edematous, resection with end ileostomy and mucus fistula using a corner of the transverse staple line in the ileostomy opening as a vent can be considered. Other options include leaving the closed distal colon segment in the abdomen (only if one can ensure that there are no synchronous large distal colon lesions), creation of formal colon mucus fistula in the contralateral abdomen, and creation of ileocolic anastomosis with proximal diverting ileostomy.

If the site of the obstruction is located more distally in the colon, more extensive resections are necessary. If there is evidence of proximal colon ischemia, then subtotal colectomy should be strongly considered (Fig. 25.9). The decision as to whether to perform anastomosis (ileosigmoid or ileorectal) should again be based on the condition of the bowel and the acute and chronic condition of the patient. If the proximal colon is dilated but not ischemic, then endoluminal stent as a bridge to formal resection can be considered. If this is not the favored approach or not possible, then Hartmann resection with proximal colostomy should be considered. Only in very rare cases should primary anastomosis, with or without proximal fecal diversion, be considered due to the risk of anastomotic leak. If primary anastomosis and proximal fecal diversion is performed, then intraoperative colonic lavage should be considered in order to clear the diverted segment of stool, which could otherwise slowly extrude out of a leaking anastomosis should this complication occur.

In cases of perforation, similar principles as discussed above are followed. One additional consideration for perforated tumors, however, is the high rate of recurrence and the need for adjuvant chemotherapy. In this situation, one should avoid creating a high-risk anastomosis that may leak and then delay or obviate adjuvant chemotherapy.

Surgical Resection for Colon Cancer in the Setting of Lynch Syndrome

Approximately 3% of all colorectal cancers develop within the setting of Lynch syndrome. These patients have an increased risk of developing metachronous colon cancers due to their genetic predisposition (42). When a curable colon cancer is diagnosed in the setting of Lynch syndrome, the American Society of Colon and Rectal Surgeons recommends total abdominal or subtotal colectomy as opposed to a

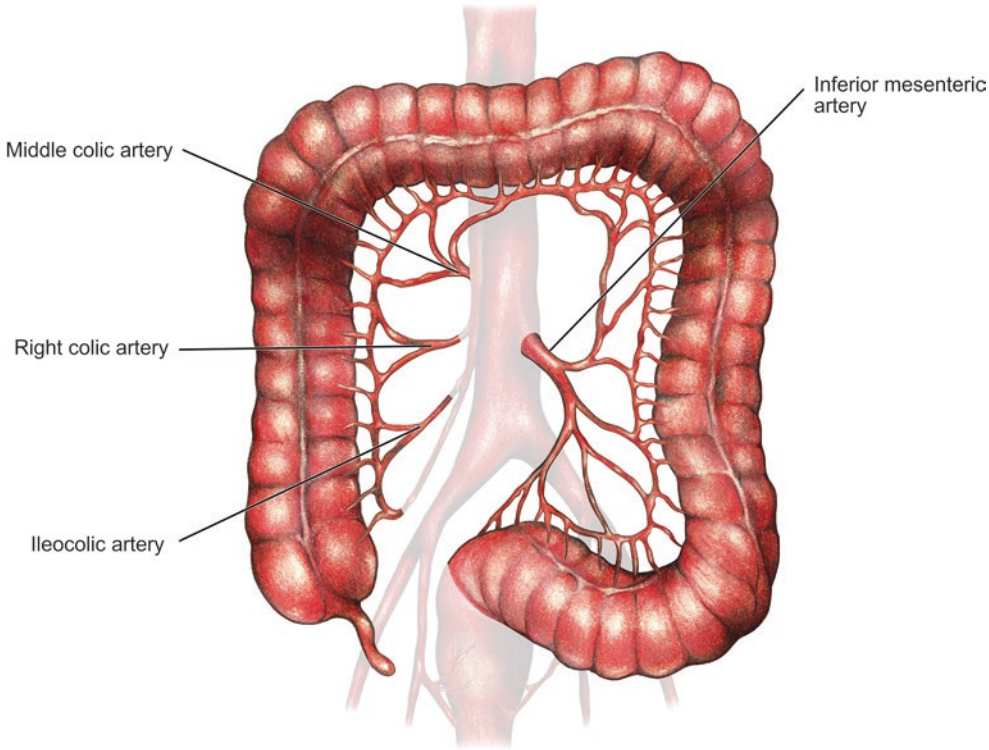

Fig. 25.9 Subtotal colectomy

segmental colectomy due to the reduced risk of metachronous cancer afforded by extended resection (43). This subject is covered in more detail in another chapter.

Rectal Cancer: Neoadjuvant Therapy

26

Steven R. Hunt and Matthew G. Mutch

Key Concepts

- Standardized surgery using the total mesorectal excision concept remains paramount for achieving local control for rectal cancer.
- Addition of neoadjuvant therapy (short-course radiation, long-course chemoradiation) along with standardized surgery improves local control.
- Neoadjuvant short-course radiation therapy and long-course chemoradiation therapy have not improved DFS or OS for patients with LARC.
- Increased time interval between the completion of radiation therapy and surgery directly impacts the pathologic response of the primary tumor.
- The administration of systemic multidrug chemotherapy in the neoadjuvant setting as either induction or consolidation relative to radiation therapy has led to improved primary tumor response, improved tolerance, and improved delivery.

Introduction

As our understanding of the management of rectal cancer evolves, the tools available to stage and treat these patients are ever-increasing in number. Just a decade ago, staging and treatment were relatively straightforward. Patients were staged with endoscopy to assess tumor location, transrectal ultrasound (TRUS) to determine depth of tumor invasion (T stage) and lymph node status (N stage), and cross-sectional imaging (typically computed tomography, CT) to assess for distant metastatic disease (M stage). Based on these results, patients were offered one of two options for definitive therapy: patients with early stage tumors (cT1-2N0M0) went directly to surgery, and patients with locally advanced tumors (cT3-4N0 or cTXN1-2M0) received neoadjuvant therapy followed by surgery. The options for neoadjuvant therapy were limited to long-course radiation and chemotherapy, with short-course radiation therapy being used in parts of Europe and sparingly in the United States. Systemic chemotherapy was typically the last mode of therapy received by rectal cancer patients. Trimodal therapy combining pelvic radiation, surgery, and chemotherapy evolved into the current "standard of care" for patients with locally advanced rectal cancer (LARC).

Improvements in rectal cancer staging, systemic chemotherapy, and our understanding of the effects the components of trimodal therapy had on both local and systemic disease have allowed for significant changes in how we utilize these three modes of therapy. The treatment paradigm of long-course chemoradiation therapy followed by surgery, and then systemic chemotherapy is being challenged.

Historical rates of local pelvic failure for LARC were upward of 25%, but the introduction of strict surgical technique and neoadjuvant chemoradiation therapy has consistently lowered the rate to between 5% and 10% [1–4]. Despite these improvements in local control, neoadjuvant radiation and optimal surgery have not translated into consistently improved overall survival [5–7]. Patients with LARC (stage II and III) currently have a 30–40% risk of distant failure, which is the most frequent cause of cancer-related death in this population [8]. Many have hypothesized that the lack of improvement in survival is a result of the long time period between initiation of neoadjuvant therapy and the delivery of multidrug systemic chemotherapy, which can be up to 20 weeks. These issues have led to studies examining the most appropriate timing and sequence of the three treatment modalities. First, distant recurrence is a result of occult micrometastases, and the longer they are left untreated, the greater the chance they have of surviving and establishing growth in a distant site [9]. Second, in attempting to define the most appropriate timing of surgery after radiation therapy, it has become clear that longer "resting" intervals have

led to a greater response rate of the primary tumor [10–13]. Third, the introduction of oxaliplatin to the systemic treatment of colorectal cancer has demonstrated an improvement in tumor response compared to 5-FU alone [14, 15]. Finally, the concept of organ preservation is becoming more accepted in patients who have a clinical complete response to neoadjuvant therapy [16]. As a result of these observations, there has been a dramatic change in rectal cancer treatment, namely, the utilization of multidrug systemic chemotherapy in the neoadjuvant setting and the introduction of the concept of total neoadjuvant therapy (TNT). This chapter will focus on the history of neoadjuvant therapy, the evolution of the use of systemic chemotherapy in the neoadjuvant setting, and the concept of total neoadjuvant therapy (TNT).

Rectal Cancer Staging
