For the purposes of this chapter, staging will be discussed only in relation to determining the need for neoadjuvant therapy. Systemic staging is important, as knowledge of the presence of distant metastatic disease may impact decisions regarding the use and timing of all three modalities of therapy – surgery, radiotherapy, and chemotherapy. Locoregional staging in rectal cancer is important for planning operative therapy and for making the decision as to whether the patient should be treated with neoadjuvant therapy. TRUS had been used in rectal cancer staging for the better part of the last 30 years, but because of its operator dependence, technical challenges, and only moderate accuracy, it has been supplanted in the last decade by magnetic resonance imaging (MRI), especially for locally advanced tumors. Currently, pelvic MRI is the recommended imaging modality for accurate local staging of rectal cancer [17]. It provides information regarding tumor size and location, the relationship of the tumor to the sphincter complex and peritoneal reflection, evidence of extramural vascular invasion, and invasion of other pelvic structures. Most importantly, MRI defines the relationship of the tumor to the mesorectal fascia. This is often termed the "circumferential resection margin (CRM)" by radiologists, although obviously the true CRM can only be determined histologically. On MR, the CRM is defined as the closest distance of the tumor to the mesorectal fascia. It is thus assumed that the surgeon will be able to accurately mobilize the rectum and mesorectum in this plane. The CRM is considered threatened or involved when the tumor extends within 1 mm or less of the mesorectal fascia and breaches the mesorectal fascia or for lower tumors, when they invade the intersphincteric plane [18]. The significance of the CRM, and more specifically an involved CRM, to local recurrence and overall survival in rectal cancer patients has been elucidated with increasing clarity over the past three decades [18–21]. Local recurrence is significantly higher in patients with a positive CRM than without [18, 22]. Furthermore, with decreasing distance to the CRM, there is a dramatic increase in rates of local recurrence, metastasis, and death [18]. MRI has emerged as consistently superior to either TRUS or CT scan for CRM assessment, while offering comparable assessment of both T and N stage [23]. In patients who have contraindications to MRI, the combination of physical exam, TRUS, and a pelvic CT scan can provide adequate information to guide therapy.

There are no widely agreed upon recommendations for restaging the primary tumor following neoadjuvant therapy. Patients with a threatened or involved CRM on initial staging exam may benefit from restaging [17]. In these patients, treatment-related tumor retraction from the CRM portends an improved prognosis [21]. However, there have been very little data to support the concept that local restaging will change operative strategy in patients initially presenting with locally advanced tumors. Because neither radiotherapy nor chemotherapy kill in a "wave front" and isolated nests of viable tumor can persist in the original volume of tumor, the surgeon should plan on resecting all tissue that was originally involved with tumor. The major exception to this recommendation regarding restaging is when one is considering nonoperative management after neoadjuvant therapy (definitive chemoradiotherapy, "watch and wait").

The National Comprehensive Cancer Network (NCCN) provides a formal definition of the rectum as beginning at a virtual line between the sacral promontory and the top of the pubic symphysis and ending at the palpable upper border of the anorectal ring [17]. While this definition is important in differentiating rectal cancer from colon cancer, it is not intended to mandate which tumors should be treated with neoadjuvant therapy. Suitability for neoadjuvant radiation often depends on the nation in which the patient is presenting. In the United States, the NCCN guidelines recommend neoadjuvant radiation for all clinical stage II and III patients [17]. The European Society for Medical Oncology (ESMO) allows for patients with early cT3 cancers (invading less than 5 mm beyond muscularis propria) to be treated with proctectomy alone [24]. The ESMO guidelines even permit surgery alone for patients with clinical N1 disease in the upper and mid-rectum, provided that the circumferential resection margin appears free on imaging.

History of (Neo)Adjuvant Therapy

For over 100 years, radiation has been used to varying degrees in the treatment of rectal cancer. In the early twentieth century, surgery was used only for salvage, as it was extremely morbid. Over time, as operative and anesthetic techniques improved, surgery became the mainstay for the treatment of rectal cancer. In the early 1980s, William Heald published multiple papers describing his technique and excellent local control with what he described as "total

mesorectal excision" (TME), which emphasized the concept of removing the appropriate amount of mesorectum in its fascial envelope, using precise technique with good visualization [1]. This was not a novel concept, but not routinely practiced by many surgeons at the time, who often removed the rectum bluntly, potentially threatening the CRM and leaving involved mesorectal nodes in situ. Despite the publications of Heald and others, widespread adoption of TME technique was slow, and surgery at that time had a high local recurrence rate. This high local recurrence rate prompted multiple trials aimed at using radiation to improve local control.

Two competing schools of thought emerged on the use of radiation in rectal cancer. Advocates for preoperative radiation touted the ability of radiation to shrink tumors prior to surgery. This camp argued that tissue oxygenation, which is requisite for maximal radiation efficacy, was adversely impacted by scarring postoperatively. Additionally, neoadjuvant delivery would minimize radiation damage to the small bowel and neorectum, as pelvic adhesions would be fewer and small bowel fixation in the pelvis less, in the preoperative period. Those supporting the concept of selective postoperative radiotherapy noted that the inherent inaccuracies of staging would lead to overtreatment of many patients and also commit some patients with lower stage tumors to adjuvant chemotherapy because the true tumor stage would be difficult to differentiate. There was also significant fear that preoperative delivery would lead to increased anastomotic and wound complications. Delay of surgery, which was the mainstay of therapy, was also cited as a reason to delay radiation until after surgery. While early trials demonstrated the value of radiation in both the preoperative [25, 26] and postoperative setting [27–29], it would take years before the optimal timing of radiation would be established.

Adjuvant Radiation

The initial early large trials for rectal cancer used radiation alone in the adjuvant setting. The Medical Research Council Rectal Cancer Working Party in the United Kingdom found that radiation delivered in the postoperative setting decreased the local recurrence rate by 50% when compared to surgery alone [30]. Meanwhile, several in vitro and animal studies demonstrated that 5-fluorouracil (5-FU) enhanced the effectiveness of radiation on various tumor cell lines [31, 32]. Additionally, the Mayo Clinic demonstrated that combining 5-FU with radiation improved palliation in patients with recurrent or unresectable rectal cancer [33]. With this background, various groups began to explore the use of combined chemoradiation in trials.

In the United States, the Gastrointestinal Tumor Study Group performed a prospective randomized study comparing surgery alone to surgery plus adjuvant therapy with either chemotherapy, radiation, or combined chemoradiation [29]. While the study was small and likely underpowered, it did show that postoperative radiation combined with chemotherapy conferred a significant 24% survival advantage over surgery alone.

The North Central Cancer Treatment Group (NCCTG) set out to determine if chemotherapy and radiation were more effective than radiation alone in the adjuvant setting [34]. Patients were randomized to groups receiving radiation alone or chemotherapy and chemoradiation. The radiation was delivered over 5 weeks to a total dose of 45 Gy, and most patients received a 5.4 Gy boost to the tumor. The patients in the combined chemotherapy and chemoradiation group received systemic chemotherapy with 5-FU and semustine (methyl CCNU) for several cycles and then radiation combined with bolus 5-FU, administered early and late during the course of radiation. This group was also given more systemic chemotherapy after the chemoradiation. With 204 patients enrolled, the authors demonstrated significant improvements in disease-free survival, local recurrence, cancer-related death, and overall survival in the combined chemotherapy and chemoradiation group. While there was no difference in the severe side effects between groups, the chemoradiation group suffered more gastrointestinal and hematologic toxicities.

Following the release of these study results, the National Institute of Health convened a Consensus Conference on colorectal cancer. It was the overwhelming opinion of the conference that both adjuvant radiation and chemotherapy should be part of the treatment of locally advanced rectal cancer. This was released as a Consensus Statement in 1990, published in the Journal of the American Medical Association [35]. In the manuscript, the authors point out that semustine had significant leukemogenesis and nephrotoxicity, and they were emphatic that future studies should attempt to find adjuvant regimens that did not use semustine. Following release of the 1990 NIH consensus statement, many patients with rectal cancer were then given adjuvant chemoradiotherapy, although the vast majority of it was administered in the postoperative setting.

Seeking to deliver adjuvant chemoradiation in a more effective and more tolerable regimen, the Gastrointestinal Intergroup performed a 2 × 2 clinical trial comparing postoperative chemoradiation with bolus 5-FU to chemoradiation to chemoradiation with infusional 5-FU delivered over the entirety of the radiation treatment [36]. Additionally, they evaluated the use of semustine delivered before and after chemoradiation because of semustine's significant toxicities. This was a large multi-institute trial involving 660 patients with stage II and III rectal cancers. All patients received systemic chemotherapy with 5-FU (+/− semustine) both before and after chemoradiation. The trial showed that there was a significantly increased time to recurrence in the group that received the 5-FU as a constant infusion. Additionally, the

authors found no benefit to the addition of semustine to the systemic chemotherapy regimen. They concluded that infusional 5-FU was superior to bolus 5-FU and that semustine was not necessary in the adjuvant regimen for rectal cancer.

While it was clear that adjuvant therapy conferred a significant benefit to rectal cancer patients, it had not been definitively proven that the addition of radiation to adjuvant chemotherapy was more helpful than chemotherapy alone. The National Surgical Adjuvant Breast and Bowel Project (NSABP) R-02 was a large trial designed to address this question [37]. As with the trials discussed above, in the radiation group, systemic chemotherapy was given before and after postoperative chemoradiation. The authors demonstrated that the addition of radiation to systemic chemotherapy significantly improved local control but did not affect the incidence of distant disease or overall survival.

Neoadjuvant Radiation

Meanwhile, advocates for preoperative radiation had been working diligently to prove the value of administering radiation prior to surgery. Out of fear that radiation would lead to significant postoperative complications, early trials used relatively low doses (<20 Gy), and none of these studies showed significant improvement in local control or overall survival as compared to surgery alone [38–40].

Eventually, higher doses of preoperative radiotherapy were utilized. The European Organization for Research and Treatment of Cancer (EORTC) demonstrated that preoperative delivery of 34.5 Gy of radiotherapy reduced the local recurrence rate from 30% to 15% when compared to surgery alone. This was one of the first large prospective studies to show a benefit to neoadjuvant radiation. While there was a trend toward improved survival, it was not significant. The authors did caution that such a "large" dose of radiation in the neoadjuvant setting may have significant morbidity in elderly and medically frail individuals [41].

The Medical Research Council Rectal Cancer Working Party evaluated the use of neoadjuvant radiation for potentially operable fixed and tethered tumors [42]. These patients were chosen because the tumors were likely to be higher stage, minimizing the chance of overtreatment. Patients were randomized to surgery alone or radiation followed by surgery. Patients in the treatment group were given 40 Gy in 20 fractions, and surgery was delayed by at least 4 weeks. There was no difference in postoperative complications between the groups. The authors showed a significant improvement in local control and disease-free survival in the patients treated with neoadjuvant radiation followed by surgery as compared to patients treated with surgery alone.

The Uppsala Trial compared preoperative and postoperative radiation delivery in what was the largest comparative trial at that time [43]. Patients randomized to the preoperative radiation group were treated with 25.5 Gy over 5–7 days followed by immediate surgery. Patients assigned to the postoperative treatment group were given radiation only if their pathologic stage was stage II or III. They were then treated with 60 Gy over 8 weeks. Local recurrence rates were significantly better in the neoadjuvant group (12% vs 21%). Despite the improvement in local control, the study showed no survival advantage to preoperative radiation. The authors did note that half of the patients assigned to the postoperative treatment group had delayed radiation therapy due to prolonged recovery from surgery.

The Foundation Trials

The foundation for the use of neoadjuvant radiation that is commonly used today arises primarily from three sequential publications around the turn of the century in the New England Journal of Medicine. The first of these studies was the Swedish Rectal Cancer Trial [3]. Based on the results in the Uppsala Trial, the study designers compared surgery alone to neoadjuvant short-course radiation followed by immediate surgery. This large randomized trial was offered to patients with resectable rectal cancer for whom abdominal surgery was planned. All patients had a minimum of 5 years of follow-up. Nearly one-third of the patients in the trial had stage I disease. The results showed a significant and dramatic decrease in local recurrence in those treated with neoadjuvant short-course radiation (11% vs 27%). There was also a difference in overall and disease-free survival, favoring those in the neoadjuvant radiation group. Critics of the trial, many of whom believed that precise surgery alone was sufficient treatment for rectal cancer, argued that the local pelvic failure rate in the surgery alone group was too high. They contended that the trial only proved that radiation mitigated problems related to poor surgical technique. Moreover, there were significantly more stage I and stage II patients in the radiation/surgery group than in the surgery alone group. Even though patients were treated with short-course radiation and immediate surgery, the authors attributed these differences to tumor downstaging from radiation.

Soon after the Swedish trial was published, another large national study addressed some of its shortcomings. The Dutch Colorectal Cancer Group essentially repeated the Swedish Rectal Cancer Trial, randomizing patients to surgery alone versus preoperative short-course radiation followed by immediate surgery [2]. However, the trial designers recognized the importance of standardizing and optimizing surgical technique. Participating surgeons were required to attend workshops and symposia on "TME surgery" and watch instructional videos and were monitored by specially trained expert surgeons. Specifically, the first five proctectomy procedures at each institution were proctored. In addi-

tion, this study standardized pathologic examination of the specimen, and the histology slides were reviewed by supervisory pathologists. The rigor of the study succeeded in improving surgical outcomes, with an overall 2-year rate of local recurrence of 5.3%. However, even with the improved surgical technique, neoadjuvant radiation still significantly improved local control compared to surgery alone with local recurrences of 2.4% in the irradiated group, compared to 8.2% in the TME alone cohort at 2 years. These findings persisted at 10-year follow-up, with local recurrence rate of 5% in the group assigned to radiotherapy and surgery and 11% in the surgery-alone group ($p < 0{\cdot}0001$). Once again, despite the improvement in local control, there was no difference in overall survival between groups. There were significantly more perineal wound complications in the radiation treatment group, but other morbidities and mortality were no different between groups. The conclusion of this study was that even with optimal surgical technique, neoadjuvant radiation improved local control.

The German trial was designed to compare preoperative and postoperative chemoradiation [7]. Because some of the large American trials had shown a survival advantage with postoperative adjuvant chemoradiation [34, 36], the study designers chose to use long-course chemoradiation with infusional 5-FU. Patients were randomized to preoperative chemoradiation and delayed surgery or surgery followed by chemoradiation. Radiation was delivered as 50.4 Gy over 28 fractions, and the postoperative group also received an additional 5.4 Gy boost to the tumor bed. Proctectomy was standardized using TME principles in much the same fashion as in the Dutch trial. All patients were intended to be treated with four cycles of systemic 5-FU as the last therapy. The principle finding was that local recurrence was significantly better in the neoadjuvant therapy group (6% vs 13%). However, again, the local control advantage did not translate into an improvement in overall or disease-free survival. The postoperative group had significantly lower completion rates of chemoradiation (54% vs 92%) and full chemotherapy (50% vs 89%). Acute and chronic toxicities were significantly greater in the group treated with postoperative chemoradiation. The authors concluded that preoperative chemoradiation was superior to postoperative treatment with regard to local control and toxicity.

Short- vs Long-Course Radiation

In summation, the foundation studies and their predecessors allow two general conclusions. The first is that radiation provides improved local control for rectal cancer patients undergoing proctectomy. Secondly, preoperative radiation is superior to postoperative radiation for local control and is associated with less toxicity that postoperative radiation. Even prior to these studies, regional factions had aligned with either the short-course radiation or long-course chemoradiation factions. In most of the United States and parts of Europe, long-course chemoradiation was the "standard of care." In some parts of Northern and Western Europe, short-course radiation was the prevailing treatment. While the foundation studies provided clear evidence that preoperative radiation was superior, they did not provide any guidance on which method of delivery was better.

Practitioners who favored short-course radiation pointed to its decreased early toxicity, convenience for the patient, and decreased cost compared to long-course chemoradiation. Those who favored long-course chemoradiation felt that this modality afforded reduction of tumor bulk and was associated with a greater chance of anal sphincter preservation. Although reducing tumor bulk may make proctectomy easier, the same effect can be achieved by waiting longer to operate after short-course radiotherapy. The lack of downstaging seen in early trials of short-course radiotherapy was simply an artifact of the short-time interval between completion of radiotherapy and surgery (typically 1–2 weeks) typically employed. Secondly, there should be no effect of neoadjuvant therapy on anal sphincter preservation rates, because, as outlined above, nests of tumor cells can persist in the field of the original tumor, and surgeons should remove all tissue originally involved with tumor regardless of its appearance after neoadjuvant therapy, if they are to perform proctectomy. Some advocates for long-course chemoradiation also felt that the higher dose in each fraction of short-course radiation would lead to increased late toxicities, although there were no definitive data to support this contention.

The first comparative trial of short- and long-course chemoradiation was conducted in Poland [44]. Rather than a non-inferiority trial, the study was designed with the specific aim of determining if chemoradiation improved the rate of sphincter preservation. Patients with cT3 or cT4 tumors were randomized to the short-course arm received 25 Gy over 5 days followed by immediate surgery. The long-course patients were treated with 50.4 Gy over 28 days with bolus 5-FU and then delayed surgery. Postoperative systemic chemotherapy was not offered to patients that had a pathologic complete response (pCR). The authors found no difference in sphincter preservation rates, overall survival, or disease-free survival. Four-year actuarial local recurrence was 11% in the short-course group and 16% in the long-course group, which was not statistically different. Severe late toxicity was equal in both groups. The authors suggested that short- and long-course might be oncologically equivalent treatment options for advanced tumors. While practitioners of short-course treatment felt validated by the manuscript, the Polish trial did not convince many American oncologists that short course was a viable option and long-course chemoradiation continued to be the preferred option in the United States. Adding to the complexity of the decision-making process is

the fairly substantial financial incentive in the United States to utilize long-course radiotherapy for the radiation oncologist.

The Trans-Tasman study provided more evidence that short- and long-course preoperative regimens are oncologically equivalent [45]. The treatment arms were similar to the Polish trial except that inclusion was limited to cT3 tumors, and the radiosensitizing chemotherapy in the chemoradiation arm was delivered with infusional, rather than bolus 5-FU. Similar to the Polish trial, this study showed no difference in local recurrence or survival between groups. Again, there was no difference in severe late toxicities between short- and long-course regimens.

More recently, the Stockholm III trial provided guidance on the timing of radiation and surgery [46]. This noninferiority study set out to determine the optimal timing of surgery following neoadjuvant radiation. The study evaluated three radiotherapy treatment options – short-course radiation and immediate surgery, short-course radiation and delayed (4–8 weeks) surgery, and long-course radiation (without chemotherapy) and delayed surgery. While the comparative results of the study are muddled by some design flaws, the study did show significantly more frequent surgical complications with short course followed by immediate surgery. The authors concluded that surgery after short-course radiation should be delayed and that such a delay might allow for earlier neoadjuvant systemic chemotherapy.

Total Neoadjuvant Chemoradiation Therapy (TNT)

Rationale

As discussed above, the US "standard of care" trimodal regimen of neoadjuvant chemoradiation and surgery, followed by systemic chemotherapy, provides excellent local control for patients with LARC. However, distant recurrence remains the greatest pattern of failure for patients with T3,T4, or N+ tumors, with a risk as high as 30–40% [47, 48]. As a result, the vast majority of prospective randomized trials examining the various neoadjuvant regimens of radiation alone or with chemotherapy have failed to demonstrate any improvement in overall or disease-free survival [2, 4, 8]. These realizations have prompted a shift in treatment paradigms, focusing efforts to improve the rate of distant failure, while preserving strategies that result in excellent local control. The traditional treatment paradigm for LACR is clearly effective, but there are several shortcomings that may contribute to its failure to improve the survival for these patients. First, in the chemoradiation therapy, surgery, and systemic chemotherapy regimen, patients with advanced disease will not receive systemic multidrug cytotoxic therapy until a minimum of 21 weeks after the initiation of their treatment. This time interval can be further lengthened by any complications or delays in recovery from surgery. There are clear data demonstrating that timely delivery of adjuvant chemotherapy improves survival for patients with colorectal cancer [9]. It has been shown that for every month that adjuvant therapy is delayed, there is a relative decrease in overall survival by 14%. Thus, by extrapolation, delivering systemic chemotherapy at the beginning of the treatment regimen may lead to improvement in survival as the micrometastatic disease is being treated up to 5 months sooner than in the US "standard" treatment. Second, having systemic therapy at the end of the treatment sequence impacts patient compliance. Failure to receive adjuvant chemotherapy can result from complications associated with surgery, prolonged recovery resulting is poor performance status, and patient preference after an already long treatment course. Finally, neoadjuvant chemoradiation therapy is associated with a complete pathologic response rate of 15–19% and downstaging rate of 40–50% [49, 50]. However, with the introduction of newer regimens including agents such as oxaliplatin and its timing within the treatment regimen, there has been an increase in primary tumor response [51–53]. By altering the order of the three modes of therapy and exposing patients to systemic chemotherapy sooner, it may lead to improved compliance with therapy, improved tumor response, and ultimately improved survival. Therefore, several studies began to examine the use of systemic chemotherapy in the neoadjuvant setting, whether it by itself or as concurrent, induction, or consolidation treatment with radiation therapy.

Utilization of Systemic Chemotherapy in the Neoadjuvant Setting

Systemic Chemotherapy Alone

After the results of the MOSAIC trial were published demonstrating the addition of oxaliplatin to the standard 5-fluorouracil (5-FU)-based chemotherapy regimen improved disease-free survival for patients with stage III and selected stage II colon cancer, the FOLFOX (5-FU, folinic acid, oxaliplatin) regimen has become first-line therapy in the adjuvant setting [14]. The subsequent ADORE trial of adjuvant FOLFOX in patients with LARC treated with neoadjuvant chemoradiation therapy demonstrated a DFS benefit compared to 5-FU alone [54]. Further, studies examining the addition of oxaliplatin to 5-FU-based regimens for patients with metastatic disease have also shown up to a 70% improvement in tumor response compared to 5-FU alone [55, 56]. Based on these results and changes in clinical practice, clinicians began utilizing systemic FOLFOX therapy in the neoadjuvant setting for patients with LARC.

The Timing of Rectal Cancer Response to Chemoradiation Consortium was one of the first groups to publish their results of a multicenter trial demonstrating the response of the primary tumor to neoadjuvant FOLFOX therapy delivered after long-course chemoradiation, the sequence of which has been termed "consolidation" chemotherapy [52]. The primary goals of the study were to determine the primary tumor response, treatment toxicity, and surgical complications. This was a phase II trial that compared the outcomes for patients who underwent surgery 6 weeks after completion of chemoradiation therapy versus chemoradiation therapy followed by two cycles of FOLFOX therapy starting after 4 weeks with surgery within 3–5 weeks. With just two cycles of FOLFOX, the authors found there was a significant overall improvement in pathologic tumor response in the FOLFOX group vs the surgery group (P = 0.0217) and improvement in T stages (T0–31% vs 23%, T1–6% vs 5%, T2–28% vs 25%, T3–28% vs 43%, respectively) (P = 0.0008), but there was no improvement in N stage (0.0854). There was no difference in treatment-related toxicity and complications or perceived difficulty of surgery.

The improved pathologic response associated with FOLFOX then led some investigators to question the necessity of radiation therapy, which is associated with several toxicities such as sexual and bladder dysfunction, anal sphincter dysfunction, increased rate of pathologic pelvic fractures, and potential bone marrow suppression. The group from Memorial Sloan-Kettering Cancer Center performed a pilot study examining the feasibility of systemic FOLFOX therapy only before proctectomy for patients with LARC [57]. Thirty-two patients with tumors located between 5 and 12 cm from the anal verge were treated with six cycles of FOLFOX plus bevacizumab for cycles 1–4 only, followed by surgery. Patients who failed to respond to therapy defined as stable or progressive disease then received long-course chemoradiation therapy before surgery. The primary outcome of the study was R0 resection, which was accomplished in all 32 patients with only 2 patients receiving neoadjuvant radiation therapy due to chemotherapy-related toxicities. Ninety-four percent of patients completed all planned neoadjuvant therapy, and it was associated with 25% complete pathologic response rate, 0% 4-year local recurrence rate, and 84% disease-free survival rate. In this pilot study, 72% of the patients had clinically positive lymph nodes, so the authors concluded that in selected patients, neoadjuvant radiation therapy can be safely omitted. One caveat regarding patient selection is that all patients were cT3 (cT4 tumors were excluded) and there was no mention of circumferential radial margin status or depth of invasion into the mesorectum. However, given the high number of clinically node-positive patients, overall this was considered a high-risk group of patients.

This trial served as the template for the ongoing multicenter prospective randomized phase III trial Preoperative Radiation or Selective Preoperative Radiation and Evaluation Before Chemotherapy and TME (PROSPECT) [58]. The PROSPECT trial is a US-based multicenter trial comparing standard neoadjuvant chemoradiation therapy to neoadjuvant FOLFOX therapy with selective radiation for non-responding or progressing tumors. The protocol was amended to eliminate the use of bevacizumab because of the results of subsequent large-scale studies have not conferred a benefit for the inclusion of bevacizumab. Given the limited single institution phase II data available at the time the protocol was developed, the trial was designed as a seamless phase II/III trial, with the co-primary endpoints of local and distant recurrence. After enrollment of the first 366 patients, interim analysis showed that the predetermined stoppage requirements were not met. As a result, the study progressed to a phase III study, and enrollment was completed in the end of 2019 with a total of 1194 patients. Results from the study have not been published at the time of this writing.

The BACCHUS Trial is a UK prospective randomized phase II trial comparing FOLFOX plus bevacizumab versus FOLFOXFIRI (5-FU, oxaliplatin and irinotecan) plus bevacizumab followed by surgery 8–12 weeks after completion of the chemotherapy [59]. Enrollment began in 2016 for patients with rectal tumors from 4 to 12 cm from anal verge and high-risk features based on MRI. The high-risk features include cT3 tumors with >4 mm invasion into the mesorectum, tumors within 1 mm of the mesorectal fascia, or clinically node-positive disease. The target accrual was 30 patients in each arm, and the primary endpoint was complete pathologic response. Secondary endpoints included R0 resection status, downstaging, local recurrence, disease-free survival, and compliance and tolerance of therapy. Unfortunately, the study closed early due to poor enrollment, but they did publish their results in relation to the primary outcome of pCR. They accrued a total of 20 patients: 10 patients in each arm (Arm 1 FOLFOX and Arm 2 FOLFOXFIRI). In Arm 1, 80% of patients completed chemotherapy and went on to surgery, and in Arm 2, 90% of patients completed chemotherapy, but all patients underwent surgery. Because of the low accrual, they were not able to meet the primary endpoint. However, they reported the pCR for each arm was 0% and 20% (10% overall). Both groups demonstrated good tumor response based on the neoadjuvant rectal (NAR) scores, with no statistical difference between the groups. Treatment-related toxicity was greater in Arm 2, but overall was well tolerated with a high rate of completion. They also reported no difference in overall survival. These results are difficult to interpret given the failure to reach the endpoint, but the experience does provide support for using systemic chemotherapy in the neoadjuvant setting with regard to tumor response.

The Chinese FOWARC study was a randomized phase III, three-arm trial that compared standard chemoradiation therapy (Arm 1) versus five cycles of FOLFOX concurrent with long-course radiation therapy (Arm 2) versus 4–6 cycles of FOLFOX only (ARM 3), with all groups undergoing surgery 6–8 weeks after completion of neoadjuvant therapy [60]. Patients with tumors within 12 cm of the anal verge and any clinical stage II or III tumors were included in the study. A total of 495 patients were randomized, with the primary endpoint being 3-year disease-free survival. At the completion of the study, the numbers of patients in the final analysis were 130 in Arm 1, 141 in Arm 2, and 147 in Arm 3. The pCR rate was highest in Arm 2 (FOLFOX + chemo/XRT) at 27.5% vs Arm 1 at 14% and Arm 3 at 6.6% [OR 0.428 (95% CI 0.237 to 0.774) $P = 0.005$]. Neoadjuvant treatment compliance was equivalent across all three arms – 88.4%, 94.9%, and 94.5%, respectively. Interestingly, patients who received radiation therapy (Arms 1 and 2) had a higher rate of toxicity and surgical complications such as anastomotic leak and surgical infections compared to Arm 3 (chemotherapy alone). After a median follow-up of 45.2 months, the authors reported 3-year DFS of 72.9%, 77.2%, and 73.5% ($P = 0.709$ by log rank test), respectively [61]. The 3-year local recurrence rate was 8%, 7%, and 8.3% (log rank $P = 0.873$) and 3-year overall survival rate of 91.3%, 89.1%, and 90.7% (log rank $P = 0.971$). The results of this trial demonstrated no difference in tumor response (pCR and tumor downstaging) between traditional chemoradiation and chemotherapy alone, but despite improved response in the FOLFOX/radiation group, this did not translate into an improvement in DFS. This study had a high rate of compliance with adjuvant chemotherapy in all groups, which may have influenced the long-term outcomes. The authors concluded that neoadjuvant treatment with mFOLFOX6 concurrent with radiotherapy had acceptable tolerability and led to a higher rate of pCR compared with single-agent fluorouracil plus radiotherapy and that this was their preferred therapy. Another way of interpreting the data would be that disease-free and overall survival were not different, and thus the treatment with the lowest toxicity should be favored. At least in terms of anastomotic "fistula," this was the chemotherapy-alone group (8% vs 20% 5-FU radiotherapy, 18% FOLFOX radiotherapy).

The role of chemotherapy alone as neoadjuvant therapy alone remains unclear. The difficulties with accrual in some trials may reflect the perceived necessity of radiation therapy from both the clinician and patients' standpoint (bias). However, the PROSPECT trial was able to ultimately complete patient accrual and once the data mature, the study will be able to provide insight into which patients may benefit from neoadjuvant chemotherapy alone.

Radiation Therapy with Systemic Chemo Therapy (Concurrent)

The utilization of systemic chemotherapy concurrently with radiotherapy has several goals: maintaining local control, reducing distant failure, and improving the primary tumor's response to neoadjuvant therapy. The French Lyon R0-04 trial in the early 2000s was one of the first phase II trials to demonstrate the effectiveness of oxaliplatin and 5-FU when given concurrently with radiation therapy [62]. Forty patients with either cT3–4 or high-risk cT2 tumors received two cycles of oxaliplatin (weeks 1 and 5 during radiation), continuous infusion of 5-FU, and 50Gy of radiation over 5 weeks followed by surgery 5 weeks later. All patients completed the regimen but 17% suffered grade 3/4 toxicity. Six of the 40 (15%) had a complete pathologic response, and another 12 (30%) had only a few microscopic tumor cells remaining at the time of surgery. The Cancer and Leukemia Group B 89901 was a phase I/II US trial that confirmed that the addition of oxaliplatin in the neoadjuvant setting was able to achieve an improved pCR rate of 25% compared to historical data for 5-FU/radiation therapy [63]. In this trial, patients with clinical stage cT3–4,N0 tumors could receive up to six cycles of oxaliplatin during the radiation therapy. Once again, treatment-related toxicity was high with grade 3 or 4 diarrhea occurring in 38% of patients. The ECOG 3204 trial introduced bevacizumab along with oxaliplatin in the neoadjuvant setting in patients with nonmetastatic cT3–4 rectal cancers [64]. Fifty-four patients received five cycles of oxaliplatin and three cycles of bevacizumab along with 45 Gy of radiation therapy followed by surgical resection 6–8 weeks later. The primary endpoint of complete pathological response was achieved in 17% of patients, with 59% of patients experiencing downstaging. Ninety-one percent of patients completed therapy, but 36% patients experienced a grade 3 or 4 acute toxicity, with diarrhea being the most common.

These phase II trials set the foundation for several prospective randomized trials comparing neoadjuvant chemoradiation therapy with and without oxaliplatin. The STAR-01 Trial from Italy randomized 747 patients to 5-FU plus 50.4 Gy or six cycles of oxaliplatin plus 5-FU and 50.4 Gy followed by surgery 6–8 weeks later [50]. The primary endpoint of the study was to detect a 30% reduction in mortality with the addition of oxaliplatin. Compliance with the study protocol was good with 83% of patients in the oxaliplatin arm received at least five cycles of therapy. Acute toxicity was significantly higher in the oxaliplatin arm with 24% vs 8% ($P < 0.001$) having grade 3 or 4 adverse events. Diarrhea (15.3% vs 4.2%, $P < 0.001$), radiation dermatitis (4.5% vs 1.8%, $P < 0.037$), and asthenia (3.1% vs 0%, $P < 0.001$)

accounted for the differences between the groups. Sixteen percent of patients achieved a complete pathologic response in each group. To date the long-term results of this study have not been published.

The National Surgical Adjuvant Breast and Bowel Project Trial R-04 was a randomized trial of neoadjuvant 5-FU or capecitabine plus radiation therapy with or without oxaliplatin [65]. This study randomized 1608 patients with clinical stage II or III tumors to four arms – 5-FU/XRT, 5-FU + Oxaliplatin/XRT, capecitabine/XRT, and capecitabine+oxaliplatin/XRT, with the primary endpoint being locoregional failure. Complete pathologic response, sphincter-sparing procedure, downstaging, and pCR were secondary endpoints. The complete pathologic response was not different between any of the regimens; 5-FU vs capecitabine was 17.8% and 20.7% ($P = 0.17$), and oxaliplatin versus no oxaliplatin was 19.5% and 17.8% ($P = 0.42$). When examining the rate of sphincter-saving surgery, there was no statistical difference between all of the groups. Once again, patients treated with oxaliplatin experience significantly more grade 3 or 4 acute toxicity, and the incidence of diarrhea ($P < 0.001$) accounted for the differences between the groups. In 2015, the study group published the long-term and cancer-specific outcomes of the trial for the primary endpoint [66]. There was no difference in 3-year local recurrence between all groups; 5-FU versus capecitabine was 11.2% and 11.8% (HR = 1, $P = 0.98$), and oxaliplatin vs no oxaliplatin was 12.1% and 11.2% (HR = 0.94, $P = 0.7$). Similarly, there was no difference between the 5-year DFS and OS for all four arms. The DFS for the 5-FU vs capecitabine groups were 66.4% vs 67.7% (HR = 0.97, $P = 0.7$) and for the oxaliplatin vs no oxaliplatin groups were 64.2% vs 69.2% (HR = 0.91, $P = 0.34$). The 5-year OS for all groups were 79.9% vs 80.8% (HR = 0.94, $P = 0.61$) and 79% versus 81.3% (HR = 0.89, $P = 0.38$), respectively. Based on the results of these large prospective randomized trials, it was generally accepted that the addition of systemic oxaliplatin to concurrent 5-FU/long-course radiation therapy did not improve the complete pathologic response rate or long-term cancer-specific outcomes but was associated with an increased rate of grade 3 or 4 toxicities.

The German CAO/ARO/AIO-04 phase III trial sought to further understand the impact of oxaliplatin in the neoadjuvant and adjuvant setting [67]. This study randomized 1265 patients with clinical stage II or III patients into the control group (chemoradiation therapy with infusional 5-FU with 50.4 Gy, surgery, and 4 cycles of adjuvant infusional 5-FU) or the experimental group (chemoradiation with infusional 5-FU and 4 cycles of oxaliplatin with 50.4 Gy, surgery, and eight cycles of oxaliplatin and 5-FU), with a primary endpoint of DFS. Both groups had an equivalent and high compliance with therapy (83% vs 81%). There was no difference in grade 3 or 4 toxicities in the preoperative setting, but grade 3 or 4 GI toxicity was higher in the investigational group. There were no differences in operative morbidity, but they did report a small but significant improvement in pCR in the investigational group (17% vs 13%, OR 1.40, 95%CI 1.02–1.92, $P = 0.038$). After a median follow-up of 50 months, they demonstrated an improvement in 3-year DFS with addition of oxaliplatin in the treatment regimen (71.2% vs 75.9%, OR 0.79, 95%CI 0.64–0.98, $P = 0.03$) [68]. Compliance with adjuvant chemotherapy was similar between the groups, but it is worth noting the 5-FU only group received four cycles of adjuvant therapy and the 5-FU/oxaliplatin group received a total of eight cycles.

Pathologic Complete Response

Pathologic complete response (pCR) rate is often used as a surrogate for the relative effectiveness of neoadjuvant treatment regimens. However, it should be realized that pCR rate is primarily influenced by the amount of time that passes between completion of radiotherapy and surgery. Tumor cell death may be initiated immediately (during neoadjuvant therapy), but it takes time for the body to resorb dead cells. The pathologist cannot accurately distinguish between live and dead cells on histologic review of a resected specimen. Thus, the pCR rate can be manipulated by changing the duration of delay prior to proctectomy and one cannot assume that one neoadjuvant therapy regimen is superior to another based on pCR rate if proctectomy occurs at different intervals following neoadjuvant therapy.

We have also realized that extending the time interval between radiotherapy and surgery is associated with a higher rate of pCR, up to a limit, as all dead cells will eventually be resorbed and the histology will once again reflect the biologic activity of the tumor. It is less clear, however, whether patients exhibiting pCR after a longer treatment interval have the same good prognosis of those who are more rapidly sterilized. Along with assessing the relative effectiveness of neoadjuvant treatment regimens, the observation that neoadjuvant therapy regimens are associated with substantial pCR rates has led us to the concept of organ preservation. Variously termed "watch and wait," "definitive chemoradiotherapy," or "nonoperative management," treatment of highly select individuals with LARC without surgery has been employed.

Consolidation vs Induction Chemotherapy

Historically, the pCR after traditional long-course chemoradiation therapy has ranged from 15% to 20% after a 6–8 week resting period before surgery [1–4]. As noted above, it has also been demonstrated that longer waiting periods are associated with a higher pCR rate [10–13]. Rather than having

resection, clinicians began investigating the potential benefits of adding systemic chemotherapy durging this "waiting" period. As previously discussed, the hypothesis is to provide ongoing treatment to the primary tumor and to occult micrometastatic disease while allowing the body to completely resorb cells rendered nonviable after radiotherapy. The goals are to improve the potential for organ preservation, local control, and disease-free survival.

In 2004, Dr. Angelita Habr-Gama published the first reports of managing patients with rectal cancer who had a complete pathologic response nonoperatively [16]. At that time, their neoadjuvant regimen consisted of 50.4 Gy over 6 weeks with concurrent infusional 5-FU/leucovorin with tumor assessment 8 weeks after completion of therapy was able to achieve a pCR rate of 26%. As their experience with "watch and wait" evolved, they refined their neoadjuvant regimen to include an additional boost of radiation to the primary tumor and the addition of systemic chemotherapy during the rest period. This newer regimen consisted of 45 Gy over 5 weeks followed by an additional boost of 9 Gy to the primary tumor and mesorectum. Patients would also receive three cycles of infusional 5-FU/leucovorin during the radiation and an additional three cycles after the completion of radiation therapy. They treated 70 consecutive patients with T2–4,N0–2 tumors with this regimen and demonstrated that 68% had an initial complete clinical response at 8 weeks after completion of neoadjuvant therapy [69]. In their most recent report of their series, in 197 select patients with a complete clinical response who were treated nonoperatively, the 5 year DFS was 60% (95% CI 53%–67%) [70]. These investigations set the stage for the development of novel neoadjuvant therapy strategies aimed at improving the primary tumor response, as well as control distant metastatic spread, which will hopefully improve disease-free survival while limiting toxicity of therapy, possibly via organ preservation.

The Timing of Rectal Cancer Response to Chemoradiation Consortium sought to define the optimal time for surgery after long-course chemoradiation therapy in patients with clinical stage II or III rectal cancer. In 2011, they initiated a multicenter, nonrandomized, phase II trial to evaluate tumor response, treatment-related toxicity, and surgical outcomes for extended intervals between chemoradiation therapy and surgery, with the administration of systemic FOLFOX therapy during the extended waiting period (consolidation therapy). The initial study compared patients who underwent surgery 6–8 weeks after completion of chemoradiation to patients who received chemoradiation therapy followed by two cycles of FOLFOX therapy with surgery 3–5 weeks later [52]. The addition of two cycles of FOLFOX resulted in a significant improvement in pCR (25% vs 18%, $P = 0.0217$). There was no associated difference in surgical complications between the groups, but the additional time interval of 37 days between completion of chemoradiation and surgery in the FOLFOX group was associated with more significant pelvic fibrosis. The next iteration of this study expanded the cycles of FOLFOX therapy before surgery and was designed as a series of four sequential phase II study groups for patients with clinical stage II or III rectal cancer [53]. Group 1 received chemoradiation therapy followed by surgery 6–8 weeks later. Once Group 1 was filled, patients were then enrolled into Group 2 consisting of chemoradiation, two cycles of FOLFOX therapy followed by surgery. Patients were then sequentially enrolled in Groups 3 and 4, where they received four and six cycles of FOLFOX, respectively. Patients were allowed to receive a complete course of adjuvant chemotherapy, but it was not mandated in the study protocol. The primary endpoint was pCR. The study enrolled 259 patients with 60 in Group 1, 67 in Group 2, 67 in Group 3, and 65 in Group 4. The pCR rate increased with each additional two cycles of FOLFOX therapy (Group 1–18%, Group 2–25%, Group 3–30%, and Group 4–38%, $P = 0.0036$), and there was no significant difference in overall treatment-related toxicity between the groups. In 2018, they published the final results from the study and conferred that the addition of FOLFOX therapy in the neoadjuvant setting was associated with improved 5-year DFS [71]. Interestingly, the improvement in survival was seen in patients receiving at least one cycle of systemic therapy. The 5 year DFS for Group 1 versus Groups 2–4 was 50% vs 81% ($P = 0.0005$). There was no difference in DFS between Groups 2, 3, and 4. This is the first large-scale trial to demonstrate an improvement in survival for patients with rectal cancer receiving neoadjuvant consolidation chemotherapy, but there are several issues that need to be considered. For example, this was not a randomized trial, it was not powered for DFS as an endpoint, and adjuvant chemotherapy was not standardized. Regardless, this was a high-quality study that has shaped subsequent clinical trials examining total neoadjuvant therapy.

The Korean Society of Coloproctology established the KONCLUDE trial in 2018 [72]. This is a multicenter randomized trial comparing consolidation chemotherapy to adjuvant chemotherapy. Patients with mid to low rectal cancers with cT3N0 or cT1-3N1-2 were randomized after chemoradiation therapy to eight cycles of FOLFOX then surgery or surgery then eight cycles of FOLFOX. The primary endpoints are pCR and 3-year DFS. The study was powered to show 15% improvement in both outcomes, so 179 patients are expected to be enrolled in each arm.

While neoadjuvant systemic chemotherapy given after the completion of chemoradiation/radiation therapy has been termed consolidation therapy, "induction chemotherapy" describes systemic chemotherapy delivered prior to neoadjuvant chemoradiation/radiation therapy. As discussed above, systemic chemotherapy appears to be beneficial in the neoadjuvant setting, but questions remain regarding whether its

timing relative to chemoradiation/radiation impacts its effectiveness. Potential benefits of induction chemotherapy have been hypothesized to be better compliance, better tolerance, and omission of radiation therapy with a good tumor response, and the shorter time interval between completion of radiotherapy and surgery may limit pelvic fibrosis. Potential benefits of consolidation chemotherapy include prolonging the time interval between radiotherapy and surgery so as to allow for better assessment of primary tumor response, which may allow for better selection of patients for possible nonoperative therapy (organ preservation).

The Spanish GCR-3 phase II randomized trial compared the use of concurrent and adjuvant chemotherapy to induction chemotherapy in patients with LARC in patients with stage II or III tumors of the mid to lower rectum [73]. Fifty-two patients in Arm A received concurrent capecitabine oxaliplatin (CAPOX) and radiation therapy, surgery, and four cycles of adjuvant CAPOX, and 56 patients in Arm B received four cycles of CAPOX followed by radiation therapy and surgery. The final results did not demonstrate any difference in pCR, (13.5% vs 14.3%), 5-year DFS (64% vs 62%, $P = 0.85$), or 5-year local recurrence (2% vs 5%, $P = 0.61$). However, they did demonstrate better compliance and tolerance in Arm B (the induction chemotherapy arm). More patients completed treatment per the study protocol in Arm B than Arm A (91%A vs 54%, $P < 0.001$), and more patients in Arm A discontinued the study protocol because of treatment-related adverse events (17% vs 2%, $P = 0.006$).

The publication of these data was then followed by a publication from the group at Memorial Sloan Kettering Cancer Center, describing a large cohort retrospective study of their experience with total neoadjuvant therapy (TNT) [74]. They compared 320 patients who received neoadjuvant chemoradiation therapy followed by adjuvant oxaliplatin/5-FU-based chemotherapy to 331 patients who received eight cycles of oxaliplatin/5-FU-based induction chemotherapy followed by chemoradiation therapy. Patients in both regimens were then offered nonoperative management if they had a complete clinical response or surgery if there was persistent disease. At 12 months, the combined raw clinical complete response rates and pCR were 21.3%% and 35.7%, respectively. The most significant finding of the study was the compliance and tolerance of the systemic chemotherapy. The TNT group received more total doses of systemic chemotherapy, had fewer dose reductions, and was more likely to receive more than six cycles of therapy. The long-term survival data has not been published to date.

There are currently two multicenter randomized trials comparing induction vs consolidation chemotherapy for the treatment of LARC. The first is a US-based trial by the Rectal Cancer Consortium [75]. Patients with rectal cancers staged by MRI to be cT2-3N0 or cT1-3N1-2 were randomized to Arm 1 (induction) or Arm 2 (consolidation). The induction arm received eight cycles of FOLFOX or six cycles of CAPOX followed by chemoradiation therapy, and the consolidation arm received chemoradiation therapy followed by the same courses of FOLFOX or CAPOX. Patients were then restaged at the completion of TNT. Those patients with persistent disease underwent resection with total mesorectal excision, and those with a complete clinical response were then allocated to nonoperative therapy. The nonoperative patients were then followed regularly with digital rectal exam, endoscopy, and cross-sectional imaging. The primary endpoints for the study are 3-year recurrence-free survival. The study is closed to accrual and is awaiting follow-up data at this point. The second trial is the CAO/ARO/AIO-12 from the German Rectal Cancer Study Group [76]. They randomized 306 patients with stage II or III rectal cancer to Group A (3 cycles FOLFOX → chemoradiation therapy → surgery) or Group B (chemoradiation therapy → 3 cycles FOLFOX → surgery), with the primary endpoint of pCR. The study hypothesis was that TNT (either arm) would achieve pCR of 25% compared to 15% for traditional chemoradiation therapy. Initial results published in 2019 found the pCR in the consolidation group was higher (25% vs 17%). With regard to the primary endpoint of the study, Group B ($P < 0.001$) and not Group A ($P = 0.210$) fulfilled the predefined study hypothesis. Additionally, there were differences in the tolerance associated with the chemoradiation therapy and the FOLFOX therapy. Ninety seven percent of patients treated with upfront chemoradiation therapy received the full dose of radiation versus 91% who received upfront chemotherapy. Conversely, more patients in Group A received all three cycles of oxaliplatin (93%) and 5-FU (92%) compared to Group B (90% and 85%, respectively). Long-term oncologic outcomes are pending.

Based on aforementioned studies, there appears to be clear benefit to the utilization of systemic chemotherapy in the neoadjuvant setting. Whether given as induction or consolidation, the reported benefits to date include increased compliance, better tolerance, and improved primary tumor response, but it is unclear if this will translate into improved long-term survival. The final results of ongoing trials will help to answer this question as well as to delineate the relative effectiveness of induction versus consolidation chemotherapy. Finally, the impact of TNT on the practice of organ preservation should be better elucidated.

Short-Course Radiation Therapy with Systemic Chemotherapy

As discussed above, there are substantial data demonstrating that neoadjuvant short-course radiation therapy (SCRT) is as effective as neoadjuvant long-course chemoradiation therapy for achieving local pelvic control after proctectomy [2, 44,

45]. Additionally, short-course radiation therapy can provide significant tumor downstaging when surgery is delayed for an extended period of time [77]. The difference in time for delivery of a full course of radiation (1 week for short course vs 5–6 weeks for chemoradiation) makes it a very appealing alternative for patients and third-party payors, because of reduced cost and reduced time away from home for patients who live remote from their treatment center. In recent years, these two concepts (TNT and SCRT) have been united, and clinical trials initiated to examine the use of SCRT with either consolidation or induction chemotherapy. The Swedish RAPIDO trial randomized patients to Arm A (traditional long-course chemoradiation therapy with surgery 8–10 week later and optional adjuvant CAPOX) or Arm B [short-course radiation (5Gy × 5 days), a 2-week rest period, six cycles of CAPOX, and surgery 4 weeks later] [78]. Only patients with very high-risk tumors, defined as having at least one of the following characteristics, were included: cT4a-b and/or cN2, extramural vascular invasion, involved mesorectal fascia, and metastatic lateral lymph nodes. The primary endpoint for the study was 3-year DFS with immediate secondary endpoints being pCR and R0 resection rates. The trial has completed patient accrual but the results have yet to be published.

Washington University completed a pilot study of short-course radiation therapy followed by four cycles of FOLFOX with surgery 4 weeks later [79]. The rationale for the pilot study was that short-course radiation is not widely utilized in the United States, so the authors sought to demonstrate safety and effectiveness prior to participating in RAPIDO. Seventy-six patients with cT3–4NXMX rectal cancers were enrolled to receive this regimen, examining the rate of tumor downstaging and gastrointestinal toxicity. There were two interim analyses after 25 and 50 cases with stopping criteria of <50% T stage downstaging or a rate of grade 3 GI toxicity >20%. After completion of the study, the authors reported an overall downstaging rate of 70% with a pCR rate of 29%. All nonhematologic grade 3 or 4 toxicity was 21% with only 9% being related to gastrointestinal toxicity. For the long-term outcomes, they compared the patients with cM0 disease from this trial to a matched group of patients with clinical stage II or III tumors treated with traditional chemoradiation therapy [80]. The only difference between the two cohorts was total cycles of FOLFOX received with the short-course group receiving 11 cycles vs eight ($P < 0.0001$) in the long-course chemoradiation group. There was no difference in 3-year local recurrence rates (92% vs 96%, $P = 0.36$, respectively), but the short-course group had a better 3-year distant metastasis-free rate (88% vs 70%, $P = 0.028$) and DFS (85% vs 68%, $P = 0.032$).

A phase II single-arm trial from the United Kingdom examined the role of short-course radiation therapy after induction chemotherapy with four cycles of oxaliplatin/5-FU [81]. Sixty patients with T3 tumors without threatened circumferential radial margin were treated with this regimen and underwent surgical resection with planned adjuvant chemotherapy. The primary endpoint was feasibility assessed by completion of the treatment protocol. Fifty seven of the 60 patients made it through the protocol including surgery. However, when comparing the chemotherapy received in the neoadjuvant versus adjuvant setting, they reported a median percent dose intensity of 100% vs 63% for 5-FU and 100% vs 45% for oxaliplatin (this is a measure of actual dose received divided the by the protocol dose) demonstrating patients were more likely to receive and tolerate systemic chemotherapy in the neoadjuvant period than after surgery. There was reasonable tumor response as downstaging occurred in 73% of cases, but the pCR rate was only 12%. It should be noted that surgery occurred within 7 days of completing the radiation therapy, which could bias the results against pCR.

The Polish Colorectal Study Group has published the only long-term data comparing short-course radiation plus consolidation chemotherapy versus traditional chemoradiation therapy [82]. Two hundred sixty-one patients with cT4 or fixed cT3 tumors were randomized to Group A (short course +3 cycles of FOLFOX) and 254 patients to Group B (long-course chemoradiation) with primary endpoints of R0 resection rate and DFS. Patients in Group A had less toxicity related to the neoadjuvant therapy (75% vs 83%, $P = 0.006$), but there was no difference in the rates of grade III or IV toxicity. The R0 resection rate (77% vs 71%, $P = 0.07$) and pCR (16% vs 12%, $P = 0.17$) were similar in both groups. Interestingly, Group A had better 3-year overall survival rate (73% vs 65%, $P = 0.046$), but there was no difference in DFS (53% vs 52%, $P = 0.86$). Finally, there was no difference in postoperative complications (29% vs 25%, $P = 0.18$), which suggests that the extended period of time between completion of short course and surgery does not make the surgery more difficult. After 7 years of follow-up, there was no difference in OS, DFS, or LR between these groups [83]. Both the RAPIDO and POLISH II trials examined very high-risk patients where there was either a threatened circumferential margin, clinically positive lymph nodes, or other high-risk MRI-based features. Despite these adverse features, the utilization of short-course radiotherapy along with neoadjuvant chemotherapy was well tolerated and provided results equivalent to those achieved with long-course chemoradiation therapy. There are little data comparing short-course radiation-based TNT with long-course radiation based TNT, but both modes of radiation therapy have demonstrated effectiveness in providing excellent local control, improving compliance with systemic chemotherapy, and improving rates of pCR and tumor downstaging. We continue to wait for long-term survival data to determine if the change in the order of delivery of trimodal therapy will ultimately prove beneficial.

Conclusion

The management of rectal cancer continues its evolution, as investigators continually seek to find treatment strategies that will improve outcomes and reduce toxicity. Historically, pelvic failure rates following surgery alone were high, so investigators focused on the importance of surgical technique and the utility of adjuvant radiation therapy. These efforts demonstrated that preoperative treatment, whether delivered as long-course radiation alone, chemoradiation or short-course radiation, improved outcomes when compared to surgery alone and when compared to postoperative adjuvant therapy. Neoadjuvant therapy and optimal surgery have improved local control, but, unfortunately, they have not been translated into consistently improved overall survival. This has been puzzling to many investigators, although one must conclude that there is an adverse impact of pelvic radiotherapy on overall survival; otherwise the improvement in local control should translate into a similar improvement in overall survival, all else being equal. The addition of oxaliplatin to the systemic chemotherapy regimen has made chemotherapy for colorectal cancer markedly more effective than it was in the past. As a result, systemic chemotherapy has been shifted into the neoadjuvant setting to treat micrometastatic disease early. This adjustment has also led to improved response of the primary tumor to neoadjuvant therapy and improved compliance and tolerance of systemic chemotherapy. Evidence is emerging that this will improve survival for rectal cancer patients. With the improved tumor response, the option of nonoperative management of rectal cancer is being explored. To date, there is no widely accepted regimen for TNT. This is because of the heterogeneity of the available data, as each study examines different patient populations, utilizes different regimens, and examines different clinical endpoints. Based on the available data, it is clear that TNT will offer some advantages over conventional trimodal therapy. The National Collaborative Cancer Network (NCCN) has recognized the importance of TNT and the heterogeneous approaches to TNT, and the new NCCN guidelines allow for almost any combination of trimodal therapy – both in the traditional delivery method and as part of a TNT protocol. As the efficacy of immunotherapy is better defined, it may also be added to neoadjuvant treatment regimens.

Rectal Cancer: Local Excision

27

John R. T. Monson and Rebecca Hoedema

Key Concepts

- Local excision of biopsy-proven rectal cancer requires en bloc full-thickness dissection.
- Predictors of lymph node metastases include tumor depth, lymphovascular invasion, poor differentiation, and tumor budding.
- Local recurrence rates for T2 rectal cancers treated with neoadjuvant therapy and local excision appear similar to those of T1 cancers treated with local excision alone.
- Transanal endoscopic surgery techniques including transanal endoscopic microsurgery (TEM) and transanal minimally invasive surgery (TAMIS) may improve surgical outcomes as compared to standard transanal excision techniques.

Introduction

Local excision for rectal tumors dates back to the early 1800s, with a report by Dr. Jacques Lisfranc describing excision of a benign rectal mass in the lower rectum [1]. Sir Alan Parks described a more modern version of transanal excision in the 1960s [2]. Conventional transanal excision techniques can be limited by the location of the tumor, anatomy of the rectum, and the tumor characteristics. This approach is ideal for lesions within 8 cm from the anal verge, <3 cm in size and occupying <40% of the rectal circumference [3]. Tumors located more proximally in the rectum can be more challenging. "Transanal endoscopic microsurgery" (TEM) using an operating proctoscope with continuous gas insufflation was developed by Buess in the early 1980s to overcome some of these anatomic constraints [4]. Although there were certainly enthusiasts of the TEM approach, high capital costs, limited mobility of the operating instruments, a formidable learning curve, and issues with the insufflation system limited enthusiasm. In 2010, Atallah described the transanal use of a single-port laparoscopic platform with the use of insufflation to perform transanal minimally invasive surgery (TAMIS) which has overcome some of the limiting factors associated with TEM and allowed for the utilization of standard laparoscopic instruments with which surgeons are familiar [5].

Patient Selection

The local excision technique was initially described for presumed benign tumors in the distal rectum, as an alternative to proctectomy. Local excision allowed the patient to avoid major abdominal surgery and could be curative, providing that negative margins could be obtained and there was no invasive cancer. Local excision for known rectal cancer was first described by Morson et al. in 1977 at St. Mark's Hospital, who reported a low rate of local recurrence after excision with negative margins [6].

The typical treatment for locally advanced rectal cancer includes neoadjuvant treatment followed by proctectomy using the principles of total mesorectal excision (TME) [7]. Variations in treatment algorithms arise primarily from differences in the sequence and dosing of neoadjuvant/adjuvant therapy elements (radiotherapy and chemotherapy). Decision-making for patients with clinically staged early rectal cancers can be more complex, as the best chance for

cure (proctectomy, with or without neoadjuvant therapy) is associated with the greatest morbidity [8], while organ preservation strategies risk undertreatment and cancer-related mortality. Reports of reasonable oncologic outcomes following local excision, and patient interest in rectal preservation has driven the continued enthusiasm for local excision [9].

Patient selection is critical when patients are being considered for local excision. Current staging modalities include digital rectal examination to assess tumor character, fixation, and relation to the anorectal muscular ring. Anal sphincter bulk and tone should also be assessed, as full-thickness local excision can adversely impact rectal compliance and/or remove a portion of the internal anal sphincter for very distal tumors. In addition to baseline carcinoembryonic antigen level (CEA), patients should be evaluated for distant metastatic spread with computed tomography (CT) of the chest, abdomen, and pelvis. Local tumor staging can be assessed with either rectal cancer protocol magnetic resonance imaging (MRI) or transrectal ultrasound (TRUS). MRI is an important tool to help differentiate cT1/cT2 tumors from cT3/cT4 tumors, which can significantly alter initial treatment plans. MRI can also be helpful in assessing the relationship of the tumor to the mesorectal fascia. However, MRI is less accurate for estimating lymph node status, although certain findings (heterogeneous signal intensity and irregular margins) are usually indicative of lymph node involvement with tumor [10]. Tang et al. demonstrated that other MRI findings, namely, the diameter of the largest lymph node and the tumor percent enhancement on the arterial phase were independent risk factors of lymph node positivity in early rectal cancer patients ($p = 0.005$ vs 0.021, respectively) [11]. Hopefully with improvements in radiographic assessment of mesorectal lymph node status and the involvement of dedicated radiologists who review all rectal cancer MRIs and participate in multidisciplinary tumor discussions, the decision-making process for patients with clinically early stage rectal cancer will be more refined.

It should be remembered that local staging provides only *estimates* of tumor stage, and there is a substantial rate of inaccuracy with any staging test, especially when estimating mesorectal nodal involvement. Treatment decisions for patients with rectal cancer occur in prospective fashion (preoperatively), when stage of the tumor cannot be known with certainty. In addition, decisions regarding initial treatment may adversely impact subsequent therapy. For example, local excision of an anterior tumor may create substantial scarring and adjacent organ adherence that may compromise future attempts at proctectomy. Thus, it is critical that the surgeon consider not only whether local excision is appropriate as the initial mode of treatment but how local excision may impact subsequent care if the clinical stage was inaccurate, negative margins were not obtained, or local pelvic failure occurs.

In the following sections, we discuss outcomes for various stage tumors thought to be suitable for local excision. This is somewhat disingenuous because, as noted above, histologic stage cannot be known with certainty until *after* operation. Unfortunately, much of the published literature on local excision reports outcomes of select patients who meet certain histologic criteria, rather than including all patients undergoing local excision on an intention-to-treat basis. This will obviously bias the results in favor of local excision. In addition to the aforementioned problem of retrospective patient selection for inclusion in studies of local excision outcomes, there are other issues with the published literature on local excision. Firstly, there has been a paucity of prospective randomized trials (RCTs) comparing local excision with proctectomy. The vast majority of reports are retrospective analyses, in which selection bias is inherent to the study design. Secondly, many published studies have heterogeneous study populations. Lastly, many trials do not report time-to-event (Kaplan-Meier) calculations of survival and/or recurrence, instead inappropriately using crude fractions, which may artifactually improve outcomes. These problems further limit our ability to rigorously compare treatment outcomes.

T1N0

In general, local excision as a sole definitive treatment for rectal cancer should be reserved for histologically favorable T1 cancers, confined to the submucosa. However, T1 cancers with unfavorable histologic features, i.e., presence of lymphovascular invasion, poor differentiation, and tumor budding, should be strongly considered for proctectomy given the risk of lymph node metastasis. Adherence to these strict criteria may produce equivalent survival for local excision when compared to radical surgery. An analysis of retrospective data from the Surveillance, Epidemiology, and End Results database reported that local excision of a T1 rectal cancer produced similar cancer-specific survival when compared to radical surgery [12]. Two meta-analyses, comparing local excision and radical surgery for T1 rectal cancer, demonstrated similar 5-year overall survival when comparing outcomes of the TEM subgroup and proctectomy [13, 14]. However, it should be noted that these meta-analyses only included one underpowered RCT; the remainder of the studies were retrospective cohort studies. In addition, one of the meta-analyses found inferior oncologic results with local excision overall [13].

If a patient undergoes local excision and final pathology unexpectedly reveals high-risk features, patients should be

considered for completion proctectomy or adjuvant chemoradiotherapy. As noted above, patients should understand prior to undergoing local excision that these are potential scenarios once final histology is reviewed. Another consideration that may drive shared decision-making preoperatively is that patients undergoing local excision typically undergo more frequent surveillance examinations [15]. This may be of importance to patients with limited resources and/or difficulty in traveling to the treating facility.

Predicting Lymph Node Metastasis

The ideal candidate for local excision is a patient who has a primary tumor that can be excised completely with negative margins and has no lymph node metastasis. In this ideal patient, local excision can be curative. However, our ability to predict lymph node metastasis is not ideal, and occult lymph node metastases may be the primary driver of the higher local recurrence rates observed following local excision as compared to radical surgery. Estimates of lymph node status in rectal cancer patients thus dramatically affect treatment recommendations.

Predicting lymph node metastasis for rectal cancer is a multifactorial calculation. The use of the preoperative staging workup, imaging modalities, and histologic findings can help determine the risk and benefit of local excision. Unfavorable histologic features in the primary tumor can predict lymph node metastasis and change the direction of cancer care. Chang et al. found multiple unfavorable histologic features, primarily lymphovascular invasion (LVI), had an additive risk for lymph node metastasis [16]. According to the American Society of Colon and Rectal Surgeons practice parameters for the management of rectal cancer last published in 2013, local excision is an appropriate treatment modality for carefully selected T1 rectal cancers without high-risk features [17].

Depth of Invasion

T1 lesions are further classified according to the depth of invasion of the tumor by dividing the submucosal layer into thirds according to Kikuchi [18]. They noted an incremental increase in risk of lymph node metastasis and/or local recurrences with a deeper depth of invasion. The risk of lymph node metastasis is 3% for lesions invading the superficial 1/3 of the submucosa (SM1), but it rises up to 23% for deeply invading lesions (SM3), and therefore local excision should be reserved for superficial or middle lesions for the best curative and oncologic results [19–21]. Tumors with a depth invading to the SM3 level were found to be similar to T2 rectal cancers in relation to lymph node metastasis and local recurrence rates [17].

The T stage and SM level of the tumor are important predictors of lymph node metastasis which in turn, significantly affects the risk for local recurrence and the long-term survival in those patients with rectal cancer treated with local excision. Analysis of the Swedish Rectal Cancer Registry demonstrated that the risk of lymph node metastasis in T1 lesions is 6% in the absence of adverse histologic features [22]. It has also been reported that histologically favorable T1 lesions with a low risk of lymph node metastasis can be potentially cured with local excision surgery alone.

Unfortunately, SM level can only be accurately assessed *after* excision of the tumor, either by full- or partial-thickness local excision or endoscopic submucosal dissection (ESD). Although occasionally SM level can be assessed in a routine polypectomy specimen, this is relatively uncommon, as there is the need for a significant portion of the submucosa within the resected specimen in order to define the deepest border of the submucosa. Therefore, SM level calculation is typically only useful after local excision to make decisions regarding recommendations for completion proctectomy or adjuvant chemoradiotherapy.

Lymphovascular Invasion and Poor Differentiation

Lymphovascular invasion is found to be the most consistent histologic feature associated with metastatic disease. Chang retrospectively reviewed 943 patients with pT1 or pT2 rectal cancers at a single institution and found lymphovascular invasion was the variable that was most strongly associated with the risk of lymph node metastasis, with an odds ratio of 11.5 and risk of 68.8% (Table 27.1) [16]. Lymphovascular invasion has recently been reported to be associated with systemic recurrence in rectal cancer patients, which is less

amenable to curative surgical interventions and associated with reduced overall survival [23, 24]. Hogan et al. found that lymphovascular invasion in rectal cancer patients portended an increase in systemic recurrence and therefore an adverse effect on survival (Table 27.2) [25].

In addition, poor differentiation on histology is associated with lymph node metastasis in rectal cancer [16, 21, 26, 27]. Bosch et al. performed a meta-analysis of 17 studies and further confirmed that poor differentiation, among other adverse histologic findings, is a strong predictor of lymph node metastasis with a relative risk of 4.9 (95% confidence interval 3.3–6.9) [28].

Tumor Budding

Tumor budding was initially described by Hase in 1993 and defined as small clusters of undifferentiated cancer cells ahead of the invasive front of the lesion [29]. A review of 663 patients who underwent curative resection of colorectal cancer found that tumors with substantial budding had more aggressive behavior than tumors without budding. Initially reported primarily in the Japanese literature as a predictor and prognostic indicator of lymph node metastasis [30, 31], more recent reports from Western centers have supported this concept [28, 32]. It has now been adopted in the reporting system and is well-established as an independent adverse prognostic factor in colorectal carcinoma that can then allow for stratification of patients into risk categories more meaningful than just the TNM staging and potentially help guide treatment decisions, especially in early rectal cancers. Consensus statements and recommendations have been put forth by the International Tumor Budding Consensus Conference (ITBCC) that support tumor budding as an independent predictor of lymph node metastasis in T1 colorectal cancer. The authors clarify that tumor budding and tumor grade are not the same and that tumor budding should be included in synoptic reporting, guidelines and protocols for colorectal cancer reporting (Table 27.3) [33].

Table 27.3 Statements of the ITBCC 2016 based on the GRADE System

	Statement	Recommendation	Evidence
1	Tumor budding is defined as a single tumor cell or a cell cluster consisting of four tumor cells or less	Strong vote: 22/22 (100%)	High
2	Tumor budding is an independent predictor of lymph node metastasis in pT1 colorectal cancer	Strong vote: 23/23 (100%)	High
3	Tumor budding is an independent predictor of survival in stage II colorectal cancer	Strong vote: 23/23 (100%)	High
4	Tumor budding should be taken into account along with other clinicopathological features in a multidisciplinary setting	Strong vote: 23/23 (100%)	High
5	Tumor budding is counted on H&E	Strong vote: 19/22	Moderate
6	Intramural budding exits in colorectal cancer and has been shown to be related to lymph node metastasis	Strong vote: 22/22	Low
7	Tumor budding is assessed in one hotspot (in a field measuring 0.785 mm^2) at the invasive front	Strong vote: 22/22 (100%)	Moderate
8	For tumor budding assessment in colorectal cancer, the hotspot method is recommended	Strong vote: 22/22 (100%)	Moderate
9	A three-tier system should be used along with the budding count in order to facilitate risk stratification in colorectal cancer	Strong vote: 23/23 (100%)	Moderate
10	Tumor budding should be included in guidelines/ protocols for colorectal cancer reporting	Strong vote: 23/23 (100%)	High
11	Tumor budding and tumor grade are not the same	Strong vote: 23/23 (100%)	High

T2

To date, local excision has been a plausible option in early rectal cancers, namely, T1 tumors, but what about T2 lesions? Proctectomy for patients with T2 rectal cancers is associated

with high cure rates at the cost of high morbidity, risk of permanent colostomy, and significant impairment to anorectal, sexual, and urinary function with an associated effect on quality of life [34–37]. However, the standard recommendation for T2 lesions remains radical resection due to the high risk of lymph node metastases, unless patient comorbidities are prohibitive or the patient refuses radical surgery and/or the possibility of a colostomy. Locoregional recurrence rates for T2 tumors after local excision alone are unacceptably high, ranging from 13% to 30%, which may be partially due to the 30–40% incidence of occult nodal involvement [9, 38, 39]. However, recent evidence suggests that local excision with adjuvant chemoradiotherapy may be effective in treating occult nodal disease and minimize recurrence [40, 41].

Techniques

Transanal Excision

A thorough surgical history and physical examination including bowel function and continence are important prior to scheduling. The examination includes a digital rectal examination along with office proctoscopy to determine the location and characteristics of the mass. Standard transanal excision technique can be a viable option if the rectal cancer is palpable with digital examination and specifically if the top of the mass can be palpated. Optimal visualization during surgery is imperative, so a mechanical bowel preparation is recommended in most circumstances, but a simple enema preparation may suffice in the appropriate patient. Typically, preoperative intravenous antibiotics are given within 1 hour of the start of the surgery. General anesthesia is most commonly used for these cases, although spinal anesthesia and MAC sedation can also be viable options in the appropriate patient.

Patient positioning is based on the location of the tumor and surgeon preference. Many surgeons would want the tumor in the dependent position. For example, if the tumor is anteriorly based, the patient would be in the prone position. A myriad of anoscopes, retractors, proctoscopes, and other self-retaining tools can be used for optimal exposure. Electrocautery is then used to mark approximately 5–10 mm around the tumor. Stay sutures can be helpful in these circumstances and dissection continues with a combination of both sharp dissection and electrocautery. For known or strongly suspected cancer, a full-thickness dissection is typically performed. For benign appearing lesions, partial-thickness resection is usually the best option, as it can be curative if the tumor is benign, damage to the rectal wall is avoided, and all future treatment options are preserved if indeed an occult carcinoma is found. Partial-thickness resection can also be performed using endoscopic ESD techniques (see Chap. 23). Closure of the defect should be completed in a transverse fashion to avoid stricture formation. If closure is not possible and the peritoneal cavity has not been entered, then leaving the wound open to heal by secondary intention can be considered (Fig. 27.1).

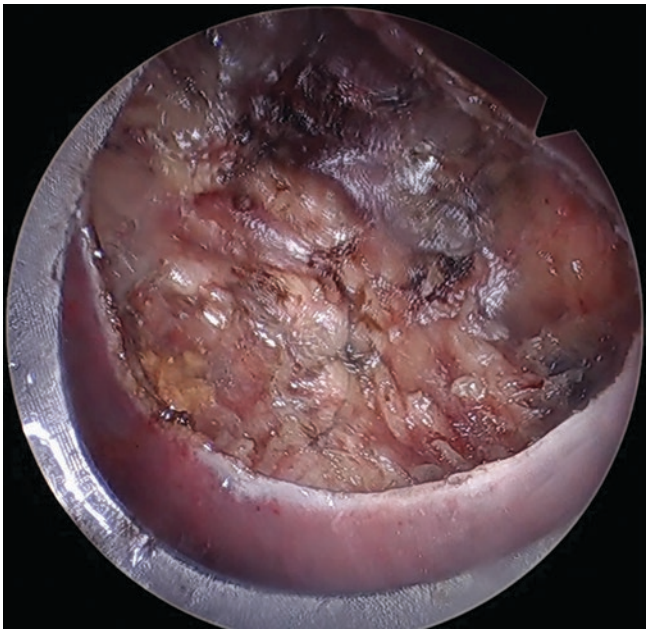

Fig. 27.1 Transanal endoscopic microsurgery defect

Transanal Endoscopic Microsurgery

Preoperative preparation is similar as for standard local excision, with the exception that some surgeons prefer the patient be positioned so that the tumor is "towards the sky," so that is naturally falls away from the rectal wall during dissection. The operating proctoscope is gently inserted into the anal canal and then attached to the table mount (Fig. 27.2). Pneumorectum is established allowing the proctoscope to visualize the target tumor. Three instrument ports are placed, and electrocautery is used to demarcate 5–10 mm around the target tumor. The tumor is removed and the defect closed. If intraperitoneal entry occurs or is suspected during a TEM procedure, laparoscopic assistance may be necessary for closure of the defect and to perform pneumatic leak testing, as one would perform following colorectal anastomosis.

Implementation of the TEM technique has broadened the application of local excision for rectal cancers and has allowed for removal of more proximal tumors compared to the standard transanal technique. As noted above, there are several limitations associated with the TEM technique, namely, cost and a steep learning curve, and many surgeons have migrated to the TAMIS technique for mid and proximal rectal tumors.

Fig. 27.2 Transanal endoscopic microsurgery device

Transanal Minimally Invasive Surgery (TAMIS)

TAMIS was first introduced in 2009 as an alternative to TEM, offering similar visibility and versatility but at a significant cost advantage [5]. Dissection can be performed in multiple quadrants, and there are fewer restrictions on patient positioning. This technique uses a flexible, disposable single-port minimally invasive platform placed transanally. Laparoscopic insufflation, camera, and tools are utilized. Dissection occurs in a similar fashion to TEM. Insufflation occurs and the tumor marking occurs in a similar way using cautery (Fig. 27.3). Closure of the defect occurs with varying techniques [42]. If the tumor is near the top of the anal sphincter, a hybrid approach using TAMIS and transanal approaches may be necessary. As noted above for TEM, if intraperitoneal entry occurs or is suspected during a TAMIS procedure, laparoscopic assistance may be necessary for closure of the defect and to perform pneumatic leak testing, as one would perform following colorectal anastomosis.

Complications

Each of the described techniques for local excision of early distal rectal cancers has limitations: incomplete resection, conversion to an alternative approach, or the need for staged

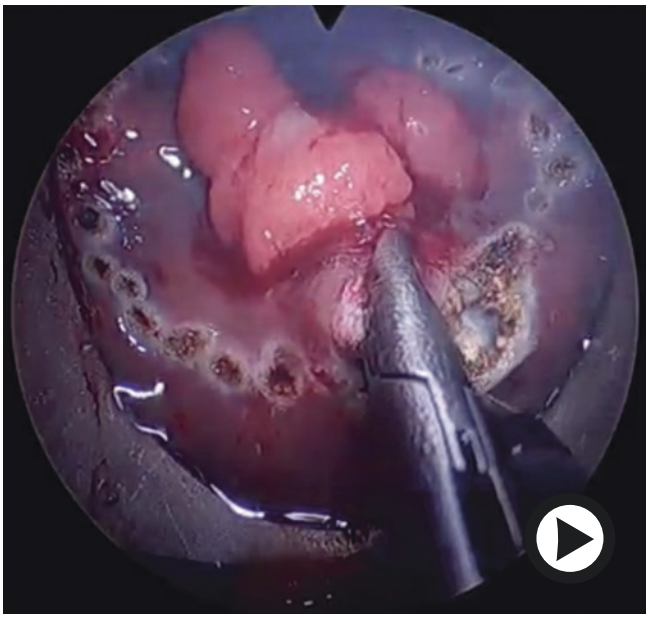

Fig. 27.3 Insufflation occurs and the tumor marking occurs in a similar way using cautery. https://doi.org/10.1007/000-33e

procedures to name a few. These events are more likely to occur if the tumor is too bulky or if the working environment/space is too tight, incomplete visualization of the entire tumor due to a fold, uncontrolled bleeding occurs, or poor bowel preparation.

Overall, the complication rate for local excision, regardless of the technical approach, is lower than for radical surgery [9, 43]. Common complications after local excision include urinary retention/urinary tract infections, bleeding, and other gastrointestinal complaints. Uncommon complications include wound infections, thromboembolic events, rectal strictures, or rectovaginal fistulas [9]. The most common complication with local excision is postsurgical urinary retention. This can occur up to 5% of patients and secondary to pressure on the urethra, anal stretch, edema, and pain [44]. This is usually self-limited and treated by either self-catheterization or placement of an indwelling catheter.

Postoperative bleeding can also occur up to 5% and tends to occur several days post-op and usually corresponds to a suture line dehiscence if the wound was closed, sloughing of any scab formation, or anticoagulation medication. Minor bleeding can oftentimes be self-limited, but frank hemorrhage warrants resuscitation, endoscopic evaluation, and treatment. After stabilization, it can usually be addressed with monopolar cautery, sutures, and/or epinephrine injection. Major intraoperative bleeding, however, is a rare event.

Pelvic abscess can also occur. It is unclear whether abscess is more frequent when an extraperitoneal defect is left open versus closed, and this is the subject of much debate. Tumors that cause a defect breaching the peritoneum necessitate closure, but there is conflicting evidence for those lesions located in the extraperitoneal rectum that do not vio-

late the peritoneal cavity. A single randomized trial showed no difference in early or late complications and determined that there is no difference in the approach to the open wound [45]. However, there were only 44 patients randomized, and the study may have been underpowered to detect a true difference. Other observational studies have equivocal outcomes. Some surgeons favor defect closure; others favor leaving the defect open [46–48]. A recent multi-institutional matched analysis at a high-volume center consisting of 991 eligible patients found no difference in 30-day postoperative morbidity in those undergoing closure of the defect versus leaving the defect open after local excision [49]. Thus, the management of the rectal wall defect after local excision is at the surgeon's discretion.

Oncologic Results

Local excision is an acceptable oncologic treatment strategy for patients with T1 rectal cancers, and local excision with chemoradiation treatment has gained some interest and can be an acceptable oncologic treatment for certain patients with T2 distal rectal cancers.

T1 Cancer

Approximately 15% of rectal cancers present at stage I. Since the first report of local excision as an acceptable alternative to radical resection, local excision without additional therapy has been offered as a treatment alternative for early distal T1 tumors [6]. This oncologic approach can be a viable option in appropriately selected patients with favorable clinical and histological features. Local excision can also be viewed as a palliative treatment for patients with more advanced disease who are medically unfit for radical surgery. The main drawback of local excision as curative therapy is the inability to excise and accurately stage mesorectal lymph nodes. T1 rectal tumors have a 6–11% risk of nodal metastasis overall, pending additional histologic information [38].

Criteria for local excision include well to moderately differentiated T1 cancer, the absence of lymphovascular or perineural invasion, and tumors less than 3 cm in diameter occupying less than one-third of the circumference of the bowel lumen [38]. In order to achieve a good oncologic outcome, optimal surgical technique is imperative. It has been shown that a positive margin following local excision of a T1 rectal cancer is associated with a higher risk of recurrence and concomitant lower 5-year overall survival [9, 50]. Hopefully, advancements and improvements in surgical techniques will greatly improve the rates of en bloc resection with negative margins in rectal cancer patients treated with local excision. As noted previously, this has been a substantial problem in prior trials of local excision. Even using more modern techniques, achieving negative margins can be challenging. Prospectively collected data from a 21-center collaborative in the United Kingdom regarding 424 patients undergoing TEM +/− adjuvant/neoadjuvant radiotherapy revealed that positive margins were found in 11%, 23%, and 42% of patients with pT1, pT2, and pT3 tumors.

Data from that same report revealed that local recurrence rates following local excision by TEM in patients with T1 rectal cancer were 10%, 13%, and 19% at years 2, 3, and 5 [51]. Local recurrence was found to be associated with three histopathologic factors: depth of invasion, tumor maximum diameter, and lymphovascular invasion. For favorable tumors (no lymphovascular invasion, SM1), local recurrence rates ranged from 3% to 8% depending on tumor size. The rates of local recurrence were found to be 18–42% for unfavorable tumors (lymphovascular invasion positivity, SM2–3).

Junginger et al. published their long-term oncologic outcomes for T1 rectal cancers after local excision [52]. Median follow-up was 8.6 years. Low-risk tumors compared with high-risk tumors had 5- and 10-year local recurrence rates of 7% and 12% versus 32% and 35%, respectively. In addition, the 5- and 10-year cancer-specific survival rates for low-risk patients were 98% and 91% compared with high-risk patients at 84.3% and 74.3% ($p = 0.05$). These studies have shown that to minimize the risk of local recurrence, it is advisable to limit local excision to T1 rectal cancers with favorable histology as mentioned previously [17, 25, 28].

T2 Cancer

Traditionally, the substantial rates of metastatic nodal disease associated with T2 rectal cancers have swayed most surgeons from treating T2 rectal cancers with local excision alone as this approach can lead to local recurrence rates of 10–66% [51]. High rates of local failure and compromise in survival outcomes have been shown, with 5-year local recurrence rates of 47% in patients undergoing local excision alone compared to 6% with proctectomy and overall survival of 65% versus 81%, respectively [53]. Despite these sobering numbers, there has been increasing emphasis on organ preservation techniques, and some surgeons have recommended expanding the indications for local excision to include some T2 rectal cancers.

Data and evidence from the Surveillance, Epidemiology, and End Results program reveal that more than 20% of patients with T2 cancer are being treated by local excision, although those treated with local excision alone had a suboptimal overall survival [54]. In an attempt to improve outcomes following local excision for T2 tumors, recent clinical trials have evaluated local excision combined with neoadjuvant or adjuvant treatment with the hope of improving outcomes and expanding eligibility for organ-sparing surgery.

Local Excision and Adjuvant Therapy

The Cancer and Leukemia Group B 8984 trial (CALGB 8984) compared oncologic outcomes in patients with T1 rectal cancer treated with local excision alone and T2 rectal cancer treated with local excision followed by adjuvant chemoradiotherapy [50]. They found that despite adjuvant therapy, the T2 group experienced worse 10-year overall survival and disease-free survival and were at higher risk of local recurrence (18% vs. 8%). A meta- analysis of oncologic outcomes for patients with T1 or T2 rectal cancers undergoing local excision followed by either adjuvant chemoradiotherapy or completion surgery included 14 studies [55]. It was found that, among patients originally undergoing local excision for T2 tumors, local recurrence occurred in 15% (range: 11–21%) of patients treated with adjuvant chemoradiation and 10% (range: 4–22%) of patients treated with completion proctectomy.

A systematic review by Cutting et al. found local recurrence rates of 6% for T1, 14% for T2, and 34% for T3 rectal cancers [56]. These studies suggest that adjuvant therapy after local excision for T2 or greater rectal cancers is inferior to radical surgery but better than local excision alone.

Neoadjuvant Therapy and Local Excision

Traditionally, locally advanced rectal cancer was treated with chemoradiotherapy followed by radical surgery with the benefit of tumor downsizing and improvement in local recurrence rates in large randomized controlled trials [57, 58]. It has been shown that up to 30% of patients will experience a complete pathologic response after neoadjuvant chemoradiation [59]. In the hope that occult tumor in mesorectal nodes could be sterilized with neoadjuvant chemoradiotherapy, some surgeons explored the concept of local excision following neoadjuvant therapy in select patients.

The American College of Surgeons Oncology Group Z6041 study was a phase II trial by Garcia-Aguilar et al. with a single arm of 84 patients with T2 rectal cancer that were treated with neoadjuvant chemoradiation and local excision [60]. Downstaging occurred in 64% of patients. Lezoche et al. compared local excision with laparoscopic proctectomy in a randomized controlled trial [61]. All patients had an R0 resection, and local recurrence rates were similar for the local excision and proctectomy groups, 8% versus 6%, respectively. The cancer-related survival rate was 89% for local excision and 94% for proctectomy ($p = 0.609$).

Another randomized controlled trial, GRECCAR 2, published in 2017 by Rullier et al. investigated patients with cT2–3 rectal cancer treated with neoadjuvant chemoradiation and then randomized to either local excision or radical surgery [62]. In a total of 145 patients, there were no statistically significant differences in oncologic outcomes between the groups, and 3-year local recurrence rates were similar for the local excision group and the proctectomy group (6% vs. 3%, $p = 0.63$). Overall survival rates were 89% and 95% respectively ($p = 0.40$). Only 8% of patients treated by completion radical surgery had nodal involvement, suggesting that radical surgery may have been unnecessary for most of them.

The recently published CARTS study investigated oncologic and functional outcomes of patients with T1–3 rectal cancers treated with neoadjuvant chemoradiation followed by local excision [63]. Of those patients recruited, 35 patients underwent local excision, and 16 patients underwent radical resection. Results showed a 5-year local recurrence rate of 8%, with 5-year disease-free survival and overall survival rates of 82% and 83%, respectively. These reports suggest that local excision after completion of chemoradiation may be an option in selected patients.

One of the major downsides of local excision following neoadjuvant radiotherapy is the problem of wound healing, as it is not uncommon for the rectal wall closure to break down in the radiated field. There is also the question as to whether local excision is even necessary in complete clinical responders (see Chap. 28). Local excision would only be helpful if there were viable tumor remaining in the rectal wall, but not in the mesorectal nodes. If there is no remaining tumor in either location, or in both locations, then local excision would not be anticipated to be of benefit to the patient.

Quality of Life

One of the goals of organ preservation with local excision is better functional outcomes with a better quality of life. Although resection of the rectal wall can have functional consequences, several studies have shown that those patients with early rectal cancers who undergo local excision compared with those who undergo radical resection have a better quality of life and better bowel function overall [64]. Pucciarelli et al. found that anorectal function 1 year after local excision with neoadjuvant chemoradiation had minimal impact on function and overall quality of life [65, 66]. As reported in the CARTS study, health-related quality of life was equal to that at baseline, with improved emotional well-being for patients treated with local excision compared to radical surgery [63].

Salvage Surgery

Population-based studies have shown that the treatment of early distal rectal cancers by various local excision techniques has more than doubled over the last two decades [9, 54]. This is likely due to advancements in local excision sur-

gical platforms, patient preference, and publication of outcome data. The increase in the use of local excision techniques for early stage rectal cancer relies on the desire for sphincter preservation and maintaining bowel continuity if the risk of lymph node metastasis is low. Local recurrence is the most common pattern of failure, ranging from 20% to 30% [43, 51, 67–70]. When patients develop a local recurrence, what surgical options are available and what are the prognosis and long-term oncologic outcomes?

Bikhchandani et al. reported an R0 resection rate of 93% on 27 patients who underwent multimodal salvage surgery for local recurrence of rectal cancer after local excision [71]. The 5-year recurrence-free survival rate was 47%, and the 5-year overall survival rate was 50%. The majority of re-recurrences were distant metastases. The long-term survival rates were disappointing and grim compared with published rates of 92–97% disease-free survival at 5 years after radical surgery for early rectal cancer [9]. This was consistent with other previously published studies that found that salvage resection for recurrence after local excision is associated with only modest success [72, 73].

You et al. performed extended resections for patients suffering local failure after local excision, with an R0 resection rate of only 80% [72]. With a median follow-up of 33 months, 3-year re-recurrence-free survival was 43%, and 5-year overall survival was 63%. Friel et al. reported outcomes following salvage surgery for recurrence after local excision and found that the results were inferior to those of initial radical treatment [74]. They stressed the importance of appropriate patient selection for local excision and cautioned against assuming that salvage surgery would be successful for patients with local failure.

The practice of local excision seems to exchange the increased risk of disease recurrence for the benefit of improved function and sphincter preservation. It is imperative to counsel patients regarding the oncologic risks of local excision and explain that salvage therapy is not always associated with good outcome.

Conclusion

Local excision alone can be offered to patients with early T1 rectal cancers in the absence of adverse histopathologic features, such as poor differentiation, lymphovascular invasion, tumor budding, or close margins. Patients with low-risk T2 tumor should be considered for local excision only in the context of palliative intent or enrolment in a clinical trial. Patients with T3 tumors should only undergo local excision as palliation (usually for bleeding). Salvage surgery for local recurrence in those treated initially by local excision is possible in some patients, but oncologic results appear to be inferior to those that would be obtained by proctectomy at initial diagnosis. All patients managed with organ preservation usually undergo intensive posttreatment multimodality surveillance, as it is assumed (but not proven) that identifying local failure early will lead to improved outcomes (See Chap. 30).

Rectal Cancer: Nonoperative Management

28

Julio Garcia-Aguilar and Rodrigo Oliva Perez

Key Concepts

- A proportion of patients with rectal cancer managed by neoadjuvant chemoradiation may achieve complete disappearance of the primary tumor (complete clinical response) during assessment of response after treatment completion.
- Establishing a complete clinical response requires the combination of clinical, endoscopic, and radiological findings consistent with the absence of residual cancer at the site of the original cancer.
- Patients that achieve a complete clinical response have been considered for organ preservation strategy with strict surveillance and no immediate surgery (Watch and Wait) to avoid the potential morbidity, mortality, requirement for stomas, and functional consequences of a proctectomy.
- Patients that achieve a complete clinical response and are managed by the Watch and Wait strategy have a 25% risk for developing local regrowth of the primary tumor.
- The majority of local regrowths are amenable to successful salvage proctectomy with negative resection margins (R0).
- Patients that achieve a cCR and are managed by Watch and Wait have similar overall survival rates when compared to patients with pCR managed by radical proctectomy. Disease-free survival rates are superior for patients undergoing radical proctectomy due to the 25% risk of local regrowth following WW requiring salvage proctectomy.
- Functional outcomes and quality of life appear to be improved among patients with complete clinical response managed by Watch and Wait when compared to proctectomy.

Introduction

The introduction of neoadjuvant therapy has led to significant changes in the management of rectal cancer. The observation of a variable degree of tumor response to neoadjuvant therapy has challenged the previously standard practice of proctectomy and has prompted the introduction of new treatment algorithms. The assessment of tumor response after neoadjuvant therapy, previously considered unnecessary, is now an integral part of contemporary rectal cancer management algorithms. Patients found to have clinical, endoscopic, and radiological evidence of complete disappearance of the primary tumor are considered candidates for deferral of surgery and active surveillance, with the ultimate goal of achieving sustained organ preservation, a strategy known as Watch and Wait (WW). In this chapter we will review rectal cancer management with an emphasis on baseline staging, neoadjuvant treatment regimens, timing and methods for assessment of tumor response, and surveillance protocols relevant for the effective and safe implementation of WW strategies that will result in optimal organ preservation. We will also provide an overview of the evidence supporting the WW strategy for rectal cancer patients who achieve a clinical complete response to neoadjuvant therapy.

Terminology and Definitions

Organ preservation strategies in the management of rectal cancer require new terms and definitions.

The final histologic stage of the tumor after neoadjuvant therapy should follow the nomenclature of the AJCC/IUCC TNM classification [1]. ypT0 indicates no residual tumor in the bowel wall in the primary tumor bed (within the rectal wall), whereas ypN0 means negative nodes in the mesorectum when part of the surgical specimen. The term pathologic complete response (pCR) should be reserved for ypT0N0 tumors in patients who had a proctectomy or for ypT0 tumors after a full-thickness local excision (LE) without radiological evidence of mesorectal positive nodes or deposits.

Patients without evidence of tumor on clinical, endoscopic, and radiological exams are considered to have a clinical complete response (cCR) [2]. The key to determining whether a WW strategy will likely be successful is based on the assumption that cCR after neoadjuvant therapy correlates with pCR after proctectomy [3].

The goal of the WW strategy is to identify patients who have no residual disease in the bowel wall after neoadjuvant therapy who can avoid surgery and preserve the rectum [4]. Therefore, the term Watch and Wait was originally used exclusively for patients *who achieved a cCR and were offered no immediate surgery with strict and close surveillance* [4]. This means that achieving a cCR is a prerequisite for entering a WW program.

Considering the lack of a "perfect" correlation between cCR and pCR, some patients with a cCR entering a WW program are at risk of local regrowth during follow-up [5]. The reappearance of the tumor in the rectal wall or in the regional lymph nodes after an apparent cCR is called local regrowth [6]. Regrowths occur more often in the bowel wall compared to the regional lymph nodes and therefore are more easily detected by digital rectal examination (DRE) and/or flexible sigmoidoscopy. Most local regrowths are potentially salvageable by surgery [7–12]. Any tumor reappearance in the pelvis after a curative-intent surgery is considered "local recurrence." Distant metastases can occur in patients with a sustained cCR but are more frequent in patients with tumor regrowth.

Historically, most rectal cancer patients entered in a WW protocol had received standard long-course chemoradiation therapy (CRT) [4, 12, 13]. As treatment strategies evolved over time, systemic chemotherapy was progressively added to standard neoadjuvant CRT regimens. Chemotherapy that is given before CRT is called *induction chemotherapy*, and chemotherapy given during and after CRT (before surgery) is called *consolidation chemotherapy* [14–17]. The full regimen of induction or consolidation chemotherapy (eight cycles of FOLFOX [leucovorin, fluorouracil, oxaliplatin] or five cycles of CapeOX [capecitabine, oxaliplatin]) in combination with CRT is called *total neoadjuvant therapy* [18].

Radiation therapy delivery has also evolved over time. Originally, most treatment regimens included external beam radiotherapy (EBRT), with or without intensity modulation techniques (IMRT). In addition to the mode of delivery, fractionation of doses may encompass two different regimens: long-course with hyperfractionation or short-course with hypofractionation. Even though a detailed description of these different approaches is beyond the scope of this chapter, suffice to say that both regimens may result in pCR and/or cCR [19, 20]. In an attempt to increase the total dose of radiation delivery, techniques have been developed to provide maximal dose (dose escalation) with minimal toxicity. Therefore, additional doses (boosts) to the primary tumor may be delivered by EBRT, endorectal high-dose-rate brachytherapy (HDBRT) or contact radiation (Papillon technique) [16, 17, 21, 22].

Rationale

The possibility of a permanent stoma has always been one of the main concerns of patients diagnosed with rectal cancer. Even though patients' perspectives may vary across different geographical areas and cultures, a permanent end-colostomy impacts body image and impairs quality of life [23]. The concept of avoiding surgery in rectal cancer patients treated with neoadjuvant chemoradiation was driven by the observation of pCR in patients treated with abdominal-perineal resection (APR) with permanent colostomy [4]. Following similar observations from anal cancer treatment, where patients with complete tumor regression after neoadjuvant chemoradiation (nCRT) avoided radical surgery with surprisingly favorable oncological outcomes, initial attempts were made to identify rectal cancer patients who had achieved a pCR, by means of clinical, endoscopic, and radiological examination [24]. However, most rectal cancer patients have more surgical options than anal cancer patients, for whom APR is the main radical surgical alternative. Depending on tumor stage, anatomy, and relation to the anal sphincter complex, many rectal cancer patients are candidates for sphincter preserving procedures. Although avoiding a permanent stoma, restorative proctectomy is often associated with significant bowel dysfunction, particularly worsened by previous exposure to ionizing radiation to the pelvis. A sizeable fraction of patients who undergo a restorative procedure with their temporary diverting stoma reversed are left with variable degrees of fecal incontinence and a constellation of symptoms known as "low anterior resection syndrome," some requiring conversion to a permanent stoma or creation of cecostomy/appendicostomy for anterograde colon lavage [25–27]. In addition, proctectomy, with or without sphincter preservation, has significant consequences in terms of sexual and urinary function [28, 29].

Despite recent advances in minimally invasive approaches to the surgical management of rectal cancer, proctectomy is also associated with immediate postoperative morbidity and mortality [30]. One of the main drivers of postoperative mor-

bidity among these patients is the risk of postoperative anastomotic leak. Prospective randomized clinical trials have shown the benefits of diverting stomas in decreasing the risk of clinically relevant leaks and the need for urgent reoperations among these patients [31]. However, the creation of a diverting stoma often results in direct morbidity associated with high-output syndromes (with ileostomy) and with subsequent stoma reversal [32]. Altogether, avoidance of potentially unnecessary proctectomy among patients with complete tumor regression after nCRT could have the potential benefits of sparing patients from the need of a permanent or temporary stoma, risk of immediate and late morbidity, chance of postoperative mortality, and negative functional consequences in bowel, urinary, and sexual functions [30–35]. In addition, patients undergoing proctectomy for rectal cancer will have potentially significant long-term financial and social burdens beyond the clinical aspects of the disease and its treatment. These patients will need resources to finance surgical treatment as well as its potential complications, the cost of supplies for the stoma, and assistance dealing with the impact of proctectomy on the activities of daily living and professional life [36].

Primary Tumor Assessment and Selection Criteria

Baseline tumor assessment for patients being considered for organ preservation is of paramount importance and is based primarily on clinical findings of DRE, endoscopic features, and radiological imaging. Neoadjuvant therapy should only be instituted after these studies are complete, and confirmatory biopsies of adenocarcinoma have been obtained and properly documented.

Accidental Versus Intentional WW

The occasional eradication of rectal cancer by radiation therapy has been known for decades. Attempts to cure rectal cancer with radiation alone were popular at the beginning of the twentieth century, when the mortality and morbidity of rectal cancer surgery were prohibitive [37]. The difficulty in identifying patients with a true complete response and increased safety of surgery ultimately led to the abandonment of the idea of treating cancer with radiation alone. Over the years, some surgeons have omitted surgery in some patients with an apparent complete or near-complete response because of advanced age, high surgical risk from comorbid conditions, or patient refusal of a permanent stoma. This "accidental" approach to WW, still the only one accepted at many institutions, should be distinguished from the systematic or "intentional" approach, in which patients with distal rectal cancer likely requiring restorative proctectomy with low colorectal anastomosis or non-restorative proctectomy with permanent colostomy are treated with optimal neoadjuvant therapy, restaged, and selectively entered in a WW protocol with the intention of achieving permanent organ preservation [38]. Chances of achieving a cCR are now anticipated, and consideration of WW is discussed prior to treatment with nCRT. The intentional WW approach is relatively straightforward in patients with locally advanced rectal cancer requiring nCRT before proctectomy for oncological purposes. However, patients with less advanced disease, not necessarily requiring nCRT before proctectomy for oncological reasons, may also be considered for WW and undergo nCRT for the primary purpose of achieving a cCR [38].

Baseline Stage

Baseline tumor stage is an important predictor of tumor response to nCRT. In general, more advanced tumors are less likely to completely respond to nCRT compared to early-stage tumors. Therefore, clinical stage has potential implications for the selection of patients for WW. Current guidelines recommend nCRT for patients with locally advanced tumors that have baseline features indicative of high risk of local recurrence following proctectomy alone [39]. A distance of the primary tumor to the mesorectal fascia of ≤1 mm (mrCRM≤1 mm including T3c,d or T4), extramural venous invasion (EMVI), extensive nodal disease (N1c/N2), or lateral pelvic sidewall nodes (LPNM) have been associated with the risk of local recurrence after proctectomy alone and therefore are currently indications for nCRT. While the presence of these features is not a contraindication for WW, a cCR is less likely in patients with such advanced tumors. In addition, clinical and radiological identification of a cCR may be quite challenging in the presence of extensive disease, where it may be difficult to ascertain whether palpable or radiographic extraluminal abnormalities are due to fibrotic changes versus remaining tumor following neoadjuvant therapy.

The indication for nCRT in patients with intermediate disease—those with mrT3a,b or N0/1 and no additional high-risk features (CRM≤1 mm, EMVI+, LPNM+)—is controversial. While such patients are still considered candidates for nCRT in international guidelines that use the TNM classification system as the basis for risk stratification (such as the guidelines of the National Comprehensive Cancer Network; www.nccn.org), data from the MERCURY trial suggest that these patients are at low risk for local recurrence after proctectomy, casting doubt on the need for nCRT [40]. While the debate about the benefits of nCRT for all intermediate-risk rectal cancer patients is beyond the scope of this chapter, offering nCRT to patients with more distal intermediate stage tumors offers the possibility of a cCR and potential organ preservation [41].

A similar treatment algorithm may be considered for patients with early-stage disease (mrT1/T2N0). As the local recurrence rate with proctectomy alone is very low, early-stage tumors are typically not considered candidates for nCRT. However, nCRT followed by local excision has been proposed as an alternative for patients with early-stage distal rectal cancer who otherwise would need a coloanal anastomosis or a permanent colostomy. Several phase II trials have shown that the rate of pCR for these patients is higher than in patients with more advanced disease [3, 42]. It is therefore reasonable to offer WW to patients with early-stage rectal cancer who seek to avoid a permanent stoma and start treatment with nCRT in an attempt to achieve a cCR.

Tumor Location

Tumor location is also important when selecting patients for WW. While any rectal cancer patient with a cCR after CRT is a potential candidate for WW, those more likely to benefit from a WW approach that may result in organ preservation are patients with tumor located in the distal rectum who may otherwise need a low colorectal or coloanal anastomosis or a permanent colostomy. Tumors in this location are also more likely to be accessible to monitoring by DRE [2].

Tumor location in the distal rectum is particularly important when considering nCRT with the goal of achieving cCR in early-stage tumors. mrT2 cancers beyond the reach of DRE are probably surrounded by mesorectal fat and are less likely to have CRM positivity and local recurrence if treated by up-front proctectomy. As most of these patients are candidates for sphincter-saving surgery, they are less likely to benefit from organ preservation. However, an exception to this rule is an obese patient with a long anal canal in whom a tumor located immediately above the anorectal ring may be just beyond the reach by DRE but who may still be a candidate for a WW strategy.

Magnetic resonance imaging using dedicated rectal cancer protocols provides valuable information about the location of the tumor in relation to other anatomical structures, such as the sphincter complex, the levator muscles, the prostate and seminal vesicles, the vaginal wall and cervix, as well as the anterior peritoneal reflection and helps the surgeon anticipate the need for a permanent stoma, the ability to perform a sphincter-saving procedure and even the type of anastomosis in case proctectomy is undertaken. This information is also very useful for the selection of patients for WW [43]. In summary, patients with lower tumors requiring a low colorectal or a hand-sewn coloanal anastomosis or an APR are more likely to benefit from a WW strategy and organ preservation. Patients with more proximal tumors that carry a low risk of local recurrence and unlikely to benefit from CRT will derive minimal benefit from organ preservation and may be better treated with up-front proctectomy.

Endoscopic Features

Some endoscopic features such as pit pattern and submucosal vascular architecture can help identify benign lesions or even superficially invasive rectal cancers that fulfill the criteria for endoscopic submucosal resection (see Chap. 23) or transanal local excision (see Chap. 27) without the need for proctectomy or nCRT [44].

Endoscopic and some DRE features related to tumor morphology have not been associated with differences in response rates to neoadjuvant treatment. Therefore, qualities commonly associated with more advanced disease, such as ulceration and tethered lesions, are not necessarily exclusion criteria for entering WW. Size has been associated with response, suggesting that smaller tumors are more likely to respond completely to treatment [45]. Still, even patients with large circumferential tumors may also achieve a cCR and successfully undergo WW. Proper documentation of the endoscopic characteristics of the tumor at baseline—ideally through endoscopic images—is important for subsequent evaluations during the assessment of tumor response. Some large, circumferential, ulcerated tumors develop a concentric scar that narrows the lumen of the rectum and prevents proper endoscopic evaluation of tumor response. Patients with such tumors may not be ideal candidates for WW because complete endoscopic assessment and surveillance are not possible.

In summary, patients being considered for nCRT with the hope of entering a WW program should have confirmation of invasive adenocarcinoma, a tumor that is (preferably) accessible to DRE, endoscopic features consistent with invasive cancer not suitable for endoscopic submucosal dissection, and an MRI showing a tumor located in the distal rectum. Baseline staging features may be useful for estimating the probability of a tumor achieving a cCR and selecting a treatment plan that will potentially include a WW strategy to achieve organ preservation.

Assessment of Tumor Response

Most rectal cancers respond to some degree to chemotherapy and radiation. The degree of response depends on intrinsic tumor characteristics, such as size, stage, and some genomic features and treatment variables, including the fractionation dose of the radiation and the time from completion of radio-

therapy to assessment of response. In a WW program, tumor response is assessed with the same diagnostic tools as for the initial staging: DRE, endoscopy, and radiology (preferably MRI).

The 6-week interval between the end of the neoadjuvant therapy and surgery in patients with stage II-III rectal cancer treated with CRT and proctectomy has been proven to be effective in terms of surgical technical difficulty and perioperative morbidity and is associated with a pCR rate of approximately 18% [46]. Retrospective studies have suggested that longer intervals between the end of radiotherapy and surgery result in higher pCR rates [47, 48]. These data, along with the growing body of evidence from patients entered in WW protocols, suggest that tumor response is time-dependent and probably nonlinear [49–51]. These findings have implications for the design of WW strategies: tumors that have responded significantly but have not achieved a cCR at the time of the initial evaluation 6–8 weeks after completion of CRT may still achieve a cCR with longer observation. Several prospective studies suggest that adding chemotherapy during the longer observation period increases the likelihood of cCR and the probability of organ preservation [15, 18].

Our current WW strategy is to assess tumor response 6–8 weeks after completion of neoadjuvant therapy. Based on the degree of tumor response, patients are stratified in one of three treatment groups (Table 28.1) [52]. Patients with an incomplete clinical response (iCR) and a clearly visible tumor, even if the tumor has decreased in size significantly from baseline, typically undergo surgery (Table 28.1, Fig. 28.1). Patients with a cCR can enter a standard WW surveillance protocol with repeat assessments every 3–4 months (Table 28.1, Fig. 28.2). Patients with a very significant response that does not meet all criteria of a cCR—termed a near-complete clinical response (nCR)—can be entered in an intensive surveillance protocol, with a repeat exam after 6–8 additional weeks (Table 28.1, Fig. 28.3). Continued observation at similar intervals may be appropriate as long as the tumor continues showing signs of ongoing response until all strict criteria of a cCR are achieved. Most patients should achieve all strict criteria within 28–34 weeks following completion of radiotherapy. While not the norm, it may take up to a year (52 weeks) for some tumors to achieve a cCR. A lack of evidence of continued response in any of the three diagnostic modalities or any sign of tumor regrowth is an indication for surgery.

Criteria for a Complete Clinical Response

The criteria of a complete clinical response are based on three pillars of assessment. Clinical evaluation with DRE should reveal a regular mucosal surface, with only minor induration of the rectal wall and no significant abnormalities. Endoscopic assessment is typically characterized by whitening of the mucosa with telangiectasias and absence of ulceration, mass, or stenosis of the rectum (Figs. 28.4 and 28.5). Radiological assessment should include the presence of an area of low-signal intensity at the original tumor location on MRI-T2W [magnetic resonance tumor regression grade 1 (mrTRG1)] (Fig. 28.6); restriction to diffusion on MRI-DW should be absent, corresponding to the area of low-signal intensity on T2-weighted images (Fig. 28.7).

Given the random distribution of cancer cells in the different layers in the rectal wall after nCRT [53, 54], endoscopic biopsies are not very useful in the assessment of rectal cancer response to CRT. A negative biopsy is not a requirement for patients with a cCR entering a WW protocol. Conversely, a negative endoscopic biopsy cannot exclude residual tumor in patients with near-complete or incomplete clinical response. Therefore, endoscopic biopsy in patients with an incomplete

Table 28.1 Clinical response and suggested management

Clinical response	Endoscopic features	Clinical features	Radiological features (MR)	Suggested management
Incomplete	Deep ulcerations, elevated borders, significant distortion of rectal wall	Hard palpable mass, significant stenosis	mrTRG3-5, mixed or high-signal intensity, restriction to diffusion in the corresponding area of the primary tumor	Surgical management
Near-complete	No visible mass, only superficial/shallow ulcer	Minimal/questionable irregularity	mrTRG 2	Reassessment in 8–12 weeks; further response should be documented in subsequent reassessment
Complete	Only whitening of the mucosa and/or telangiectasias	Smooth surface in DRE	Low-signal intensity (T2-weighted images), absence of diffusion restriction (corresponding area), mrTRG1	WW, reassessment in 12 weeks

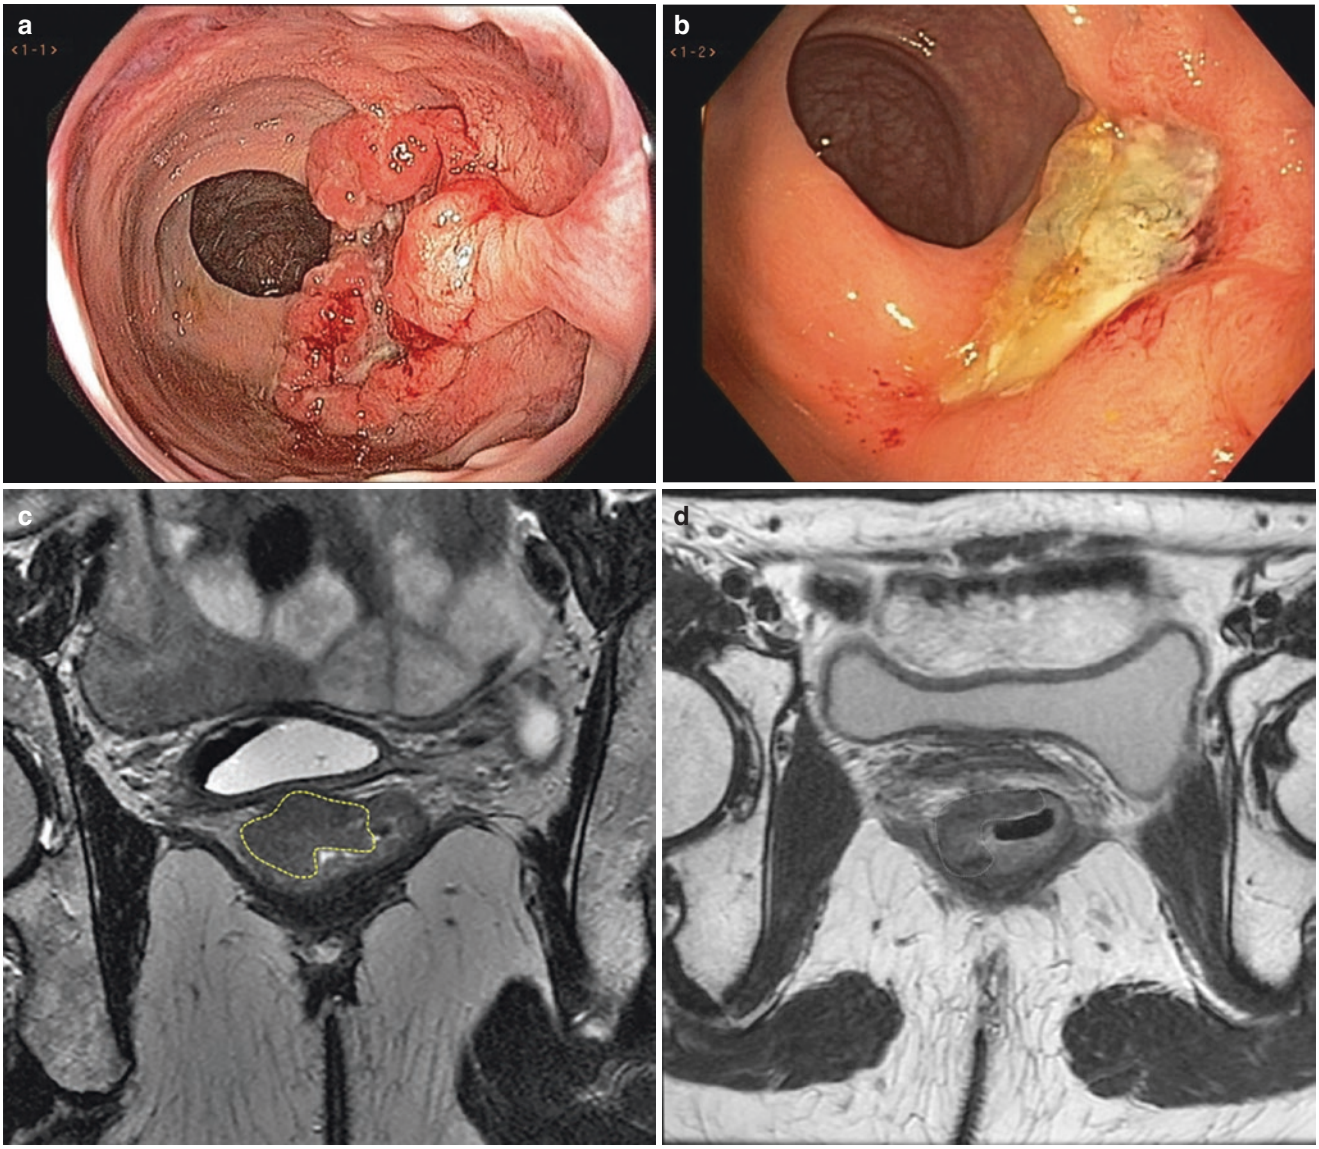

Fig. 28.1 Partial response (*not* near-complete). Endoscopic view of a rectal cancer at baseline (**a**) and exhibiting a clear large and necrotic residual ulcer (≤70% response) by endoscopy at 6 weeks (**b**). Similar findings can be seen in baseline MR showing a mrT3N0 (**c**, dotted yellow line) and ≤70% response (mrTRG3, dotted yellow line) at 6 weeks (**d**). Achievement of a cCR is unlikely

response, for the purpose of convincing patients that they have residual cancer in the setting of incomplete clinical response, is risky because a negative biopsy may give the patient a false sense of security and an argument to refuse a recommended operation [55].

One of the challenges for broad implementation of WW is establishing uniform and reproducible criteria for tumor response. Each modality is accurate but imperfect. Combining modalities increases accuracy [56]. In their investigation of the accuracies of DRE, endoscopy, and MRI in predicting pCR or sustained cCR, Maas et al. found that clinical assessment was the most accurate. When all three modalities were consistent with absence of residual tumor, the accuracy of predicting complete response was 98% [56]. A three-tiered response assessment schema currently being tested in the OPRA trial (organ preservation in rectal adenocarcinoma) consists of DRE, endoscopy, and T2- and diffusion-weighted MRI [52]. Based on that assessment, patients are considered complete responders, incomplete responders, or near-complete responders. Studies aimed at validating the reproducibility of that response assessment schema are underway.

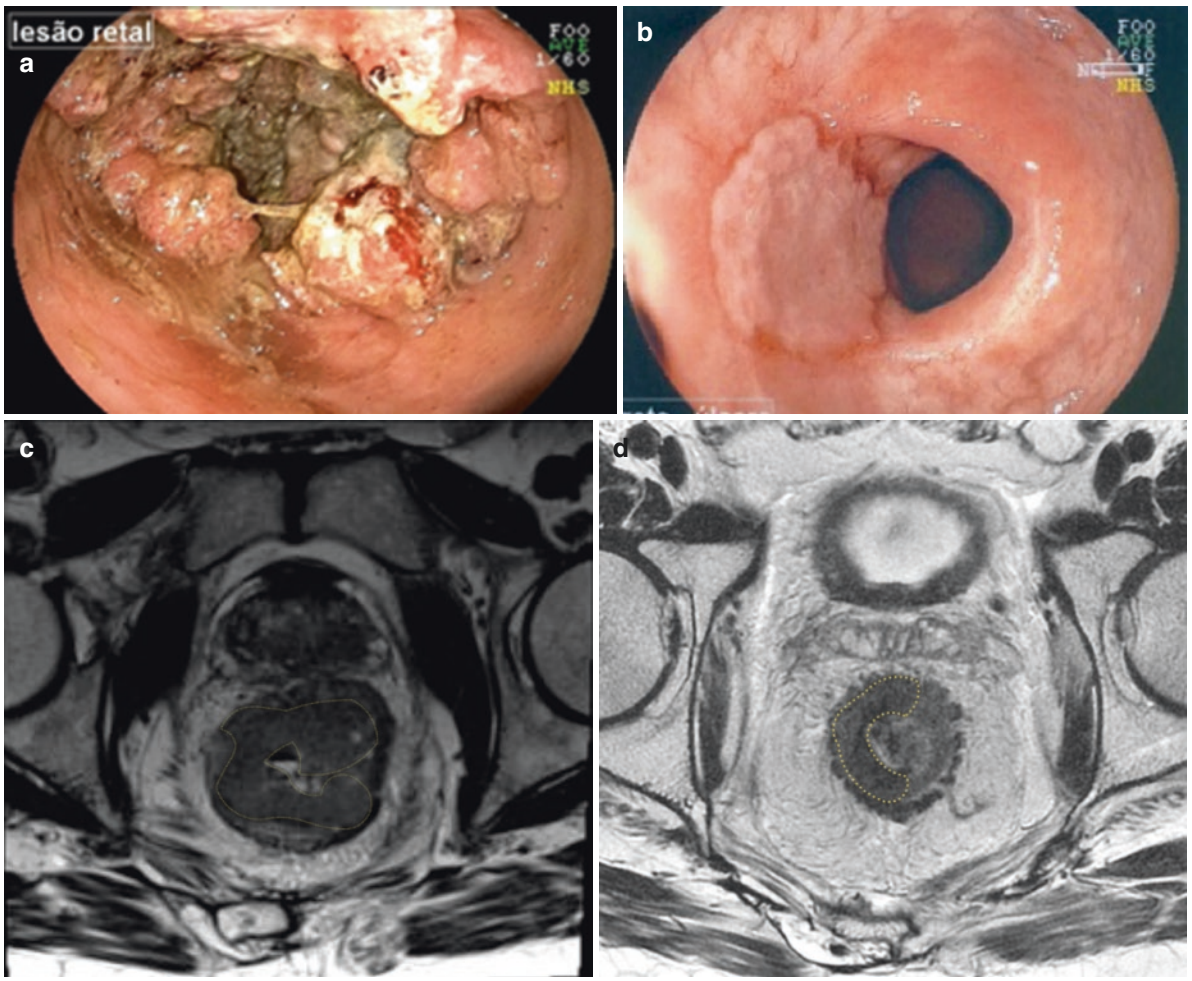

Fig. 28.2 Near-complete response followed by cCR. Endoscopic view of a rectal canvcer at baseline (**a**) and exhibiting near-complete/major (>70%) response by endoscopy at 6 weeks (**b**). Similar findings can be seen in baseline MR showing a mrT2/T3aN0 (**c**) and >70% response (mrTRG2) at 6 weeks (**d**). Achievement of a cCR is more likely, and patients should be reassessed in 6–8-week intervals. Further reassessment of response at 16 weeks showed cCR by endoscopy and MR

Endoscopic and Clinical Assessment

Historically, the first experiences of WW were reported prior to the development and standardization of radiological imaging in rectal cancer. Therefore, assessment of tumor response relied mostly on clinical (DRE) and endoscopic assessment [4].

DRE may seem like a simple and a rather straightforward tool for assessment of tumor response. However, DRE may be quite challenging for distinguishing between cCR and residual disease in many clinical scenarios. In this setting, it is recommended that the colorectal surgeons involved in organ-preserving programs be able to examine patients by DRE at baseline and during assessment of response. A DRE assessment of the baseline features of the primary tumor may aid the interpretation of response to treatment. Usually, cCR should result in a smooth and regular mucosal surface of the rectum. Even though slight induration of the rectal wall may often be palpated, ulcerations, nodules, stenosis, and masses should always raise the suspicion for residual cancer, and patients with these characteristics are thought not to be appropriate candidates for WW [2].

Endoscopic assessment may be equally challenging. Even though rigid proctoscopy may suffice for the identification of a cCR with strict criteria (see above), flexible endoscopy provides additional benefits in terms of improved visualization, more accurate documentation, training, and patient comfort. In addition, flexible instruments may provide the opportunity for retroflexion and more precise examination of the areas immediately adjacent to the dentate line. Finally, magnifying

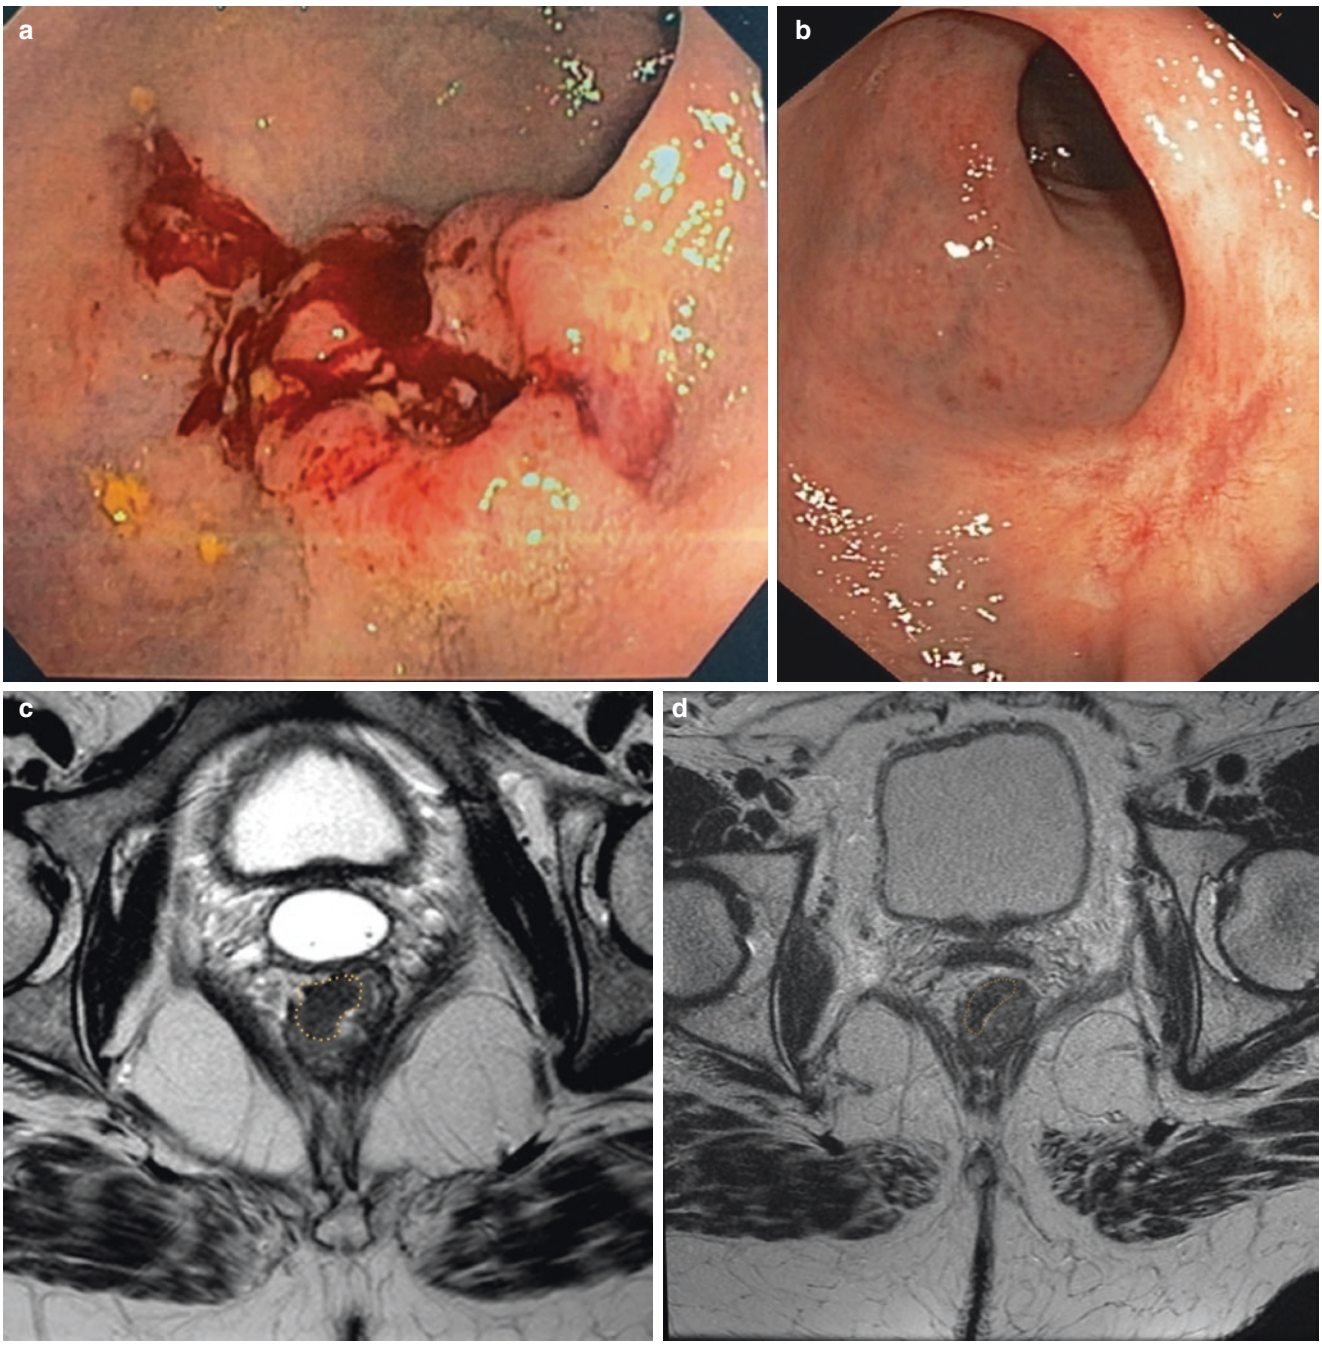

Fig. 28.3 Complete clinical response. Endoscopic view of a rectal cancer at baseline (**a**) and exhibiting strict criteria of cCR by endoscopy at 6 weeks (**b**). Similar findings can be seen in baseline MR showing a mrT2 (**c**, dotted yellow line) and mrTRG1 (**d**, dotted yellow line) at 6 weeks

endoscopic features including narrowband imaging may provide additional advantages during the assessment of tumor response after nCRT (Fig. 28.8).

Radiological Studies

Several radiological tools have been tested in clinical practice for the assessment of tumor response to nCRT. Endorectal ultrasound (ERUS) was originally used in baseline staging for rectal cancer and was also used for the assessment of tumor response to nCRT. This imaging modality provides good accuracy for the identification of complete response in the primary cancer (ypT status). However, patient discomfort and the difficulties in assessing mesorectal disease away from the rectal lumen contributed to the replacement of ERUS by alternative radiological imaging modalities [57, 58].

Magnetic resonance is currently the imaging modality of choice for baseline staging and assessment of response to

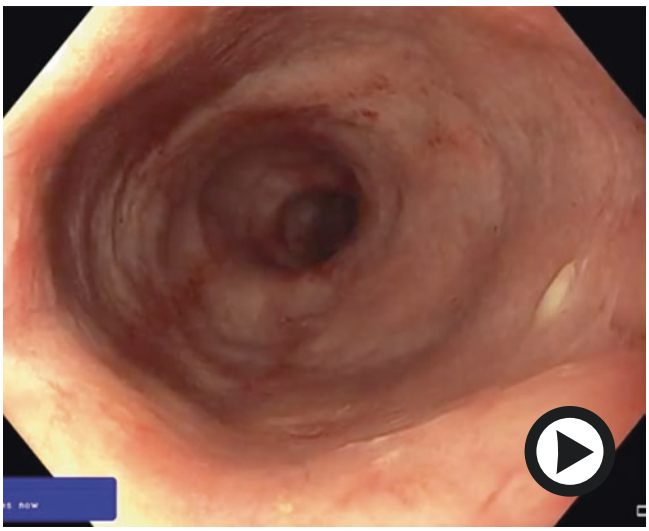

Fig. 28.4 Complete clinical response. Endoscopic view of a cCR showing clear whitening of the mucosa, telangiectasias in the submucosa, and no ulceration of the mucosa. (https://doi.org/10.1007/000-33g)

neoadjuvant therapy in rectal cancer [43]. High-resolution protocols, synoptic reporting, and T2-weighted images are usually sufficient for the assessment of response and identification of patients who are appropriate candidates for a WW program. Typical findings consistent with a cCR include areas with low-signal intensity and variable shapes/distribution in the rectum, as previously described [59]. Currently, these low-signal intensity areas are graded by a classification system similar to pathological classification systems used for tumor regression grades (TRG) [60]. mrTRG classification attempts to estimate the histologic TRG, where mrTRG1 corresponds to maximal regression and mrTRG5 corresponds to no regression. Strict criteria of a cCR include the presence of mrTRG1 areas within the area of the original

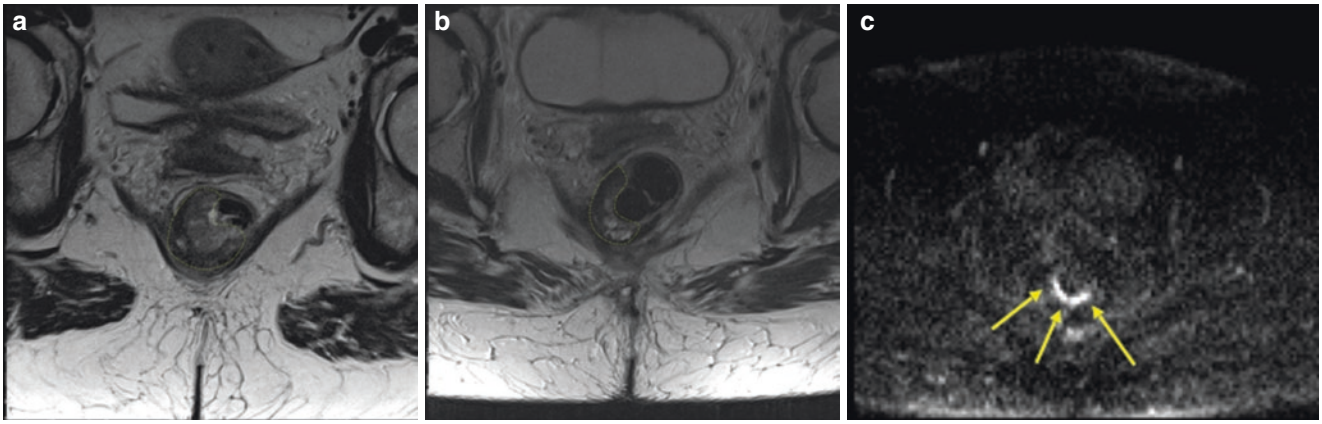

Fig. 28.7 MR and DWI incomplete response. Radiological assessment of tumor response to nCRT. Posttreatment axial T2-weighted images indicate the presence of a high-signal-intensity (**a**) area at the site harboring the original tumor at baseline (**b**). DWI sequences indicate the presence of restriction, likely representing residual cancer (**c**)

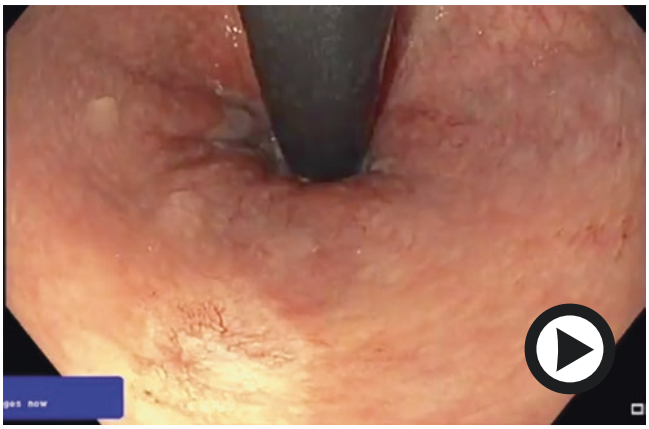

Fig. 28.8 Complete clinical response: narrowband imaging. Endoscopic view of a cCR using narrowband imaging showing clearly the presence of submucosal telangiectasias. (https://doi.org/10.1007/000-33h)

rectal cancer in the rectal wall and/or the mesorectum. MR also allows for functional imaging of rectal cancer using diffusion-weighted imaging (DWI) sequences. By detecting the restriction of water molecule movement within the area of previous cancer, DWI indicates areas of high-signal intensity [confirmed by apparent diffusion coefficient maps] highly suspicious for the presence of cancer cells. Data suggests that DWI may provide additional information and help radiologists in confirming the presence of cCR or residual disease [61, 62].

Metabolic imaging modalities including positron emission tomography (PET) alone or combined with computed tomography (PET/CT) have also been studied in the setting of tumor response assessment after neoadjuvant treatment for rectal cancer. Even though initial studies including both PET alone and PET/CT imaging were disappointing [63], more recent data supports the potential role of PET/CT in the selection of patients for WW [64, 65]. A decrease in metabolic activity as indicated by the difference in standard uptake values and in metabolic tumor volumes between baseline and posttreatment studies seems to be the best predictor of response by PET/CT (Fig. 28.9) [65, 66]. Future studies using PET/MR may provide additional information for the precise selection of these patients.

Surveillance/Follow-up Strategy

Even though multiple series have reported on the outcomes of patients with rectal cancer under WW using different surveillance protocols, most schedules and assessment modalities vary only in subtle details. Surveillance schedules need to address the risk of local tumor regrowth and the risk of distant metastasis. Even though the risk of local regrowth at 3 years may reach nearly 30%, the majority of local regrowths are detected within the first year. Therefore, most follow-up schedules have recommended more intensive and strict surveillance during this initial period of observation (Fig. 28.10) [8, 10, 11].

Local Reassessment After Achievement of a cCR

One of the premises of the WW strategy is appropriate surveillance. Therefore, this strategy should be considered only in patients committed to complying with a strict surveillance program. Once patients have achieved a cCR and formally entered a WW program, intensive surveillance for local regrowth is needed, especially during the initial 2 years. Tumor response is usually reassessed by clinical and endoscopic measures every 3 months. MRI has been progressively incorporated into surveillance schedules to complement clinical and endoscopic assessments and is now recommended every 6 months during the first 2 years. Recent

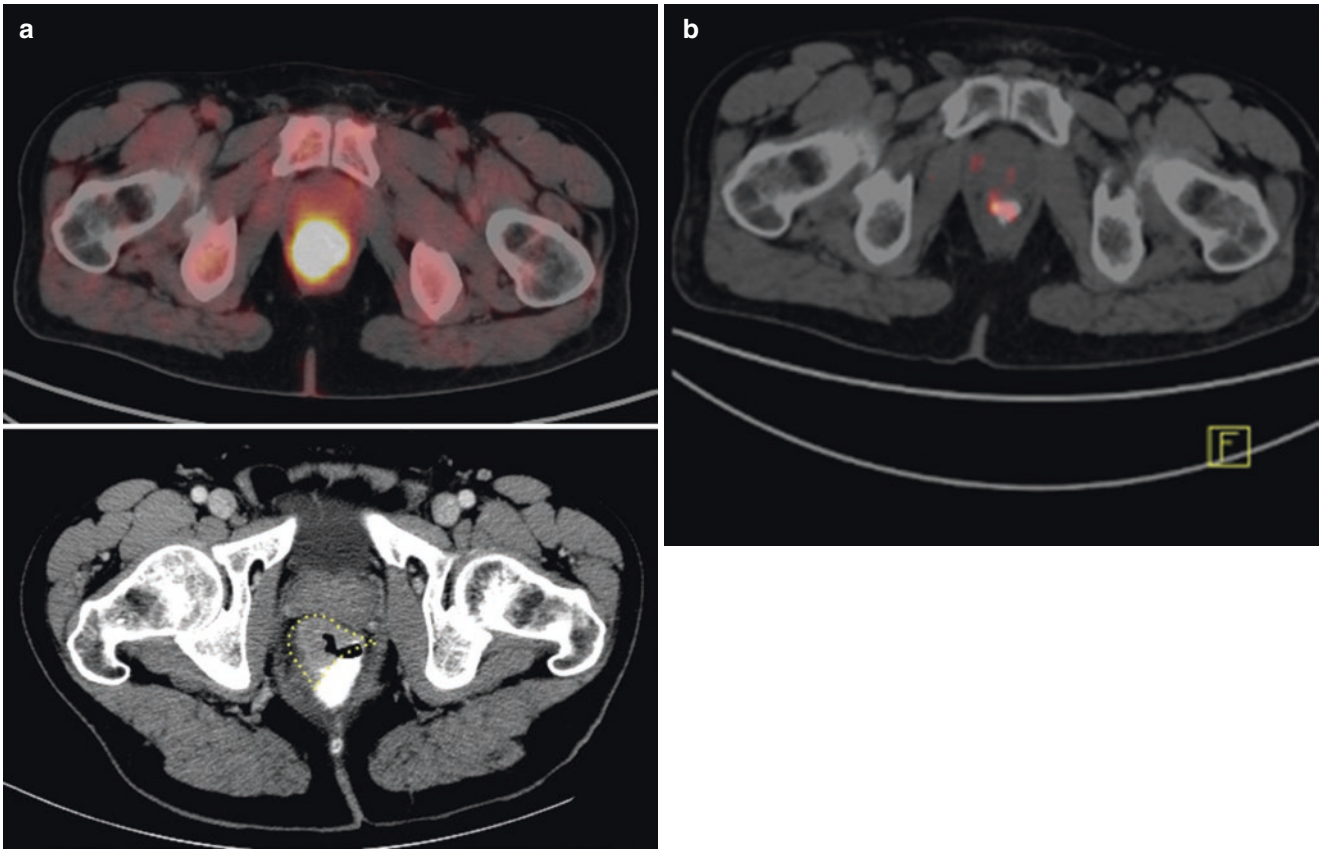

Fig. 28.9 PET/CT. Molecular imaging using fluorodeoxyglucose (FDG) PET/CT for the assessment of tumor response to nCRT. Baseline images show obvious FDG uptake in the primary tumor (**a**, PET and CT images fused with FDG uptake [top] and CT thickening of the anterior rectal wall [bottom]). Posttreatment scans show significant decrease in FDG uptake and metabolic tumor volume (**b**). This patient achieved a cCR and entered a successful WW program

data using conditional survival estimates indicate that in patients with a cCR sustained for 2 years, the risk for local regrowth is low (≤10%), suggesting that intensive follow-up schedules are less critical after 2 years [67].

Once patients have completed 2 years of follow-up, we typically reassess for continued tumor response every 6 months for the following 3 years. The need for additional surveillance beyond 5 years remains an unanswered question. Some series have reported the detection of local regrowths as late as 7 years after completion of nCRT [68]. Therefore, in the absence of long-term data, we recommend that patients who have undergone WW management should be monitored on a yearly basis indefinitely within a survivorship program.

Surveillance for Metastatic and Metachronous Disease

Patients with rectal cancer who achieve a cCR are still at risk for developing metastatic disease or metachronous colorectal cancer [10, 12, 68]. Even though the risk of metastatic disease among patients with cCR is significantly lower, surveillance strategies for metastatic disease usually follow the same recommendations as for any colorectal cancer, preferably with a CT of the chest, abdomen, and pelvis [69]. The need for a restaging CT is particularly important for patients with initial cCR who develop a local regrowth, as these patients are apparently at higher risk for metastatic disease [12]. Also, endoscopic surveillance of the colon (full colonoscopy evaluation) should follow current guidelines for patients with a high risk for developing colorectal cancer (personal history of colorectal cancer).

Local Regrowth

The actuarial rate of local regrowth at 2 years is around 25% and appears as an exponential curve, with most of the recurrences being detected during the first year of follow-up [7, 8, 10–12]. The vast majority of local regrowths have an endoluminal component and are therefore amenable to endoscopic and/or clinical detection during active surveillance (Fig. 28.11) [5, 7]. A small percentage of regrowths are

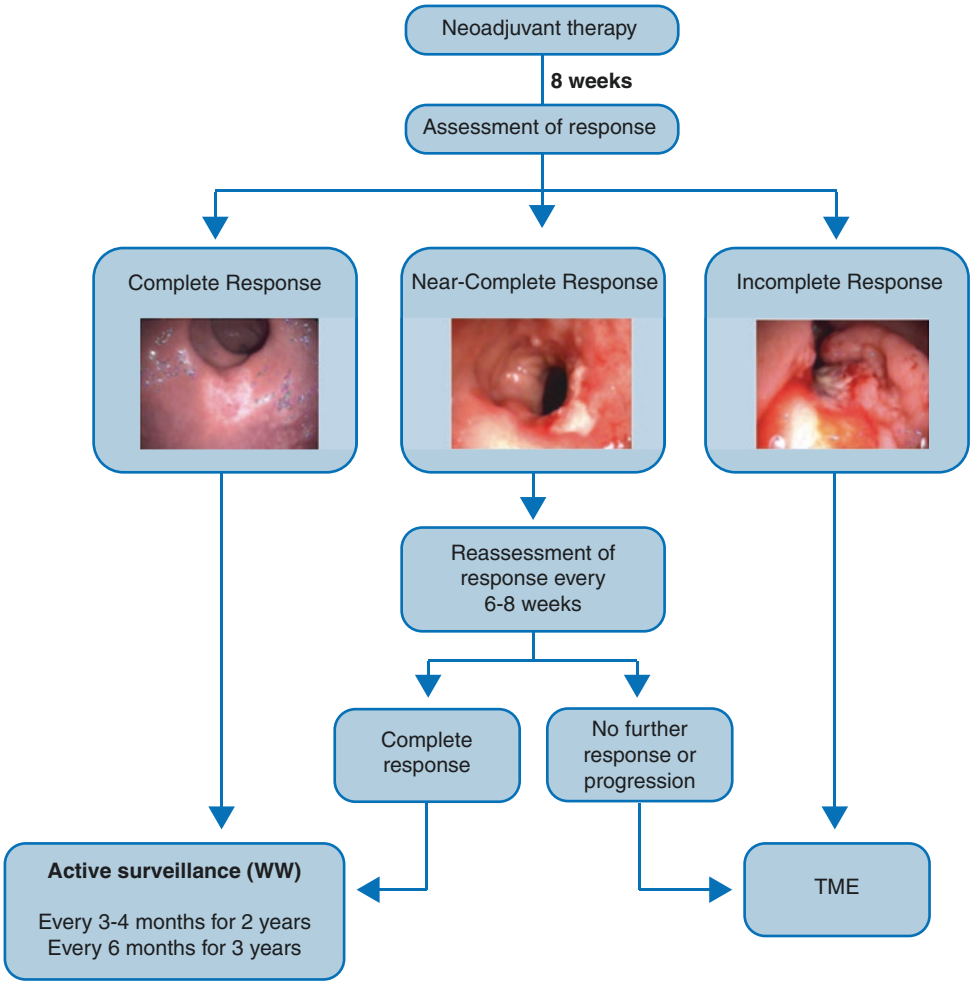

Fig. 28.10 Treatment algorithm for rectal cancer patients treated with neoadjuvant therapy interested in the WW approach for organ preservation

detected exclusively outside the rectal wall (mesorectal or lateral pelvic sidewall disease) (Fig. 28.12) [5, 7].

Risk factors for local regrowth have been investigated across many studies [11, 70, 71]. So far, the only risk factor for the development of local regrowth seems to be clinical T stage at baseline [11, 70]. Data derived from one study and a meta-analysis using individual participant data of patients undergoing contemporary MR staging suggests that for every increase in baseline clinical T stage (cT2, cT3, and cT4), there is a 10% increase in the risk for local regrowth (20%, 30%, and 40%, respectively) [11]. The influence of cT stage on local regrowth appears to be restricted to the first 2 years after cCR is attained. Based on conditional survival estimates, the risk of a local regrowth/recurrence after a cCR has been sustained for >2 years appears to be independent of baseline cT stage [67].

Systematic reviews of retrospective studies suggest that nearly 90% of local regrowths are amenable to R0 salvage resection [10]. In most cases, the salvage surgery is proctectomy [7, 12]. Patients who undergo salvage proctectomy have similar rates of R0 margins, postoperative morbidity, and oncological outcomes as patients who undergo proctectomy within 8–12 weeks after an incomplete response to nCRT [72]. Transanal local excision may also be a salvage option for tumor regrowth in patients with baseline early disease (cT2N0) entered in a WW protocol. However, transanal local excision is not routinely offered as the primary salvage surgical option for tumor regrowth in patients with baseline clinical stage II or stage III entered in a WW protocol.

Systemic Recurrences

Overall, patients with a cCR who are managed nonoperatively appear to have lower rates of distant metastases than patients with incomplete response to neoadjuvant treatment. In addition, most studies comparing patients with cCR to patients with pCR indicate no differences in the rates of distant metastases, suggesting no benefit of radical surgery in preventing M1 disease in these patients [10]. This lack of a difference is particularly notable in view of the fact that in most studies of WW, patients with cCR did not routinely receive adjuvant chemotherapy, whereas nearly 50% of

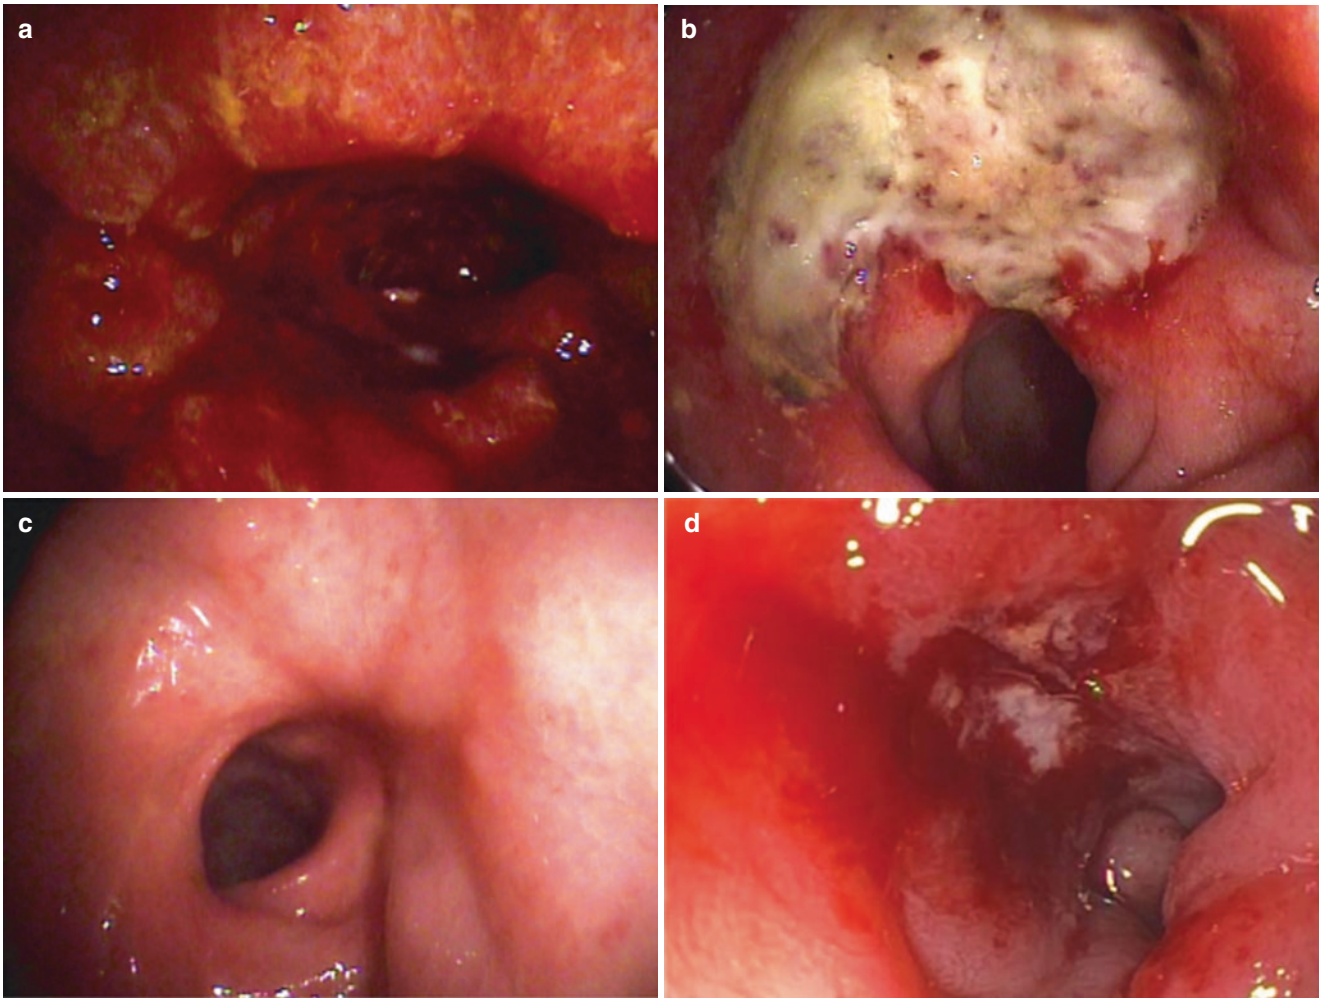

Fig. 28.11 Tumor regrowth in the bowel wall. Endoscopic view of a rectal tumor at baseline (**a**) in a patient with LARC treated with TNT (CRT followed by consolidation chemotherapy). The tumor had a partial response at the completion of CRT (**b**) and a cCR 4 weeks after completing 8 cycles of consolidation mFOLFOX-6 (**c**). Signs of mucosal regrowth were seen in follow-up 20 weeks after completion of TNT (**d**)

patients with pCR after radical surgery had received adjuvant systemic chemotherapy, mostly based on baseline staging characteristics [73].

However, patients with local regrowth after a cCR appear to be at increased risk for distant metastasis compared with patients with no regrowth after a cCR [12, 70]. It is possible that tumor regrowth may be related to a more aggressive tumor biology, which may explain the difference in the rates of metastasis. It remains unclear whether an up-front proctectomy would have prevented development of metastatic disease in patients who underwent WW instead.

Oncologic Outcomes

The current evidence on the safety and efficacy of the WW strategy in rectal cancer is based on retrospective institutional case series. Even though original reports of WW were based on the rationale of providing long-term organ preservation without oncological compromise, most of the currently available series include patients who were treated with WW accidentally, because they refused or were unfit for surgery. These studies are heterogenous regarding patient selection, imaging studies for baseline staging, neoadjuvant treatment regimens, time to assess tumor response after neoadjuvant therapy, and strategies and length of follow-up. More important the clinical and radiological criteria of tumor response were variable and not defined prospectively. In addition, the total number of patients treated during the study period was not consistently reported. In this setting, several limitations for the interpretation of the data may arise, including a strong potential for selection bias and a lack of a complete denominator. In the absence of this information, it becomes difficult to provide an accurate estimate of the proportion of patients that may potentially benefit from organ preservation. The combined experience of these series, sum-

Paired endoscopic (**a**, **c**, **e**) and axial T2 MRI (**b**, **d**, **f**) images of a patient with rectal cancer at baseline (**a**, **b**), 14 weeks after completion of total neoadjuvant therapy (**c**, **d**), and 20 months after completion of total neoadjuvant therapy (**e**, **f**). Arrow points to mesorectal regrowth. Pathology confirmed the diagnosis of adenocarcinoma

marized as systematic reviews and a large pooled analysis, suggests that between 3% and 30% of patients entered in a WW protocol will develop regrowth of the primary tumor, in most patients within the first 2 years of follow-up [8–11, 68]. In one pooled analysis, the calculated 2-year rate of regrowth was 15.7% (95% CI 11.8–20.1) [8]. Most regrowth occurs locally at the site of the primary tumor in the bowel wall, with or without involvement of the regional lymph nodes. Isolated regrowth in the mesorectum without involvement of the rectal wall is unusual. A curative (R0) surgical resection after regrowth was achieved in 80–100% of patients (average 95.4%; 95% CI, 89.6–99.3) [8, 68]. The reported rate of distant metastasis ranged from 0% to 16.7% (average 6.8%) of patients and was found to be higher in patients with local tumor regrowth, compared to patients without it [8, 10, 52]. To estimate the oncologic benefits of the WW approach, some studies have compared the survival of patients with a clinical complete response entered in the WW protocol with patients with tumors of similar clinical stage treated with neoadjuvant therapy and proctectomy who had a pathological complete response. Patients treated with proctectomy had a better disease-free survival compared to patients treated with WW (pooled HR 0.47, 95% CI 0.28–0.78); however, there was no difference in overall survival between groups [8, 9]. Also, differences in DFS here are mainly driven by the risk of local regrowth where the possibility of salvage resection is between 80% and 100% [8–11, 68].

The ideal study to prove the safety and efficacy of WW will be a randomized trial comparing WW and proctectomy in patients with a clinical complete response after neoadjuvant therapy. However, it is unlikely that patients with a clinical complete response will agree to a randomization between WW versus proctectomy. The organ preservation in rectal adenocarcinoma (OPRA) trial is prospectively investigating the impact of WW on disease-free survival for patients with clinical stage II and III rectal adenocarcinoma treated with total neoadjuvant therapy [52].

Functional Outcomes

Very few studies have specifically assessed functional outcomes in patients who underwent WW management after achieving a cCR. There seem to be significant differences in the quality of life and anorectal, sexual, and urinary functions between proctectomy patients and WW patients [74]. Patients with a sustained cCR after 2 years of WW had better quality of life and general health (SF36 and EORTC-QLQ-C30), fewer defecation problems (Vaizey and low anterior resection syndrome scores), fewer urinary problems (International Prostate Syndrome Score), and better sexual function (EORTC-QLQ-C30) compared to a matched group of patients treated with proctectomy. However, one third of the WW patients still had considerable symptoms associated with low anterior resection syndrome, suggesting a potential effect of nCRT on functional outcomes despite the avoidance of proctectomy [74]. WW patients also had superior functional outcomes compared with patients who had undergone local excision after nCRT, based on fecal incontinence scores and anorectal manometry [75].

Prediction of Tumor Response

An accurate tool for the prediction of a sustained tumor response to neoadjuvant therapy will help improve the selection of patients for WW and avoid overtreatment of patients unlikely to respond to chemoradiation who have early clinical stage tumors that would otherwise proceed directly to proctectomy. Individual gene mutations and genomic instability have been associated with tumor response to nCRT [76, 77]. A large institutional series suggests that tumors of the microsatellite instability (MSI) phenotype, found in ≤5% of all rectal cancers, are more sensitive to nCRT compared to microsatellite stable tumors [78]. However, these results were not confirmed in a retrospective review of the National Cancer Database [79]. Tumors with K-ras or K-ras/p53 mutations appear to be more resistant to nCRT [80, 81]. Although they may help identify a subset of patients less likely to achieve a cCR, these genetic alterations provide no WW-relevant information for the majority of rectal cancer patients.

Prediction of tumor response based on differential gene expression profiles has been largely unsuccessful [82, 83]. Significant intertumoral and intratumoral heterogeneity may explain gene signatures with a very low number of overlapping genes and inaccurate separation between poor and good responders [84][8]. However, a prediction score based on DNA repair genes has been recently suggested for this particular purpose [85]. In that study, low scores were associated with poor response to nCRT regardless of the DNA expression platform used. A low score (observed in nearly 40% of the patients tested) resulted in poor response to nCRT in 70–90% of the cases. Using this strategy in consecutive cT2N0 patients is expected to result in avoidance of unnecessary nCRT in 36% of patients, restriction of nCRT to 60% of patients, and good response and the possibility of organ preservation in nearly 75% of the cases [85].

Another interesting strategy for the prediction of tumor response is the use of patient-derived rectal cancer organoid cultures. These “tumoroids” appear to retain molecular features of the primary tumors from which they were derived. In addition, their ex vivo responses to chemotherapy and radiation treatment correlate with the clinical responses

observed in individual patients' tumors. Therefore, future studies attempting to predict complete tumor response to different neoadjuvant treatment strategies using this ex vivo platform may help lead to the development of an algorithm for accurate selection of ideal candidates for WW [86].

Proctectomy for Rectal Cancer

29

John Migaly and Eric G. Weiss

Key Concepts

- Removal of the rectum and mesorectum should routinely be performed using sharp dissection in the plane surrounding the mesorectal fascia to ensure removal of all mesorectum at risk for nodal spread.
- The quality of the mesorectum should be graded and the non-peritonealized radial margin of resection inked so that the pathologist can measure circumferential margin status.
- Multidisciplinary decision-making regarding the use of neoadjuvant and/or adjuvant therapy improves outcomes in patients with rectal cancer.
- Functional derangements are common following restorative proctectomy. Minimizing these derangements should be kept in mind when choosing type of neorectal reservoir and/or whether to perform anastomosis. Patients suffering from anterior resection syndrome may benefit from ongoing support and counseling.
- Adherence to oncologic principles should be maintained when performing proctectomy using minimally invasive surgical techniques.
- Locally advanced rectal cancer extending into other organs requires expertise at dissection outside of the usual tissue planes. With proper planning and combined surgery with other specialties, patients may enjoy good long-term outcomes.
- Pelvic failure rates have improved significantly over the past several decades as a result of increased attention to detail during proctectomy and the increased use of neoadjuvant therapy.

Background

As recently as four decades ago, pelvic recurrence following resection of locally advanced rectal cancer was estimated to be about 30%, with over 80% of those recurrences becoming clinically evident within the first 2 years following surgery. During this same time period, the overall recurrence rate was noted to be approximately 40% for generalist surgeons and between 10% and 20% for specialist surgeons, bringing attention to the concept that operative technique may have a profound impact on prognosis [1]. Since that time, there has been a focus on the quality of proctectomy for rectal cancer and the use and timing of adjuvant radiotherapy and chemotherapy that has improved outcomes for patients.

Bill Heald et al. demonstrated that attention to anatomic detail during proctectomy was associated with good outcomes and were successful in promoting this concept throughout the surgical community. Heald emphasized that appropriate resection of the mesorectum in rectal cancer surgery was the key to minimize pelvic recurrence. The embryologic planes are defined by the fascia propria of the mesorectum and the structures contained within this fascia: perirectal fat, blood vessels, and the lymph nodes and channels. Heald encouraged surgeons to strive for extirpation of the contents of this space along embryologic fusion planes, as a means to reduce local recurrence of rectal cancer [2].

At the same time, Phil Quirke, a pathologist colleague of Heald, described optimal gross and histologic evaluation of proctectomy specimens, specifically the measurement of circumferential radial margin (CRM) and grade of mesorectal excision. As opposed to prior custom, where only the proximal and distal margins of resection were thought to be of importance, it became clear that assessment of CRM was critical, as the most common cause of pelvic failure was not the axial extent of the tumor but rather the radial spread of the tumor. This should not have been surprising, as one would assume that all margins of resection are equally important. Pathologic data dating back three decades demon-

S. R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, https://doi.org/10.1007/978-3-030-66049-9_29

strates that rectal cancer with less than a 1 mm circumferential resection margin (<1 mm considered a positive resection margin) has a greater than 50% local recurrence rate, while those with a greater than 1 mm margin had a 17% local recurrence rate [3, 4]. Achieving negative CRM can be challenging, because of the bony confines of the pelvis, along with key vasculature and urogenital structures at the margins of resection.

The work of Heald and Quirke heralded the era of "specimen-oriented surgery," as they promoted the concept of "total mesorectal excision" (TME). The complete excision of the contents of the mesorectal envelope at risk for mesorectal metastases is the driving principle of proctectomy. It is the sharp dissection along these planes and the intact removal of the mesorectum and the contents therein that minimizes the risk of local recurrence. In head-to-head comparisons of "traditional" low anterior resection or abdominal perennial resection versus utilization of the technique of TME, TME technique yields significant reduction in the local recurrence rates.

The now routine utilization of radiation and chemotherapy in the neoadjuvant setting for the treatment of locally advanced rectal cancer represents the second most significant leap forward in improving cancer related outcomes after proctectomy. Anna Martling and her colleagues provided additional data to legitimize the idea that radiotherapy in combination with TME, further reduces the risk of recurrence of rectal adenocarcinomas in comparison to TME alone [5–7].

Anatomy of the Rectum and Mesorectum

A nerve sparing proctectomy that utilizes the technique of TME is facilitated by a working knowledge of the embryologic origins of the structures within the pelvis; this yields greater understanding of the dissection planes and patterns of lymphatic and non-lymphatic spread of rectal tumors.

The hindgut develops into the rectum and the upper portion of the anal canal. The last portion of the hindgut becomes the cloaca with the allantois. The urogenital septum forms between the cloaca and allantois and form the perineal body which separates the urogenital structures from the terminal gastrointestinal tract. These planes form the basis of the planes utilized for TME.

The blood supply to the rectum can be considered to be segmental; however, in truth, the rectum has a rich interconnected submucosal vascular plexus which makes the rectum very difficult to truly devascularize during proctectomy. The hindgut receives its blood supply from the dorsal mesentery which eventually becomes the mesorectum. The upper rectum receives its blood supply from the inferior mesenteric artery (IMA) which comes directly off of the abdominal aorta. The IMA splits into left colic artery and superior rectal (hemorrhoidal) artery 2–3 cm from its origin at the aorta. The left colic artery courses superiorly toward the splenic flexure and the superior rectal artery courses inferiorly toward the rectum at the root of the mesentery.

It should be noted that there is not universally agreed upon nomenclature regarding the IMA and its branches, as some surgeons assert that the IMA becomes the superior rectal artery when it "crosses the common iliac artery," after it has given off some of the sigmoidal arteries. This latter designation is potentially problematic, as it ignores the principle of naming arteries based on their branch points, and because it is difficult to ascertain exactly where an artery "crosses" another anatomically in space, especially after mobilization of the mesosigmoid. This distinction is important during proctectomy for rectal cancer, as a precise definition of arterial anatomy is key to understanding potential differences in outcome following "high" versus "low" ligation of the IMA/superior rectal artery. One surgeon's "high" ligation of the IMA might be considered "low" ligation (of the superior rectal artery) by another.

The superior rectal artery supplies blood to the upper third of the rectum, while the middle rectal artery supplies the blood to the mid rectum. Despite being a structure included in all anatomic and surgical texts, the middle rectal artery is identifiable in about 10–20% of patients at the time of surgery. The inferior rectal artery supplies the lowest third of the rectum and arises from the terminal branches of the internal iliac artery. The venous drainage of the rectum somewhat mirrors the arterial blood supply, with the venous supply of the upper rectum draining into the portal circulation via the inferior mesenteric vein and the remainder of the rectum draining into the systemic system via the iliac veins.

The mesorectum itself contains lymph nodes, blood supply, perirectal fat, and connective tissue associated with the rectum. The mesorectum is surrounded by an envelope of tissue referred to as the fascia propria of the rectum. Along the "sacral hollow," there are the iliac vessels, the hypogastric nerves, and the presacral veins which are covered by a thin lining anteriorly of what is referred to as the presacral fascia. Between the presacral fascia and the fascia propria of the rectum is an avascular, loose areolar plane which is the plane of dissection for an oncologic proctectomy for tumors that do not broach the mesorectal fascia. This is what Bill Heald refers to as the "holy plane" of dissection (Fig. 29.1). The degree of precision by the surgeon while dissecting in this plane determines whether or not the patient has a complete oncologic resection and a complete mesorectum on pathology review. Violating the fascia propria of the rectum can result in retained mesorectum after extirpation, which increases the likelihood of recurrence, and violating the presacral fascia can result in nerve injury leading to subsequent sexual and/or bladder dysfunction. Violating the presacral

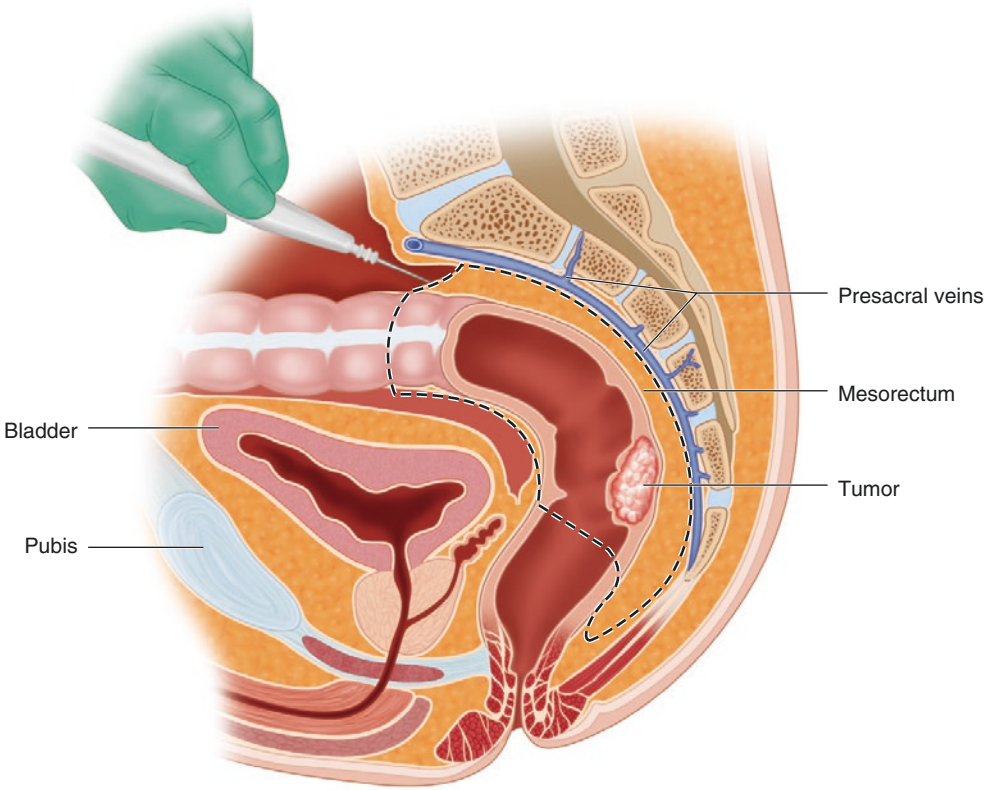

Fig. 29.1 The "holy plane" described by Heald is demonstrated

fascia can also result in bleeding from the iliac vessels or the presacral venous plexus. Bleeding from the presacral venous plexus can be quite problematic, as the venous pressure in the pelvic plexus can be comparable or even higher than the pressure in the inferior vena cava. The dissection for an oncologic proctectomy or TME when performed correctly should be sharp and bloodless.

Anteriorly, at about the middle third of the rectum, the rectum is separated from the prostate/seminal vesicles and autonomic nerve plexus by a thin septum known as Denonvilliers' fascia. Remaining outside or posterior to Denonvilliers' fascia during dissection decreases the likelihood that the periprostatic or perivaginal autonomic nerves being injured (Fig. 29.2). There is usually very little or no mesorectal tissue between the rectum and the prostate or vagina anteriorly at the lowest third of the rectum.

Posteriorly, at approximately the level of S4, the presacral fascia and the fascia propria of the rectum connect and thicken to form Waldeyer's fascia, which needs to be divided during a proctectomy to fully mobilize the rectum posteriorly to the levator muscle complex [8].

The sympathetic innervation of the urogenital organs originates from the superior hypogastric plexus and the parasympathetic innervation arises from the pelvic splanchnic nerves. The superior hypogastric plexus travels caudally from about the level of the inferior mesenteric artery toward the bifurcation of the aorta along the anterior surface of the aorta. At the level of the sacral promontory, the hypogastric plexus splits into two discrete nerves: the left and right hypogastric nerves. The hypogastric nerves travel along the pelvic side wall, lateral and posterior to the pelvic plexus. They are joined by the pelvic splanchnic nerves, also known as the pelvic autonomic nerves, the *nervi erigentes*. When these sympathetic and parasympathetic nerves intermingle, they are known as the inferior hypogastric plexus. The inferior hypogastric plexus can be tethered to the mesorectum inferolaterally and must be separated carefully during dissection. Injuries to these nerves can result in urogenital abnormalities such as urinary retention, retrograde ejaculation in the case of sympathetic nerve injury, and loss of erection in the case of parasympathetic nerve injury [9].

Priorities in Proctectomy for Rectal Cancer

The innumerable permutations of neoadjuvant therapy for locally advanced rectal cancer, ranging from short-course radiation only to total neoadjuvant therapy, do not obviate the need for a skilled surgeon with impeccable operative technique. The effects of neoadjuvant therapy and optimal surgery are additive, not compensatory. There are an ever-expanding number of technologies available to the surgeon, which adds additional complexity to the options; however, priorities in rectal cancer surgery should stay constant:

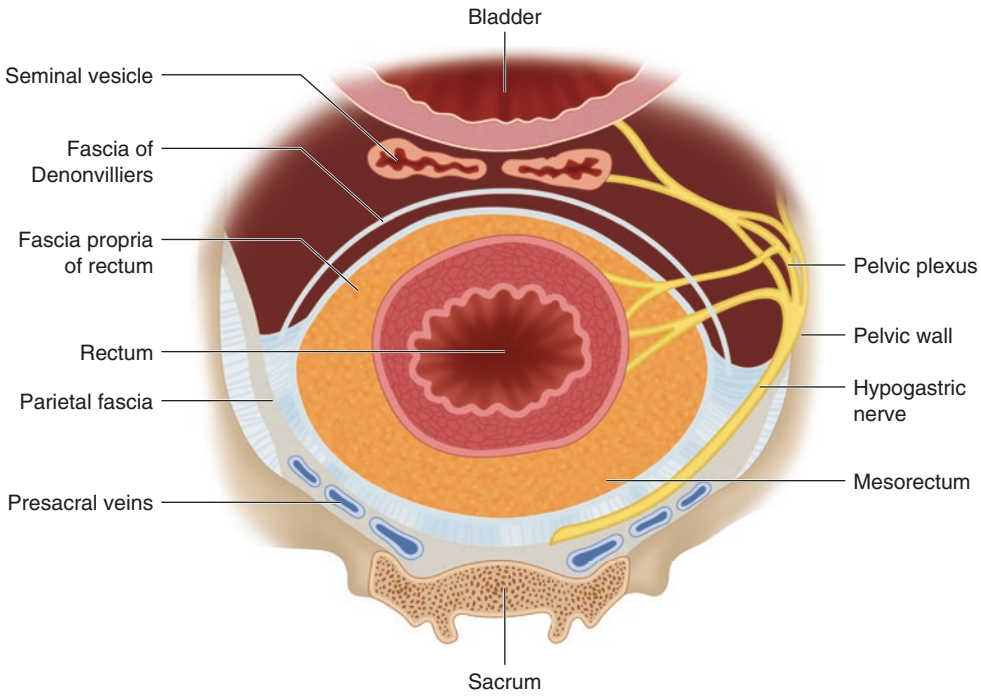

Fig. 29.2 Axial view of the rectum demonstrating the relevant anatomical structures to perform nerve sparing total mesorectal resection

1. An appropriate mesorectal excision using sharp dissection should be performed to provide the optimal oncologic resection.
2. Nerve sparing proctectomy should be performed.
3. Continent reconstruction should be performed whenever possible, but not at the expense of positive resection margin or poor functional outcome.

Preoperative Preparation

Typically, patients undergoing elective proctectomy will undergo cathartic bowel preparation and oral antibiotics (neomycin/erythromycin or neomycin/metronidazole). Rectal washout in the operating room or enemas immediately preoperatively can be helpful to clean remaining stool from the rectum, but should not be used in lieu of oral mechanical bowel preparation (MBP) in combination with oral antibiotics (OA).

Despite the decades-long debate that follows Nichols' work in colon antisepsis and the multiple paradigm shifts that ensued, currently there is high-quality registry data that support the use of MBP in combination with OA [10–14]. In a study of 9940 patients in the Veteran's Affairs Surgical Quality Improvement Program, it was found that patients undergoing colectomy with both MBP and OA had half the rate of surgical site infection (SSI) as those patients who underwent MBP alone and also half the rate of SSI when compared to those patient who underwent no bowel preparation [15]. In a series of 4999 patients using the National Surgical Quality Improvement Program (NSQIP) registry, patients who received MBP with OA had significant lower SSI, anastomotic leak, and procedure-related readmission when compared with those who had no bowel preparation, MBP alone or OA only [16]. An additional NSQIP study of 8442 patients found that combined MBP with OA was independently associated with a reduced rate of anastomotic leak and postoperative ileus [17].

The most recent version of the American Society of Colon and Rectal Surgeons Clinical Practice Guidelines Committee's published practice parameters recommends the combined use of both "MBP" with OA for the use of bowel preparation before elective colon and rectal surgery [18]. Margolin et al. published the largest series to date looking at 27,804 undergoing elective colorectal resections and recapitulated prior findings of the benefits of combined MBP and OA on SSI, deep organ space infection, and anastomotic leak but also showed no increased risk of *Clostridium difficile* infection in these patients [19].

Studies examining the benefits of rectal enemas versus traditional MBP are predominantly small limited series that are poorly designed; therefore we do not advise substituting rectal enemas for MBP with OA [20–23]. Furthermore, if restorative proctectomy with proximal fecal diversion is contemplated, enemas will not adequately clear the stool from the intervening colon (between the loop stoma and the anastomosis). If anastomotic leak occurs, this residual stool may slowly extrude from the leak site.

Potential stoma sites should be marked preoperatively and the patient educated regarding stoma care by an enterostomal therapist (ETRN)/certified wound ostomy continence nurse (CWOCN).

Operative Approaches

Open Low Anterior Resection

The patient is placed in the low lithotomy or split-leg position. Lithotomy is necessary for cases in which handsewn coloanal anastomosis is contemplated; split leg is preferred when stapled anastomosis will be performed. In open cases, ureteral stents are not usually helpful unless it is a reoperative pelvic procedure (e.g., recurrence) or a patient with markedly elevated body mass index (BMI). A digital rectal examination should be performed to both localize the tumor and assess diameter and compliance of the anus, which will assist in selection of stapler size for stapled end to end anastomoses. If the tumor cannot be palpated, it may be helpful to perform proctoscopy at this time to localize the tumor. Proctoscopy should also be used liberally throughout the rectal dissection to ensure that tumor location is precisely identified. Palpation of the tumor through the rectal wall during proctectomy may be inaccurate, especially in cases where the tumor is small or the patient has undergone neoadjuvant therapy. Flexible video endoscopy with carbon dioxide insufflation is preferred, as the entire operating team can view the images and the use of carbon dioxide will limit bowel distention.

A midline incision is typically performed so as to accommodate temporary intestinal stoma sites. It can be extended as cephalad as necessary to allow for safe mobilization of the splenic flexure. In rare cases of patients with a redundant sigmoid colon identified on preoperative imaging and low BMI, a Pfannenstiel incision can be utilized.

Dissection typically begins with sigmoid colon in a lateral to medial technique along the white line of Toldt. The sigmoid colon is mobilized off of the retroperitoneum in a cephalad direction toward the descending colon. The left-sided gonadal vessels can be located during the sigmoid colon mobilization at the level of the pelvic inlet, and the vessels can be traced to their entrance into the inguinal canal. The left ureter can be located medial to the left gonadal vessels at the level of the bifurcation of the left common iliac artery. It is sometimes helpful to place a vessel loop around the left ureter to aid with subsequent confirmations of the location and course of the left ureter. Mobilization of the left colon continues to include the mobilization of the splenic flexure. The loose attachments to the spleen are sharply taken, and the colon is mobilized off of Gerota's fascia. Attention is then turned toward entering the lesser sac at the level of the mid-transverse colon; the transverse colon is retracted and the omentum is retracted away from it. The omentum is usually split into two leaflets, both of which must be divided in order to enter the lesser sac. The correct plane is identified when the surgeon can see the anterior surface of the body and tail of the pancreas and the posterior wall of the stomach. Once this is assured, the transverse colon can be liberated from its omental attachments by sequentially dividing the omentum from the transverse colon toward the flexure. The splenic flexure must be completely mobilized to allow for maximal mobility.

The inferior mesenteric vein is identified at its root at the level of the ligament of Treitz. A high ligation of the IMV is performed, after meticulously assuring that there are no arterial branches in the tissue to be divided. A high ligation of the IMV will sometime supply as much as an additional 15 cm of reach of the left colon into pelvis. Any remaining mesenteric attachments of the left colon are taken off the tail and body of the pancreas flush with its lower border.

Once this is done, the patient is placed in slight Trendelenburg, and the small bowel is placed behind moist lap sponges in the right upper quadrant to facilitate pelvic dissection. The rectosigmoid junction is retracted upward and out of the abdomen. The sacral promontory is identified along with the superior rectal artery immediately above it at the root of the rectosigmoid mesentery. There should be a bare area in the sulcus between these two structures. The cautery is used to score the investing layer of the mesentery at this location beginning 1–2 cm superior to the sacral promontory, just posterior to the arc of the superior rectal artery, and then extending the division of the peritoneum to the root of the IMA. Dissection in this space allows for entry into the areolar plane between the presacral fascia and the fascia propria of the rectum beginning at the sacral promontory. The hypogastric nerve plexus is swept posteriorly and preserved. Once this space is opened up, the surgeon passes the hand below the superior rectal artery and through to the other side of the mesentery. Then the dissection is carried cephalad in this avascular plane along the anterior surface of the aorta until the inferior mesenteric artery is identified. The artery is skeletonized, taking care to assure that the nerve fibers of the superior hypogastric plexus are brushed downward and preserved.

The surgeon then decides whether to divide the IMA at the aorta or whether to divide the superior rectal artery at its origin (about 2 cm from the aorta) while preserving the left colic artery. This is a decision based on mobility and quality of the colon conduit, as there have been no demonstrable differences in oncologic outcomes when comparing the techniques. The advantage of dividing the IMA at the aorta is greater mobility; the downside is that arterial supply to the conduit is solely from the left branch of the middle colic artery which must be meticulously preserved during mobilization of the splenic flexure and division of the IMV. The advantage of dividing the superior rectal artery at its origin is that the conduit has dual blood supply from both the middle colic artery and IMA (via the left colic artery, which rotates on its axis inferiorly provided that the splenic flexure was completely mobilized and the IMV divided); the downside is loss of some mobility of the conduit. In patients with distal rectal tumors, it is typical that division of the IMA at the

aorta is necessary. In patients with proximal rectal tumors and a redundant sigmoid colon, it is often possible to preserve the left colic artery. In order to assure adequate length of the left colon conduit, the tip of the mobilized conduit should be able to reach the base of the penis in a male and the mons pubis in a female.

The colon is then divided at approximately the descending sigmoid junction, and the intervening mesentery is divided. Division of the colon should be undertaken by a method consistent with the planned anastomotic technique. If a straight stapled end-to-end anastomosis is contemplated, the colon can be divided sharply, purse-string suture placed, and anvil of the stapler inserted. The distal side of the colon on the specimen can be oversewn with suture. There is no need to utilize a mechanical stapler to divide the colon at this juncture, as both sides of the staple line will ultimately be removed from the patient, and using a stapler will thus be a needless expense. However, if a colonic J-pouch or Baker anastomosis is contemplated, and then it is appropriate to divide the colon with a linear cutting stapler. If a handsewn coloanal anastomosis is planned, the colon can be divided sharply and closed with suture or stapled to minimize any chance of spillage when the conduit is passed to the anus. The left colon conduit is then placed behind moist lap sponges along the small bowel in the upper abdomen.

Attention is then turned toward the rectal dissection. The operating surgeon, most commonly using a St. Marks retractor, retracts the rectum anteriorly and toward the pubic symphysis to accentuate the plane between the presacral fascia and the fascia propria of the rectum; this plane is referred to as "the holy plane." Posteriorly the left and right hypogastric nerves are identified and kept out of harm's way. The dissection should be done entirely utilizing sharp dissection with the electrocautery or scissors (Fig. 29.3). This dissection should be bloodless if the appropriate planes are maintained. The loose areolar fibers are divided posteriorly in small brush like strokes as the assistant periodically repositions the St. Marks retractor deeper and deeper as the posterior dissection proceeds. As the dissection proceeds posteriorly toward the tip of the coccyx, this loose areolar tissue coalesces and thickens to form Waldeyer's fascia. Waldeyer's fascia is subsequently divided until the superior portion of the levators is encountered. The lateral stalks are taken in the same fashion down to the pelvic floor. Alternatively, a bipolar vessel sealing device can be utilized to divide the lateral stalks at the pelvic sidewall, which may minimize bleeding from the middle rectal arteries. As always, the benefit must be balanced with the cost of the device. Anteriorly the plane between the rectum and the seminal vesicles/prostate or vagina must be carefully dissected so as to ensure complete removal of the tumor and also to avoid injury to the prostate/vagina and nerves that lie adjacent to Denonvilliers' fascia. For mid and distal rectal cancers, the rectum must be freed up anteriorly down to the pelvic floor so that a stapler can be used to transect the rectum flush with the levators. Prior to transection of the rectum, it is imperative that tumor location is confirmed. Flexible video proctoscopy allows for the abdominal surgeon to identify the exact level of the tumor just prior to rectal division. Rectal transection at this level can be challenging. Options include utilizing a low-profile transverse stapling device or a laparoscopic linear cutting stapler.

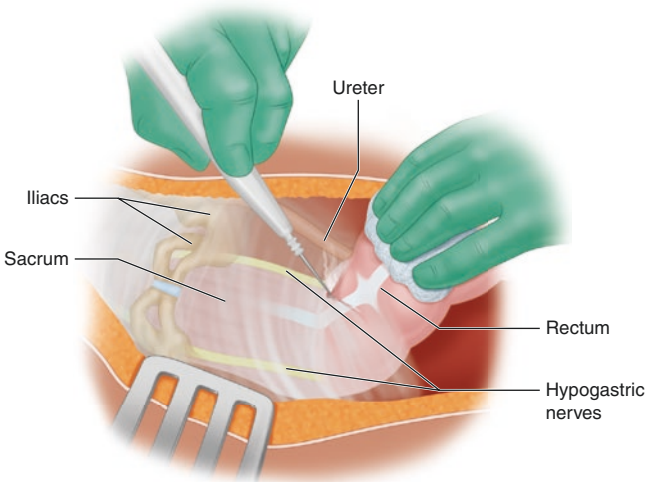

Fig. 29.3 The loose areolar tissue is sharply divided with electrocautery

For proximal rectal cancer, there is no oncologic benefit to removal of mesorectum more than 5 cm distal to the tumor; thus a "tumor specific mesorectal excision" may be performed. This will allow preservation of the distal rectum, which is associated with improved functional outcomes and lower anastomotic leak rates as compared to removal of nearly the entire rectum and distal colorectal or coloanal anastomosis. It is, however, critical to divide the mesorectum at the appropriate level perpendicular to the longitudinal axis of the rectum and avoid "coning in" on the mesorectum. Unfortunately, the moniker "TME" is used to describe this technique as well, which causes some confusion. Overall, it is better to think of "TME" as a technique of dissecting in the avascular plane surrounding the mesorectum, rather than as an operation. "Proctectomy" is the more appropriate term for the operation.

For very distal cancers that do not invade the anal sphincter muscles or pelvic floor, it may be appropriate to divide the rectum via a transanal approach. This can be done prior to, after, or synchronously with the abdominal mobilization. Placement of a self-retaining retractor and utilization of any of a number of operating anoscopes may facilitate exposure. The rectum is typically divided using electrocautery in full-thickness fashion at an appropriate distance from the tumor. The dissection proceeds proximally in the appropriate plane outside of the mesorectum, with the goal of connecting

with the mobilization performed by the abdominal operator. It is frequently helpful to have the abdominal operator help guide the dissection by placing a hand in the pelvis in the previously dissected spaces which can then be identified by palpation from the perineum.

In an effort to restore intestinal continuity despite the presence of a tumor in the most distal rectum, some surgeons have advocated performing "intersphincteric resection" with removal of some or all of the internal anal sphincter muscle and construction of coloanal anastomosis. Others have extended the resection to include a portion of the external anal sphincter muscle when indicated by tumor anatomy. Interpreting data regarding oncologic and functional outcomes has been challenging, as there is no precise definition of "intersphincteric resection" with regard to how much of the sphincter is removed, and there is a paucity of prospective randomized trials. Results from case series (mostly from Japan and South Korea) have been mixed, although it appears that ypT3 disease and partial external anal sphincter resection during restorative proctectomy are associated with suboptimal outcomes [24–28].

Once the rectum is passed off of the table, the surgeon should observe a layer of glistening tissue overlying the mesorectum which represents an intact fascia propria of the rectum without any noticeable divots in the mesorectum (Fig. 29.4). The non-peritonealized radial margin should be marked with ink, optimally by the surgeon prior to sending it to the pathology laboratory. Typically, low colorectal and coloanal anastomoses should be constructed in conjunction with a proximal diverting loop ileostomy, placed approximately 25–30 cm proximal to the ileocecal valve. In rare cases, patients will have a redundant proximal colon that will allow for diverting loop distal transverse colostomy, which may be preferable as colostomy is associated with less risk of dehydration than ileostomy.

Straight Stapled Anastomosis

For continent reconstruction, there are several options that will be described. A straight stapled colorectal/coloanal anastomosis is the most common anastomosis described; it is performed using an end-to-end stapler and the anvil placed via a purse-string suture in the distal end of left colon conduit. The stapler is then passed transanally, and the pin of the stapler is brought out through the rectum as close as possible to the rectal transection staple line to avoid an ischemic ridge of tissue adjacent to a newly created anastomosis.

Following anastomotic construction, endoscopic inspection and pneumatic leak test should be performed. This is ideally accomplished using flexible video endoscopy with carbon dioxide insufflation. The proximal colon is occluded,

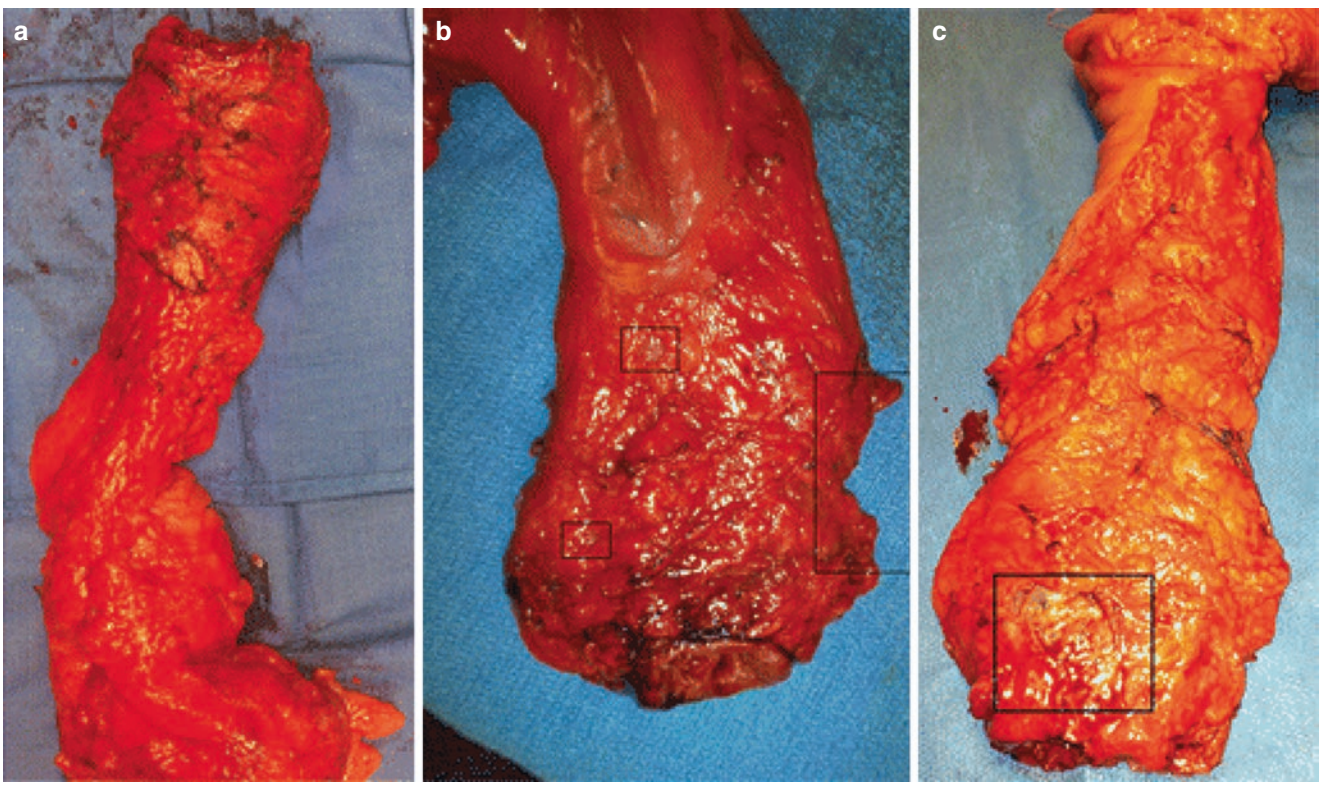

Fig. 29.4 TME specimens. (**a**) Complete TME specimen. (**b**) Nearly complete TME specimen. (**c**) Incomplete TME specimen. The *black outlines* indicate areas of mesorectal fascia violation. (Reused with permission from Fleshman [88]. Copyright © 2016 Springer Nature)

the pelvis is filled with saline, and gas is instilled via the colonoscope. Bubbling indicates a defect in the anastomosis, which should be repaired. The mucosa should be pink and healthy both proximally and distally, indicative of adequate arterial flow. Any areas of pulsatile hemorrhage can be addressed, typically using endoscopic clips.

Handsewn Coloanal Anastomosis

A handsewn coloanal anastomosis can be used in one of two situations: when an ultralow anastomosis is required or when there is a stapler misfire, wherein a handsewn technique can be used to salvage a technical mishap. It is often helpful to have orienting sutures on the colonic conduit to avoid twisting as it is passed by the abdominal operator to the perineal operator. Typically the anastomosis is created using single-layer absorbable suture, placed in interrupted and/or running fashion. Initial placement of sutures in the four quadrants of the anastomosis may facilitate exposure and orientation for the remaining sutures.

Colonic J-Pouch Anastomosis

The reservoir function of a straight coloanal anastomosis may not be ideal for many patients, and thus in select patients, there is the option of performing colonic J-pouch reconstruction. In brief, the distal conduit is folded into a "J-type" configuration that is approximately 7 cm in length and the antimesenteric bowel surface of the apex of the "J" is opened so that an 75–80 mm linear stapler can be passed into each limb of the colon and then fired, thus creating an approximately 7–8 cm common channel. If a double-stapled anastomosis is possible, the anvil of the stapler is subsequently sewn into the apex of the J-pouch, and an end-to-end anastomosis is performed as previously described (Fig. 29.5). If a handsewn coloanal anastomosis is performed, sutures are placed at the apex of the J-pouch, and it is delivered via the anus, the apex opened, and a handsewn anastomosis created as described above. J-pouch reconstruction is only possible if the folded colonic conduit will both reach to the anus and fit in the pelvis. Patients with visceral obesity and a narrow pelvis are often not suit-

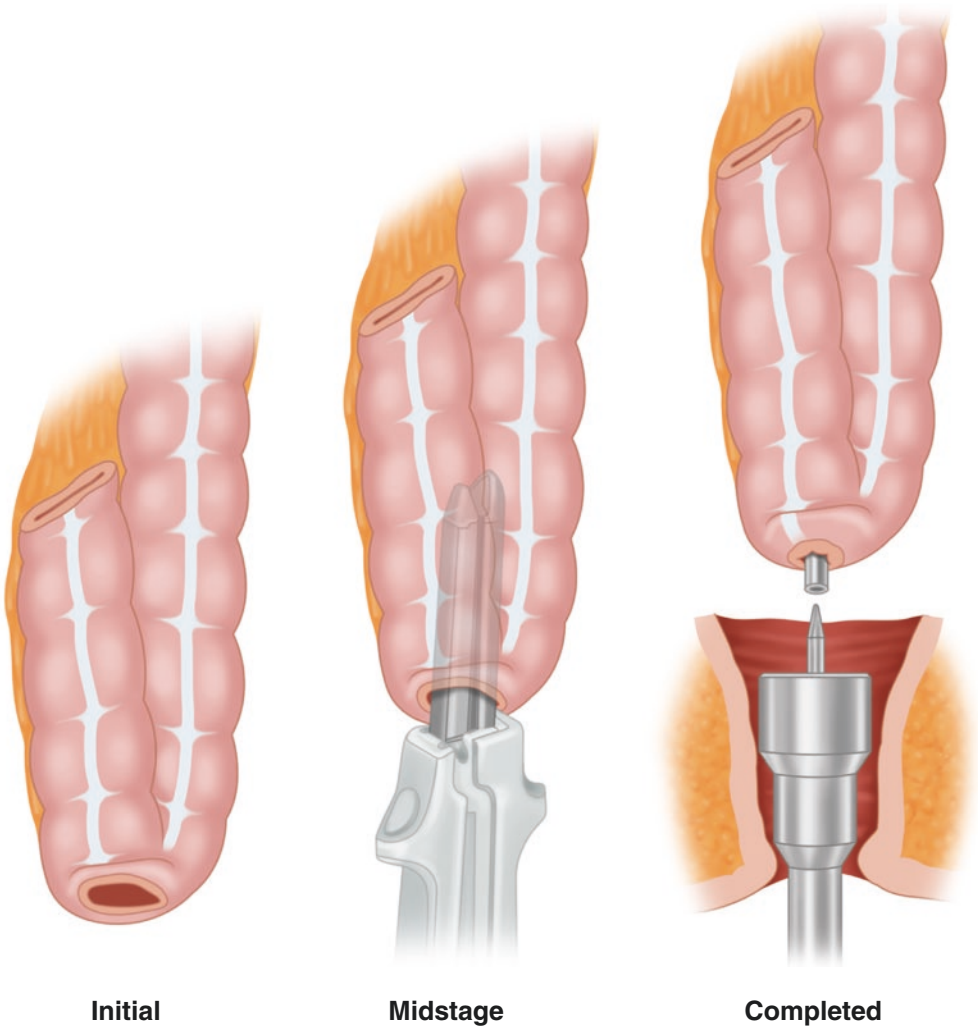

Fig. 29.5 The colon is folded onto itself and a J-pouch is created

able for this reconstruction. These parameters should be carefully assessed prior to construction of the pouch.

End-to-Side Anastomoses

In many cases, particularly in the narrow pelvis of males, or in obese patients, a colonic J-pouch is too bulky to be placed into pelvis. Another option for reconstruction is an end-to-side anastomosis which is a variant of a "Baker" reconstruction. A 3 cm side segment seems to be the most reasonable configuration. Several studies and reviews have found the Baker anastomosis is associated with function similar to that of a colonic J-Pouch [29].

Transverse Coloplasty

Transverse coloplasty is a technique to create a neorectum that avoided the need to pass the double thickness of colon with its mesentery into the pelvis, as is required for J-pouch anastomosis. An 8–10 cm incision is made along the longitudinal axis of the colon terminating about 5 cm proximal to the distal end. The incision is then closed transversely, creating a small pouch. Coloplasty was performed more frequently in the past, although recently its use has declined, as several studies have shown higher likelihood of leak and no difference in function when compared to other neorectal configurations [30–32].

Laparoscopic Low Anterior Resection

There are a variety of techniques that have been described to successfully accomplish laparoscopic low anterior resection (see Chap. 36). What follows is a description of the authors' preferred method. The patient is placed in the low lithotomy or split-leg position with both arms tucked. The knees should be no higher than the shoulders so that there is no potential for interference with the instruments during splenic flexure mobilization. The perineal area and buttocks should overhang the edge of the bed so that access to the perineum and anus are not obstructed and so the stapler can be easily angulated upward or downward. The chest is secured to the bed to allow for the extreme Trendelenburg and airplaning required.

After achieving pneumoperitoneum with a Veress needle in the left upper quadrant, the Veress needle is replaced with a 5 mm port. Diagnostic laparoscopy is then performed to assure that there is no evidence of peritoneal carcinomatosis, liver metastasis, or other factors that may alter the operative plan. After this, the following ports are placed under direct laparoscopic visualization: a supraumbilical 12 mm trocar, a 5 mm left iliac fossa trocar, a 5 mm right upper-quadrant trocar, and a 12 mm right iliac fossa trocar. The 5 mm camera is usually upsized to a 10 mm, 30° laparoscope. The 10 mm laparoscope typically provides a better-quality image and requires fewer camera exchanges (Fig. 29.6).

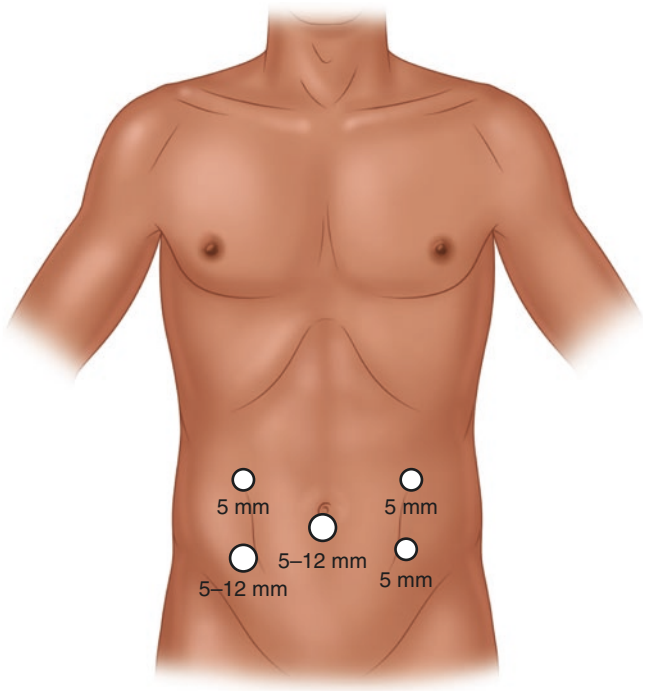

Fig. 29.6 Port placement for a laparoscopic low anterior resection

The sigmoid colon is placed on tension such that the IMA is clearly identified at its origin. We typically approach the mesentery from medial to lateral. The electrocautery is used to incise the investing layer at the root of the rectosigmoid mesentery. The mesentery is scored at a point just above the sacral promontory but beneath the superior rectal artery, and the incision is taken toward the root of the IMA. The loose areolar plane between the underside of the sigmoid mesentery and the retroperitoneum is identified, and the dissection is taken laterally with the goal of identifying the left ureter and the left gonadal vein. The origin of the IMA is skeletonized, and the ureter is once again identified before typically performing a high ligation of the IMA (see above). The inferior mesenteric vein (IMV) is then ligated proximal to any branch points. The high ligation of the IMA and the IMV is necessary not only from and oncologic perspective but also to assure that the left colon conduit can reach easily into the pelvis for a tension-free anastomosis. (See discussion above.)

The dissection is then continued underneath the sigmoid and the left colon mesentery until the left abdominal side wall is encountered. The left colon is then rotated and flipped medially, and the white line of Toldt (now purple in color) is easily taken with scissors or energy device.

The next task is to perform a complete laparoscopic mobilization of the splenic flexure. The lesser sac is entered, and

the splenic flexure is mobilized from the transverse colon side and from the left gutter. Attention is then turned toward the rectal dissection.

The assistant retracts the rectosigmoid junction of the colon toward the abdominal wall and slightly leftward. The operating surgeon retracts the rectum upward and toward the pubic symphysis to accentuate the plane between the presacral fascia and the fascia propria of the rectum; this plane is referred to as "the holy plane." Posteriorly the left and right hypogastric nerves are identified and kept out of harm's way. The loose areolar fibers are divided posteriorly identically in the fashion of a total mesorectal excision, past the tip of the coccyx, dividing Waldeyer's fascia until the superior portion of the levators are encountered. The lateral stalks are taken in the same fashion down to the pelvic floor. Anteriorly, the plane between the rectum and the seminal vesicles/prostate or vagina must be carefully dissected so as not to injure the prostate/vagina or nerves that lie adjacent to Denonvilliers' fascia. The rectum must be freed up anteriorly down to the pelvic floor so that a stapler can be used to transect the rectum flush with the levators. The rectum is pulled upward out of the pelvis and leftward, and then a laparoscopic bowel stapler is brought through the right iliac fossa 12 mm trocar and articulated so that the angle between the staple line and rectum is as close to 90° as possible. It is unlikely the pelvis will be wide enough to accommodate a 60 mm stapler; therefore, a 45 mm or 30 mm long stapler is usually the stapler of choice. The stapler is advanced across the rectum as far as possible and the stapler is fired. It is rare that the rectum can be completely transected with one stapler fire. However, minimizing the number of fires will minimize the number of crossing staple lines and subsequently the likelihood of a staple line leak. Once the rectum is transected, the specimen is exteriorized through any one of a number of incisions: periumbilical, left lower quadrant, Pfannenstiel, or from the site that will be used for the ileostomy/colostomy. After extracting the specimen, the colon is divided proximally at the sigmoid/descending colon junction. Usually if the exteriorized left colon can reach the pubic symphysis, there is sufficient length for a low colorectal anastomosis.

A purse-string suture is placed at the open end of the colon conduit and stapler anvil inserted. The colon is reduced back into the abdomen and the abdomen is reinsufflated. The colon is grasped, and care is taken to assure that the colon and mesentery are not twisted. An anvil grasper is used to draw the anvil into the pelvis. The assistant then passes the stapler transanally and engages it with the anvil under direct laparoscopic visualization. In female patients, as the stapler is closed, care must be taken to assure the posterior wall of the vagina is not incorporated into the staple line. After the stapler is closed, a vaginal exam is helpful in assuring that the posterior wall of the vagina moves freely and is not in any way tethered. The stapler is then fired and the anastomotic donuts are examined for completeness. Endoscopic inspection of the anastomosis and pneumatic leak test should be performed as described above. Construction of temporary proximal fecal diversion (loop ileostomy or colostomy) should be strongly considered, as described above.

Robotic Low Anterior Resection

The robotic surgery platform has rapidly become many surgeons' preferred approach for minimally invasive proctectomy. The ergonomics, magnification, 3D visualization, and wristed instrumentation make robotic surgery an attractive alternative to traditional laparoscopy. Most surgeons have evolved to a single-dock technique for LAR, particularly in light of the versatility of the da Vinci® Xi™ system. While there are innumerable port site configurations, below is a fairly simple single-dock port setup.

Pneumoinsufflation is established by placement of a right upper-quadrant optical trocar which then subsequently serves as the "assistant port." The bed is then placed in about 30° Trendelenburg and approximately 8° right side down. A diagonal line is drawn from the right anterior superior iliac spine (ASIS) through the umbilicus and to the left subcostal margin. The first robot port is placed along this line midway between left ASIS and the umbilicus. The next port is placed to the left of the prior port (along the same diagonal line) approximately 8 cm away with the final two ports, each being placed 8 cm to the left of the prior port along the same line. The first robot port will be the stapling port and the second will serve as the camera port. The robot will be brought in from the patient's left side.

The dissection in a robotic LAR is fairly identical to the technique for standard laparoscopy described earlier. After transection of the rectum, the specimen can be exteriorized after the robot is undocked. The remainder of the case, including anastomosis can be completed using standard laparoscopy.

Transanal Total Mesorectal Excision

Transanal total mesorectal excision (taTME) is a more novel technique that attempts to facilitate the most troublesome part of a minimally invasive proctectomy, namely, the final 3–6 cm of distal rectal dissection and distal rectal transection. The taTME is described as a two-team simultaneous approach, wherein one team works laparoscopically from the abdomen to mobilize the colon and splenic flexure, ligate the IMA and IMV, and mobilize the upper half of the rectum.

The other team works via a transanal approach by first starting with a circumferential full-thickness transection beginning in the intersphincteric plane and proceeding in a

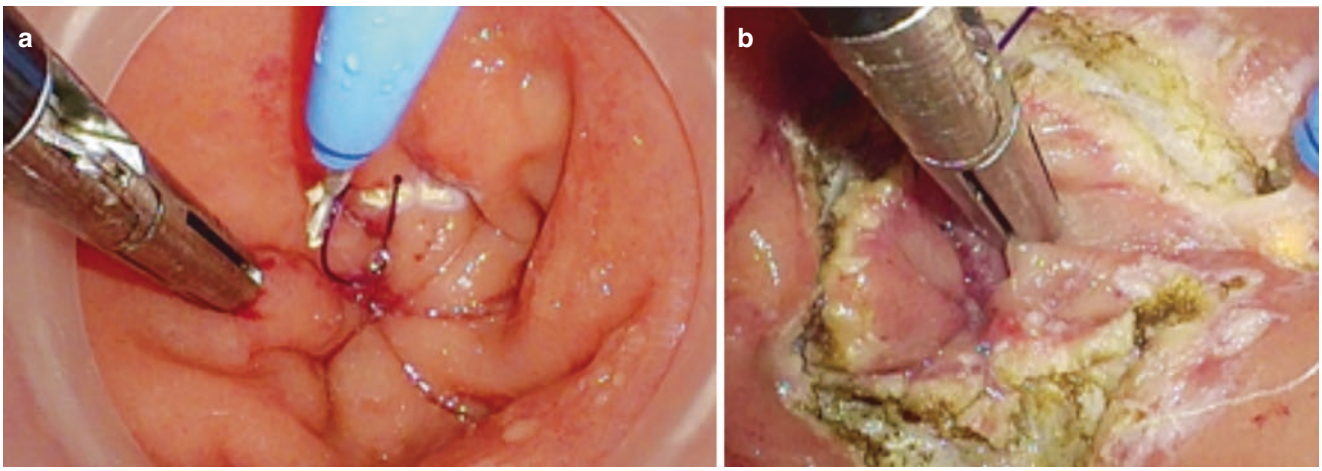

Fig. 29.7 Transanal anal view of taTME. (**a**) Rectal purse-string closure. (**b**) Full-thickness circumferential transection. (Reused with permission [33]. Copyright © 2007 Elsevier)

cephalad direction up to the top of the anorectal ring (Fig. 29.7). Once this achieved, a rectal pneumoinsufflation device is placed in the rectum, and the rectum is insufflated with CO_2. The team then proceeds to perform the distal half of the proctectomy from an anal approach via what is essentially transanal, single-port laparoscopy in a "down-to-up" approach (Fig. 29.8) [33]. When the two teams meet, the fully mobilized rectum is then pulled out of the transanal site and transected. A handsewn or stapled low colorectal/coloanal anastomosis is then performed, typically with diverting loop ileostomy/colostomy.

Proponents of taTME claim that the technique allows for a better distal margin and greater lymph node harvest; however, a meta-analysis of 11 studies encompassing 757 patients could not demonstrate any difference in cancer-/pathology-related outcomes and short-term complications with taTME in comparison with traditional laparoscopic LAR [34].

Results from the International taTME registry seem to indicate that there are more intraoperative adverse events than would be expected for this type of procedure. Many of these events involve serious complications such as bleeding or urethral transection. The taTME is a novel technique with a fairly steep learning curve whose potential benefits have not been clearly demonstrated. Further data needs to mature before the true utility and transferability of this technique can be evaluated [35–37].

Abdominoperineal Resection

The subset of rectal cancer patients who undergo abdominoperineal resection (APR) is decreasing over time, most likely because many patients with ultralow tumors that do not invade the external sphincter muscle, or pelvic floor are now undergoing restorative proctectomy with low colorectal/colo-

anal anastomosis rather than APR. However, patients who have a tumor invading the external sphincter muscle or pelvic floor would be most appropriately treated by APR. Incontinence alone is not an indication for APR, as there is no need to subject the patient to excision of their pelvic floor unless invaded by tumor. Incontinent patients with rectal cancer may be best served by Hartmann resection or intersphincteric proctectomy with preservation of the pelvic floor musculature if blowout of a short rectal stump is of concern.

The abdominal approach to APR is similar to that for restorative proctectomy, using either open, laparoscopic, or robotic techniques described above. The major difference is that the splenic flexure does not need to be mobilized routinely for APR. It is the authors' preference to perform the abdominal portion of the procedure, extending the dissection to the pelvic floor, and then to create the colostomy, close the abdomen, and place the patient in the prone position for the perineal portion of the dissection. Although some surgeons complete the dissection in the lithotomy position, we feel that the exposure afforded by the prone position facilitates accurate dissection and is our favored approach.

Before placing the patient prone, a large cylindrical bump or pillow should be placed on the table to elevate patient's pelvis and buttocks and create flexion at the hip. After the patient is placed prone on the table, the buttocks are taped widely apart, and the perineum is shaved. The anus is sewn shut to prevent fecal soilage. The perineal area is then prepped and draped. The important landmarks for the perineal portion of the case are the tip of the coccyx, the ischial tuberosities, and the midpoint of the perineum. These should be marked prior to incision. An elliptical incision around the anus is made from the coccyx to the midpoint of the perineum, outside of the anal sphincter muscle. The dissection is initiated posteriorly at the level of the coccyx, and the incision is deepened through the anococcygeal ligament and then onto the anterior surface of the coccyx until the pelvis is entered. This is the safest and easiest place enter the pelvis from the perineum. The dissection is then taken posterolaterally through the levators and then laterally from ischial tuberosity to ischial tuberosity [38].

Once the posterior two-thirds of the anus and rectum (including the levators) are liberated, then the specimen can be everted through the perineum, leaving only the distal anterior portion of the rectum and anus still attached

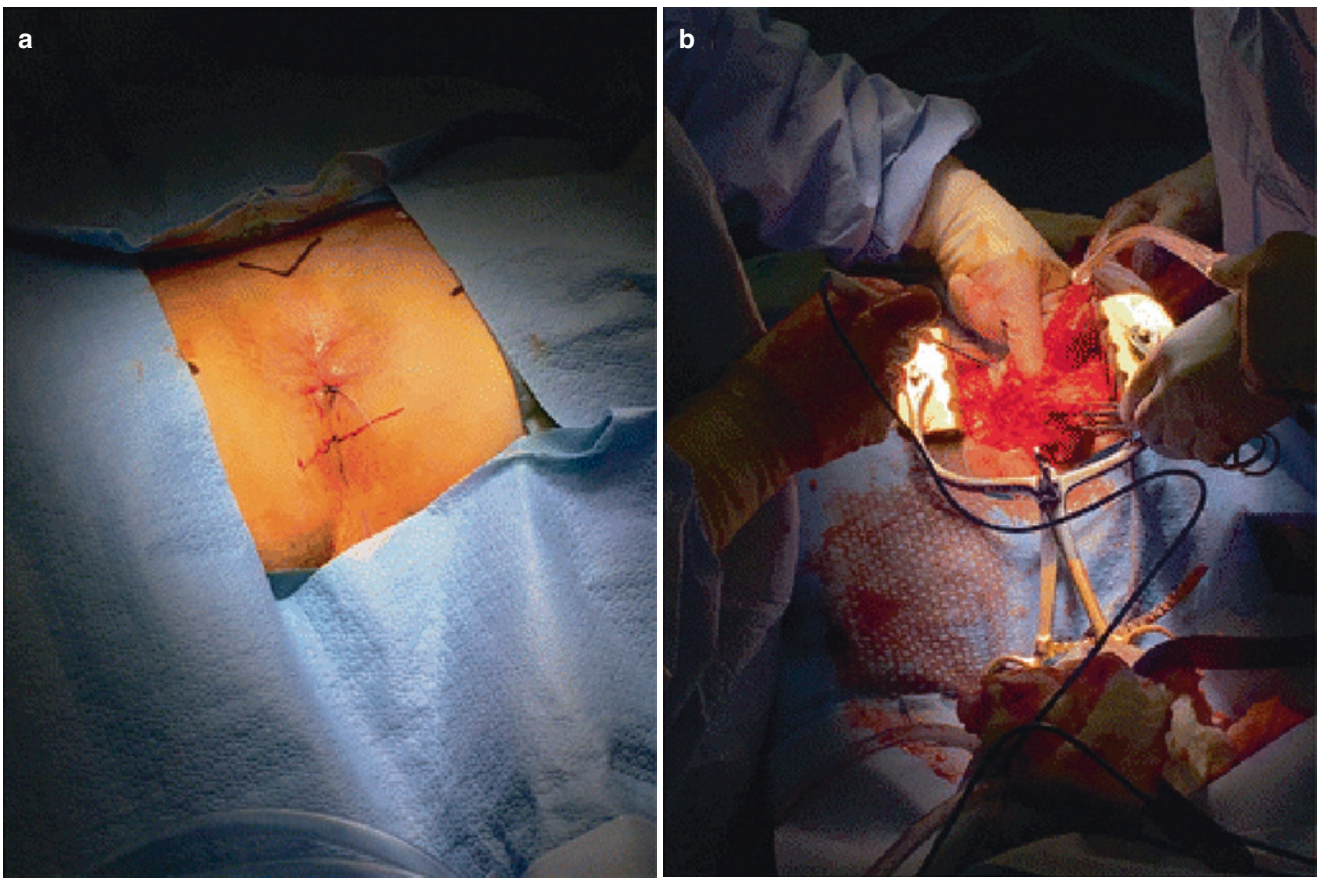

Fig. 29.9 Perineal dissection. (**a**) The anus is sutured closed. The coccyx, perineal body, and ischia are identified. (**b**) The specimen is exteriorized thorough the posterior opening with lateral division of the levators. (Reused with permission [38]. Copyright © 2018 Springer Nature)

(Fig. 29.9). The anterior dissection is performed last as it is typically the most challenging. There are multiple possible pitfalls including injury to the membranous urethra/prostate, inadvertent vaginotomy, or specimen perforation.

Once the specimen is removed, the perineum can be closed primarily in layers or using any number of adjunctive tissue transfer technique described in the next section (Fig. 29.9).

The extralevator abdominoperineal excision (ELAPE) has been described as an alternate method to decrease the likelihood of a positive circumferential resection margin and specimen perforation. This ELAPE or cylindrical APR is meant to be a much wider excision of the pelvic floor and is meant to avoid "the waisting" of the specimen that usually happens when dissecting the distal rectum to the pelvic floor during the abdominal portion. The dissection stops at a much higher point during the abdominal portion, and the cylindrical APR is completed from the perineal portion to create a specimen that is more uniform with less narrowing at the pelvic floor (Fig. 29.10). However, in one of the largest nationwide database studies examining the short-term oncologic outcomes of ELAPE versus traditional APR including 954 patients, there was found to be no benefit to ELAPE [39]. In patients with non-circumferential tumors, there would seem to be no obvious benefit to the wide resection of the pelvic floor contralateral to the tumor. This should be considered during operative planning, as pelvic floor defects after ELAPE can be substantial, most requiring tissue transfer for closure.

Reconstruction After APR

The perineal wound is the most common source of morbidity after APR, with wound complication rates estimated to be as high as 66% with primary closure. Many perineal wound complications are not only attributable to the wound being located in a weight-bearing area, but in addition, the overwhelming majority of these patients have received neoadjuvant radiotherapy to the pelvis. There are many reconstructive options available such as a gracilis flap, vertical rectus myocutaneous muscle (VRAM) flap, anterolateral thigh flap, and gluteal-based fasciocutaneous flaps. Some flaps may be harvested with the associated skin pedicle to reconstruct the posterior vagina after proctectomy with en bloc vaginectomy. Many of the flaps themselves often result in donor site complications or morbidity. For example, a VRAM flap very often results in an abdominal wall hernia but may provide the greatest tissue mass to the pelvis. When considering the use of flap coverage for a perineal wound, consideration should be given to the size of the defect, use of preoperative external beam radiotherapy, and the likelihood and impact of donor site morbidity [40–45].

A well-vascularized omental pedicle flap placed into the pelvis can serve as a very useful adjunct to a primary closure of the perineum, especially in cases of uncertain radial margins where postoperative boost dose radiotherapy is being considered. Filling the pelvis with omentum may help to avoid small bowel toxicity due to radiotherapy. Placement of fiducials guides radiation delivery in these cases. Closed-suction drainage of the pelvis can also prevent excessive fluid buildup which could affect healing of a perineal wound [46–48].

Low Anterior Resection Syndrome

As oncologic outcomes have improved following close adherence to the principles elucidated above, there has been increased focus on function and quality of life following rectal cancer treatment, particularly as it relates to bowel function [49]. There has been persistent controversy as to whether patients with distal rectal cancer have a better quality of life with a restorative or non-restorative proctectomy [50, 51]. There is almost no patient that when initially diagnosed with rectal cancer isn't concerned that they may need a permanent stoma. Yet, it is virtually impossible for the patient to truly comprehend the potential for poor functional outcome that may occur following restorative operations, particularly those with low or ultralow anastomoses (coloanal or intersphincteric), especially following radiotherapy. The patient's

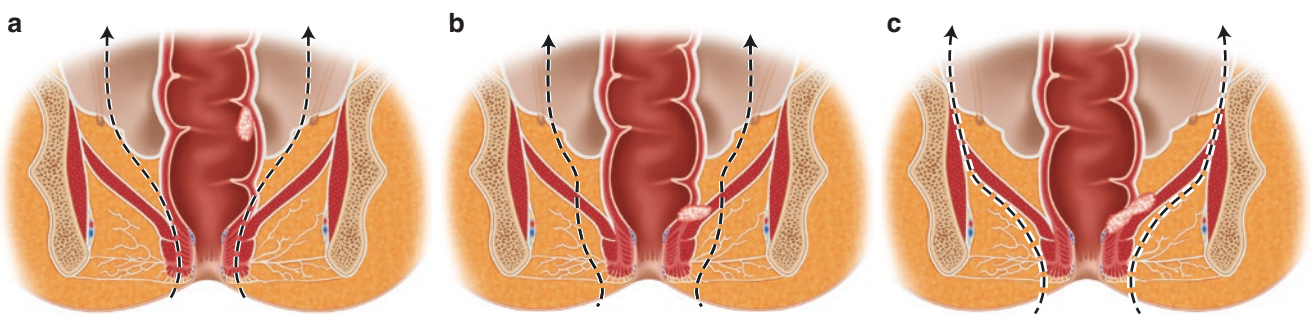

Fig. 29.10 Planes for APR resection. (**a**) Intersphincteric. (**b**) Extrasphincteric. (**c**) Extralevator

desire to avoid a stoma and the surgeons desire to accomplish that goal lead most to choose a restorative operation if it is an option, as opposed to a permanent colostomy.

Studies have shown that when less than 4 cm of native rectum is left in situ following low anterior resection, there is loss of rectal reservoir function and significant alterations in bowel function [52]. As noted previously, surgeons have employed several types of neorectal reservoir configurations including colonic J-pouches, coloplasty pouches, ileocecal reservoirs, and side-to-end anastomoses in an effort to mitigate the effect of rectal loss on bowel function [53–55]. It remains unclear which reconstructive technique offers the best functional outcomes; however, coloplasty pouches have all but been abandoned, as have ileocecal reservoirs, in favor of colonic J-pouches and side-to-end anastomoses. Several recent comparisons of colonic J-pouches and side-to-end anastomoses showed similar long-term function between the two methods with slightly better short-term function (up to 6 months) with a colonic J-pouch [56, 57].

The recognition that patients suffered substantial alterations in bowel function following restorative proctectomy dating back to at least the 1980s was termed "anterior resection syndrome" and described as "disordered bowel function after rectal resection, leading to a detriment in quality of life" [58]. Anterior resection syndrome typically includes some degree of fecal incontinence, incomplete evacuations, clustering of bowel movements, straining at bowel movements, and discomfort associated with bowel movements. Initially thought to be transient and to resolve over time, it is now known that these symptoms may persist indefinitely. Although improvement does occur, it tends to plateau at about 2 years following resection. In addition to loss of rectal reservoir, other potential etiologies for this syndrome include anal sphincter damage and dysfunction, sensory neural dysfunction in the neorectum, and disordered motility of the neorectum.

Recently a Delphi method of consensus among multiple societies considering surgeon, patient, and other healthcare workers' perspectives was published, broadening and better defining the symptoms and consequences of what is now termed "low anterior resection syndrome" (LARS) [59]. In this consensus, eight symptoms and eight consequences were agreed upon, and any given patient must have at least one of each to meet the new definition of having LARS. The symptoms include variable and unpredictable bowel function, emptying difficulties, altered stool consistency, urgency, incontinence, increased stool frequency, repeated painful bowel movements, and soiling. The consequences include toilet dependence, preoccupation with bowel function, dissatisfaction with bowel habits, strategies and compromises to manage symptoms, and adverse impact on mental and emotional well-being, social and daily activities, relationships and intimacy, and roles, commitments, and responsibilities. Having at least once symptom and one consequence would qualify a patient to meet the criteria for having LARS.

The severity of LARS can be determined in part by utilizing a scoring instrument such as the LARS score, initially described in 2012 [60]. The LARS score uses five questions/items (incontinence for flatus, incontinence for liquid stools, clustering, frequency, and urgency) that are scored to come up with a composite score from 0 to 42. A score of 0–20 is not consistent with LARS; a score of 21–29 equates with "minor LARS"; and a score of 30–42 equates with "major LARS." Other scoring systems such as the Bowel Function Instrument (BFI), created by Memorial Sloan Kettering Cancer Center, have not been widely adopted, despite it being more comprehensive than the LARS score [61].

Once diagnosed, a variety of treatment options are available, ranging from simple medical therapy aimed at symptom improvement to redo anastomoses adding some form of rectal reservoir. Some authors have proposed that there are two distinct sets of symptoms and propose classifying patients to guide therapy. One group has incontinence, frequency, and urgency, while the other group has constipation and incomplete evacuation [62]. However, some patients have a combination of symptoms.

Medical therapy should begin with dietary modification, instructing patients to take between 25 and 35 g of dietary fiber daily. This should be accompanied by a fluid intake of 6–8 glasses of a non-caffeinated beverage throughout the day. Depending on the stool consistency, using stool softeners and/or laxatives may also be added to this regime. Dietary consultation for more specific inclusions and exclusions within one's diet may further improve bowel function. If basic therapy should fail, then escalation to other treatments should be considered.

Biofeedback therapy or pelvic floor physical therapy may improve fecal incontinence scores, number of bowel movements, and anal manometry results [63]. Sacral nerve stimulation (SNS) has been reported in seven studies in LARS included as part of a systemic review [64]. SNS had a reported "success rate" of 74%, a result that is comparable to that seen with SNS for fecal incontinence from any cause. Overall, 32 of 34 patients having permanent implantation experienced clinical improvement, and two failed to respond to treatment. Other options include 5HT3-receptor antagonists, transanal lavage, probiotics, and a stoma.

Multivisceral or Extended Resections

Although the need for multivisceral or extended resections occurs more commonly when one is contemplating the surgical management of recurrent rectal cancer, there are times

where these resections need to be considered at the time of initial diagnosis and treatment of primary rectal tumors. Approximately 10% of primary rectal cancers invade other organs [65]. Due to only a few organs or structures in proximity of the rectum, a limited number of multivisceral or extended resections of adjacent organs or structures are performed. Anteriorly the vagina, uterus, prostate, seminal vesicles, and bladder may be involved by direct extension of the cancer. Laterally the ureters and iliac vessels may be involved in upper rectal cancers. Anything more laterally involved and within the pelvic sidewall is usually deemed unresectable. Posteriorly the coccyx or sacrum may be involved. In a single-institution series reporting on 61 patients with locally advanced rectal cancer, multivisceral resection most often involved urogenital structures anteriorly with bladder, prostate, uterus, ovaries, and vagina being the most commonly resected en bloc [66]. This should not be surprising, as tissues anterior to the rectum are soft viscera, while posterolaterally there is bone and pelvic sidewall.

In women, involvement of the uterus, cervix, and/or vagina can typically be managed by en bloc resection of those organs, which usually includes the ovaries and fallopian tubes. Depending on the amount of vagina resected and the size of the residual defect, primary closure vs some form of plastic surgical flap reconstruction may be required. In men, anterior extension of the dissection can be more challenging. En bloc resection of the seminal vesicles and/or prostate is possible, but it is technically more straightforward, with greater likelihood of achieving an R0 resection if pelvic exenteration (proctectomy with en bloc cystoprostatectomy with urinary conduit) is performed. It should be noted that if pelvic exenteration is performed, creation of a colonic urinary conduit is usually straightforward and has the advantage of avoiding intestinal anastomosis, as compared to ileal conduit. Isolated distal ureteral involvement can be managed by en bloc resection and primary ureteral reimplantation into the bladder. If the tumor extends posteriorly to the bony pelvis, more extensive preoperative planning is usually necessary. En bloc coccygectomy is relatively straightforward, but sacrectomy is more complex. Multispecialty planning and operative involvement by an orthopedic oncologist and/or neurosurgeon are paramount to achieving a safe resection (see Chap. 31). Lateral sidewall involvement is the most difficult and often does not allow for an R0 resection. Consideration for intraoperative radiation therapy should be considered in these cases if a resection is attempted in those who appear to have resectable disease [67].

Locally advanced rectal cancers invading other structures are staged as T4b. Patients with T4b rectal cancers often require surgery that has been described as "primary rectal cancer beyond TME planes" (PRCbTME) by the Beyond the Total Mesorectal Excision Collaborative and require surgery outside of the standard planes to achieve an R0 resection [68]. These planes are not well understood by most colorectal surgeons, unless they routinely perform resection of T4b or recurrent rectal cancers. The typical mesorectal plan or "holy plane" described by Heald that all are familiar with is not the plane at least in the area of the en bloc resection that is utilized [69]. Becoming familiar with planes of "extended resections" which would be the plane outside the mesorectal plane lateral to the ureters and the deeper plane exposing the iliac vessels and lateral pelvic nerves and lateral lymph nodes is important so that en bloc resections can be safely and properly performed.

Typically if any of these structures are involved or locally invaded at the time of initial diagnosis of rectal cancer and confirmed by imaging including MRI of the pelvis, there should be strong consideration for some form of neoadjuvant therapy to improve the chance of resectability and increase the chance of an R0 resection. The ability to achieve an R0 resection is paramount to being able to obtain long-term, disease-free survival. A systematic review of multivisceral resections reported a 5-year overall survival of 53% which was higher than resections for recurrent rectal cancers at 20% [70].

Neoadjuvant chemoradiation therapy with long-course radiation, 5400 Gy combined with intravenous 5-fluorouracil or oral capecitabine allows for excellent tumor regression. Regression can lead to higher rates of R0 resection, make borderline resectable tumors resectable, and result in tumor downstaging that may improve overall outcomes. Multiple scoring systems are available that assess tumor response either histologically or radiographically following neoadjuvant chemoradiation therapy. Most commonly some form of tumor regression grade (TRG) is utilized. Regardless of which system is used, there is a positive correlation between TRG grade and outcomes such as local recurrence [71]. Currently the concept of "total neoadjuvant therapy" (TNT) is gaining popularity (See Chap. 26). TNT delivers all adjuvant therapy prior to surgery, typically delivered as short-course radiotherapy or long-course chemoradiotherapy followed by multidrug cytotoxic chemotherapy. This type of regimen is better tolerated, and chemotherapy completion rates are higher than with standard split regimes, and further downstaging and regression can occur [72]. TNT may be considered for any patient with locally advanced primary rectal cancer.

As with all rectal cancer management, presentation at a multidisciplinary tumor board is beneficial, especially when patients require multivisceral or extended resections. Review of treatment planning with colleagues in the fields of medical oncology, radiation oncology, radiology and pathology, as well as other surgical specialists in urology, gynecology, orthopedics or neurosurgery, and plastic surgery is critical to achieving good outcomes [73, 74].

Oncologic Outcomes

As discussed in the introduction, four decades ago the diagnosis of rectal cancer portended an abysmal course with recurrence rates as high as 30% and poor functional outcomes. Fast forward to present day where there is the routine use of chemotherapy and radiation, the routine use of the TME technique for proctectomy and multidisciplinary evaluation. This has resulted in vast improvement in outcomes for locally advanced rectal cancer. The local recurrence rate worldwide is now estimated to be between 4% and 8%. An analysis of 372,130 patients utilizing the SEER database comparing survival of locally advanced rectal cancer patients versus colon cancer patients found that, stage for stage, survival of locally advanced rectal cancer patients was equivalent, if not superior to that of colon cancer patients [75].

The surgical approaches to the treatment of locally advanced rectal cancer over the past decade have increasingly skewed toward minimally invasive surgical approaches. It is concerning that two large randomized controlled trials, ACOSOG Z6051 in the United States and the ALaCaRT trial in Australia and New Zealand failed to demonstrate noninferiority of the laparoscopic approach using a composite assessment measure of successful resection (radial margin negative, distal margin negative, and mesorectal grade complete or nearly complete), all of which have been demonstrated to have prognostic significance in other trials [76, 77]. It is reassuring, however, to note that despite the concerns regarding the quality of the mesorectal dissection in the laparoscopic groups, there have been no demonstrable differences in survival. Review of non-randomized data from the National Cancer Database (NCDB) including 18,765 patients demonstrated equivalence of the MIS and open procedures [78]. Long-term survival outcomes of ACOSOG Z6051, ALaCaRT, and NCDB have demonstrated equivalence between the two techniques [79–85].

Multidisciplinary Rectal Cancer Care

The regionalization of rectal cancer care in Europe and Asia has created national programs that espouse data-driven approaches to rectal cancer care. The OSTRICH consortium queried the NCDB to assess variations across the United States in the appropriate delivery of chemoradiotherapy for patients with LARC. Adherence was highest in high-volume centers in comparison to community centers (78% vs 69%, OR = 1.46, $p < 0.001$) [85]. This same group also found that the rate of circumferential margin positivity was 17.2%, which is double the rate seen in Europe [86]. The Commission on Cancer's National Accreditation Program for Rectal Cancer (NAPRC) will address many of these issues through creating uniformity in the process measures related to rectal cancer care, such as mandatory MRI staging of all new rectal cancers and requiring the discussion of all patients with newly diagnosed rectal tumors at a multispecialty tumor board [87].

Conclusion

The oncologic and functional outcomes following treatment of curable rectal cancer are overwhelmingly dependent on the skill of the surgeon and his/her familiarity with the appropriate conduct of proctectomy using the technique of total mesorectal excision. Strict adherence to these principles not only minimizes the risk of recurrence but also maximizes the likelihood of nerve preservation. Each surgeon's comfort level with open and minimally invasive approaches needs to be understood so that cancer-related outcomes are not jeopardized in the effort to use varying technologies or approaches. Lastly, in absence of the ability to regionalize rectal cancer care in the United States, formal process-oriented measures such as those described by the NAPRC are some important first steps to improving outcomes and care for curable locally advanced rectal cancer.

Colorectal Cancer: Postoperative Adjuvant Therapy and Surveillance

30

David A. Kleiman and David W. Larson

Key Concepts

- All patients with resected stage III, and most with high-risk stage II, colon cancer should be considered for adjuvant chemotherapy for 3–6 months.
- Adjuvant therapy for rectal cancer is more complex. Multiple options exist with regard to the order and timing of multimodal therapy.
- Patients with clinical stage II and III rectal cancer should be considered for preoperative radiotherapy and systemic chemotherapy for a total of 4–6 months of treatment.
- Radiotherapy used as an adjunct to proctectomy for rectal cancer is more effective and less toxic if it is given preoperatively, as compared to postoperative administration. Postoperative radiotherapy should be avoided if possible.
- Intensive postoperative surveillance has not been proven to be associated with improved survival, as compared to less intense surveillance or no surveillance.
- Surveillance is only indicated in patients who wish to undergo treatment for recurrent tumor, *and* who are candidates for liver, lung, and/or intestinal resection, and/or multidrug chemotherapy. Patient desires, age, and comorbidities should be considered prior to initiating a surveillance plan.
- Detection of asymptomatic liver metastasis and local regional recurrence are more likely to be amenable to curative-intent salvage resection than symptomatic recurrences, although it is unclear whether this strategy improves survival when compared with no surveillance.
- Use of carcinoembryonic antigen (CEA) testing and computed tomography (CT) scans is associated with increased detection of asymptomatic recurrence. However, there remains no evidence to support the use of other laboratory or image-guided testing in routine surveillance.
- Risk of locoregional recurrence is higher in patients with advanced rectal cancer compared to colon cancer. Risk factors include the omission of chemoradiotherapy, positive circumferential margin, and T4 and N2 histology.
- Surveillance after resection of stage I colorectal cancer remains controversial. Typically, colonoscopy to look for metachronous neoplasia is the only test recommended.

Introduction

Colorectal cancer is the fourth most common cancer in the United States among men and women and is the second leading cause of cancer-related death [1]. Although surgery is the mainstay of treatment, recurrence following curative-intent surgery for stage II and III colorectal cancer can be as high as 40%. Patients at highest risk of recurrence (high-risk stage II and all stage III) should be considered for adjuvant therapy. Treatment of recurrent disease may prolong survival. Therefore, otherwise healthy colorectal cancer patients with reasonable life expectancy should be considered for regular postoperative surveillance. This chapter will review the role of adjuvant therapy following curative-intent resection of colorectal cancer and will discuss surveillance strategies.

First, we would like to offer a few general comments regarding the concept of cancer "recurrence." Although commonly referred to as such, there is no evidence that true "recurrence" ever occurs. Rather, the malignant cells responsible for the "recurrence" were present at the time of initial treatment, but of such small volume as to render them undetectable by current technology. Thus, it is more proper to refer to tumor detected subsequent to primary therapy as either local or distant "failure" of treatment. Throughout this chapter, the term "recurrence" is utilized, as it has become embedded in the common lexicon. However, the treating physician should realize the limitations of the term.

Second, our ability to detect distant disease, or locally recurrent disease, depends upon the sensitivity and specificity of the diagnostic testing modalities of the time. As sensitivity of tests improves, and more patients undergo more frequent testing, results of non-randomized clinical trials of surveillance and/or treatment will be subject to both stage migration and lead-time bias. This is especially true when comparing more recent results with historical controls.

Colon Cancer

Stage III Colon Cancer

Patients undergoing curative-intent resection of stage III colon cancer should be considered for adjuvant chemotherapy, as it has been consistently shown to decrease recurrence and increase survival compared to surgery alone [2]. The overall 5-year survival following surgery alone for stage III colon cancer is 40–60%, whereas modern chemotherapy regimens have increased the expected overall survival to 70–80% [3, 4].

The benefits of adjuvant chemotherapy for stage III colon cancer have been demonstrated since 1990, when Moertel et al. reported a 41% relative reduction in cancer recurrence and a 33% relative improvement in overall survival with 12 months of postoperative adjuvant fluorouracil and levamisole [5]. The International Multicentre Pooled Analysis of Colon Cancer Trials (IMPACT) investigators pooled data from three prospective randomized controlled trials comparing surgery alone to surgery followed by six cycles of 5-fluorouracil (5-FU)/leucovorin. This demonstrated an increase in 3-year overall survival from 62% to 71% with <3% incidence of WHO grade 4 toxicities [6]. Several subsequent trials then demonstrated that 5-FU combined with leucovorin was superior to levamisole and that 6 months of adjuvant therapy achieved similar survival benefits compared to 12 months [7–9]. Thus, 6 months of adjuvant 5-FU plus leucovorin became the accepted standard of care for stage III colon cancer from the early 1990s until the late 2000s.

Oxaliplatin was introduced as adjuvant chemotherapy for colon cancer in 2004. It inhibits DNA synthesis by forming inter- and intra-strand DNA cross-links, preventing transcription and replication. Several studies demonstrated the benefits of oxaliplatin when added to a regimen of 5-FU and leucovorin [10, 11]. In the landmark MOSAIC trial, 2246 patients with stage II or III colon cancer were randomly assigned to receive either 5-FU and leucovorin (LV5FU2) or 5-FU and leucovorin plus oxaliplatin (FOLFOX4) for 6 months following curative surgery [3]. When comparing FOLFOX4 to LV5FU2 in patients with stage III disease, a 5-year disease-free survival was 73% versus 67% ($p = 0.003$), and a 6-year overall survival was 73% versus 69% ($p = 0.023$). No differences were seen in the stage II population.

Capecitabine is an oral 5-FU prolog that works via the same mechanism as 5-FU. Its oral dosing makes it an appealing alternative to infusional 5-FU and leucovorin. Oral capecitabine alone was shown to be at least equivalent to infusional 5-FU and leucovorin with regard to disease-free survival and is associated with fewer adverse effects [12]. Adjuvant capecitabine combined with oxaliplatin (CAPOX) has been demonstrated to improve 3-year disease-free survival following curative-intent resection in stage III colon cancer patients from 67% to 71% when compared to 5-FU and leucovorin [13]. Given that the relative improvement in survival was similar with both CAPOX and FOLFOX in the adjuvant setting, CAPOX is considered an equivalent alternative (although with slightly different durations of therapy) to FOLFOX for patients with stage III colon cancer.

The duration of adjuvant chemotherapy for stage III colon cancer had traditionally been 6 months for all patients. However, toxicity of oxaliplatin (particularly peripheral neuropathy) becomes more severe (and potentially permanent) with longer courses of treatment [14]. In the International Duration Evaluation of Adjuvant Therapy (IDEA) collaboration, nearly 13,000 patients with stage III colon cancer were randomized to either 3 or 6 months of adjuvant FOLFOX or CAPOX in a non-inferiority trial design [15]. Overall, 3 months of treatment failed to meet the criteria for non-inferiority as compared to 6 months of treatment, when 3-year disease-free survival was utilized as the outcome variable. However, subgroup analysis showed that among low-risk tumors (T1–3N1), 3 months of CAPOX was non-inferior to 6 months of treatment. Non-inferiority could not be proven for 3 months of FOLFOX versus 6 months. Among high-risk tumors (T4 and/or N2), non-inferiority could not be proven with 3 months of CAPOX versus 6 months, and 3 months of FOLFOX was inferior to 6 months. Therefore, the 2020 National Collaborative Cancer Network (NCCN)® colon cancer guidelines now recommend either 3 months of CAPOX or 3–6 months of FOLFOX for low-risk stage III colon cancer (T1–3N1), whereas high-risk stage III cancer (T4 and/or N2) is recommended to receive CAPOX for 3–6 months (with category 1 data supporting 6 months) or 6 months of FOLFOX [16].

Stage II Colon Cancer

Several landmark adjuvant chemotherapy trials included both patients with stage II and stage III disease, and subgroup analysis of the stage II patients has offered conflicting data on the efficacy of adjuvant chemotherapy. The IMPACT B2 (International Multicentre Pooled Analysis of B2 Colon Cancer Trials) found no difference in 5-year overall survival

(OS) in patients with stage II resected colon cancer who were randomized to 5-FU-leucovorin versus observation (82% vs. 80%, $p = 0.57$) [17]. In the intergroup analysis, the subset of stage II colon cancer who received adjuvant 5-FU-leucovorin had a 4% improvement in disease-free survival (DFS) (76% vs. 72%, $p = 0.049$) but no difference in OS (81% vs. 76%, $p = 0.113$) [18]. In the QUASAR (Leucovorin and Fluorouracil Compared with Observation in Treating Patients with Colorectal Cancer That Has Been Surgically Removed) trial, patients who received adjuvant chemotherapy had a 22% decrease in recurrence ($p = 0.001$) and an 18% reduction in death ($p = 0.008$), but the 5-year OS absolute benefit was only 3–4% [19]. Two landmark trials, MOSAIC and NSABP C-07, were both designed to investigate the added efficacy of oxaliplatin to 5-FU in resected stage II and III colon cancer [3, 11]. In both trials, subgroup analysis of patients with stage II disease found no difference in DFS or OS with the addition of oxaliplatin to 5-FU. In summary, when considered as a uniform group, there has been at best a very modest and inconsistent benefit of adjuvant 5-FU-leucovorin for patients with resected stage II colon cancer, with no additional benefit of oxaliplatin.

The American Society of Clinical Oncology and the European Society for Medical Oncology both recognize the broad range of presentations among stage II colon cancers. Both groups have published similar definitions of high-risk clinicopathologic features [20, 21], as outlined in Table 30.1, that should prompt consideration of adjuvant chemotherapy. However, at present, there are no definitive data to support the utilization of adjuvant chemotherapy for stage II colon cancer patients.

Analysis of the tumor for microsatellite instability (MSI), immunohistochemistry for expression of mismatch repair (MMR) proteins, and BRAF mutational analysis also play important roles in risk stratification for stage II colon cancer. MSI-high/MMR-deficient tumors generally have improved overall survival and lower risk of lymph node and distant metastases compared to MSI-low/MMR-proficient tumors [22]. Furthermore, MSI-high/MMR-deficient tumors tend to be resistant to 5-FU therapy, and oxaliplatin is typically required to confer treatment response [23]. Therefore, assessment of MSI/MMR status can help avoid administering cytotoxic chemotherapy to patients unlikely to benefit from it. The BRAF (V600E) mutation is associated with worse OS, and there is an additive prognostic significance with MMR status. In pooled analysis of two NSABP trials, patients who had BRAF wild-type and MMR-deficient tumors had the highest 5-year OS (89.7%), whereas patients who had BRAF-mutant and MMR-proficient tumors had the worst 5-year OS (69.1%) [24]. Therefore, the presence of the BRAF (V600E) mutation should prompt consideration for adjuvant chemotherapy. As such, routine assessment of MSI/MMR status with reflex testing for BRAF (V600E) has become standard for all colorectal cancer resection specimens in many institutions.

There are several commercially available multigene assays available to predict the risk of recurrence of stage II colon cancer. These are discussed in more detail later in this chapter ("Molecular Profiling" section). This information can be useful in deciding who should be offered adjuvant chemotherapy.

Radiation for Colon Cancer

There is a very limited role of adjuvant radiotherapy for colon cancer. Unlike the rectum, which is fixed within the pelvis allowing for precise targeting of the tumor and surrounding lymph nodes with minimal risk to surrounding structures, most of the colon is intraperitoneal and/or closely approximated by loops of the small bowel. Therefore, the risk of inadvertent radiation enteritis is unacceptably high, and therefore it is not routinely recommended [25]. Moreover, the primary benefit of radiation is to improve local control. This is much more problematic for rectal cancer, in which positive circumferential resection margins (CRM) can be seen in upward of 17% of cases, whereas the risk of a positive CRM in colon cancer is much lower.

To date, there has only been one prospective randomized trial investigating the use of adjuvant chemoradiation in addition to chemotherapy for high-risk stage II (T4) or stage III colon cancers [26]. No difference was seen in 5-year OS or DFS between the groups, although the study was terminated early due to slow accrual. Furthermore, significant toxicity was seen in 54% of the patients who received radiation.

A situation where adjuvant radiation may be considered is for T4 colon cancers that invade adjacent solid organs and have a close or positive margin following surgery. However, a recent study using the National Cancer Database (NCDB) and Surveillance, Epidemiology, and End Results (SEER) Program data analyzed over 28,000 patients with T4 colon cancer treated with adjuvant chemotherapy either with or without radiation, and no difference in OS or DSS (disease specific survival) was observed [27]. Therefore, even this may have limited utility. If a close or positive radial margin is suspected at the time of surgery, the margins of the area of

concern should be marked with surgical clips or fiducials to help define the radiation field postoperatively. Rotation of an omental flap to cover the area may help isolate the area from direct small bowel adhesion and minimize radiation damage.

Neoadjuvant Chemotherapy and Radiation for Colon Cancer

Neoadjuvant systemic chemotherapy can be considered for locally advanced colon cancers. It has been demonstrated that neoadjuvant chemotherapy is more effective than postoperative adjuvant chemotherapy in locally advanced esophageal, gastric, and rectal cancer, and it is now utilized routinely for these tumor types. The potential benefits of neoadjuvant chemotherapy include earlier systemic treatment and more effective eradication of occult micrometastatic disease, improved tolerability and dose intensity, and assessment of response to guide adjuvant therapy decisions. Theoretically, chemically debulking tumors before surgery may reduce the frequency of tumor cell shedding during surgery and improve R0 resection rates. Data from the FOxTROT Collaborative Group showed significant tumor downstaging, less apical node involvement, and fewer positive margins, favoring preoperative treatment in patients with locally advanced, resectable colon cancer [28]. Neoadjuvant chemotherapy seems to be well tolerated and safe, with no increase in perioperative morbidity and a trend toward fewer serious postoperative complications. There are also data that suggest that neoadjuvant chemotherapy in clinical T4b colon cancer may improve survival, although this benefit was not seen in T3 or T4a disease [29].

Neoadjuvant chemoradiotherapy can be considered in highly select patients, such as those with sigmoid tumors invading the bladder or other pelvic organs, provided that the radiation dose to surrounding small bowel can be limited. Neoadjuvant chemoradiotherapy can also be considered for highly select patients with more proximal colon tumors invading other vital structures such as the duodenum and pancreas, although data are limited to case reports and small series, and thus no definitive conclusions can be made regarding relative efficacy. As chemotherapy becomes more effective, it is likely that neoadjuvant chemotherapy will supplant chemoradiotherapy in these highly select situations, as risk of small bowel radiotherapy damage would be eliminated.

Figure 30.1 shows a treatment algorithm for adjuvant therapy for stage II and III colon cancer.

Rectal Cancer

Compared to colon cancer, the multimodal management of rectal cancer is far more complex, primarily due to the fact that the fixed location of the rectum in the pelvis allows for the safe delivery of targeted radiotherapy to the operative field with minimal risk of collateral damage to adjacent structures. Furthermore, the risk of local recurrence following curative resection for rectal cancer is significantly higher than for colon cancer, and so great effort has been placed on developing a multimodal treatment approach to reduce the risk of local recurrence as well as to improve overall survival.

Multimodal treatment of rectal cancer may include chemotherapy, radiation, local excision, proctectomy, or some

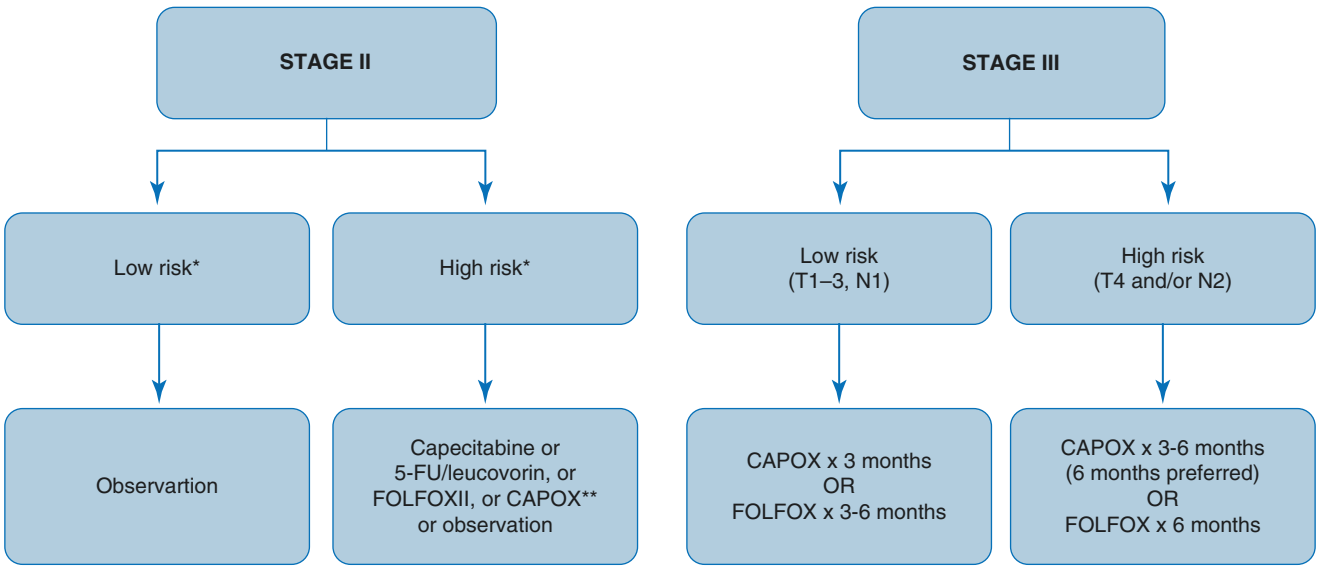

Fig. 30.1 Treatment algorithm for adjuvant therapy for stage II and III colon cancer following surgery with curative intent. (*High-risk features include T4 tumor, poor differentiation, lymphovascular invasion, perineural invasion, close or positive margin, bowel obstruction, and <12 lymph nodes harvested. **Oxaliplatin required if MSI-L or MMR proteins are expressed)

combination of the above. There are also a multitude of options available for the order in which multimodal therapy can be delivered, often resulting in great confusion for surgeons and patients alike. Some of the most significant changes in treatment algorithms in recent years have involved moving adjuvant chemotherapy forward in the treatment schematic so that systemic chemotherapy and radiotherapy are both administered prior to surgery (total neoadjuvant therapy). There has also been a rapid evolution of the role of non-operative management ("watch-and-wait") for rectal cancer. Both of these concepts are covered elsewhere in the textbook; thus we will focus the discussion here to only adjuvant treatment options following curative-intent surgery.

Adjuvant Chemotherapy Following Neoadjuvant Radiation

A series of landmark prospective randomized clinical trials in the 1990s and early 2000s established that treating stage II and III mid and low rectal cancers with preoperative radiation given as either short course (5 Gy/day × 5 days followed by surgery) or long course (1.8–2.0 Gy/day × 5 days a week to a total dose of 45–50 Gy along with a sensitizing agent such as 5-FU or capecitabine) is associated with significant improvement in local pelvic control, although improvement in overall survival was only demonstrated in the first of these three trials [30–32]. Therefore, for stage II or III mid and low rectal cancer, the 2020 NCCN® guidelines recommend neoadjuvant radiation (short course or long course) followed by surgery, as well as additional systemic chemotherapy given either before or after surgery for a total of 6 months of perioperative therapy [33].

Neoadjuvant radiation often downstages the tumor, and therefore it has been a matter of debate as to whether to determine the need for adjuvant chemotherapy based on initial clinical stage or final histologic stage. Although not supported by definitive data, the current NCCN® guidelines recommend adjuvant chemotherapy for patients with clinical stage II/III rectal cancer who received neoadjuvant radiation, regardless of final histology [33].

Data are conflicting with regard to who benefits from adjuvant chemotherapy as well as what the ideal chemotherapy regimen is. Two prospective randomized clinical trials demonstrated a modest disease-free survival advantage with FOLFOX compared to 5-FU/leucovorin without oxaliplatin for stage II and III rectal cancer following neoadjuvant chemoradiation and surgery [34, 35]. However, a recent meta-analysis of nearly 1200 patients with stage II and III rectal cancers who received 5-FU-based chemotherapy following neoadjuvant chemoradiation and surgery showed no difference in overall survival, disease-free survival, or distant recurrences with adjuvant therapy [36].

One reason why there has been inconsistency with demonstrating the benefits of adjuvant chemotherapy is that many such studies were plagued with treatment interruptions, thereby diminishing the incremental benefits of the additional chemotherapy. In fact, it has been estimated that only 50% of patients complete the full prescribed course of adjuvant chemotherapy without interruption and that each 4-week delay in treatment can decrease survival by 14% [37]. This has caused many to advocate for moving the adjuvant chemotherapy forward in the sequence of multimodal therapy, to be given prior to radiotherapy/chemoradiotherapy (induction chemotherapy), the entire regimen referred to as "total neoadjuvant therapy." Multiple studies have demonstrated fewer treatment interruptions, increased pathologic complete response (pCR) rates, and less chemotherapy-related toxicity with induction chemotherapy compared to conventionally sequenced multimodal therapy [38, 39]. Since 2015, NCCN® guidelines have included induction chemotherapy followed by chemoradiation and then surgery as an option for management of locally advanced rectal cancer [33].

Adjuvant Therapy Without Neoadjuvant Radiation

One of the inherent difficulties of determining the optimal treatment for patients with rectal cancer is the dependence upon preoperative imaging to determine clinical stage. Even with modern high-resolution MRI, it is estimated that the specificity of MRI for determining T category is only 75% and lymph node status is only 71% [40]. Therefore, tumor mis-staging can occur in upward of 20–25% of cases, and patients who undergo upfront surgery and are found to have stage II/III rectal cancer may not have received any neoadjuvant therapy prior to surgery. The treatment team is then faced with the dilemma of whether to offer adjuvant radiation, systemic chemotherapy, both, or neither. Unfortunately, there are limited data available to guide such decisions, and the latest NCCN guidelines leave several options available to the clinicians since high-level data are lacking.

Postoperative adjuvant radiation is associated with considerable morbidity. Adjuvant radiation may damage loops of the small bowel that may have fallen into the pelvis within the radiation field, resulting in radiation enteritis. Postoperative radiation is especially morbid if a restorative proctectomy has been performed. Radiation may damage the colonic conduit, remaining the rectum and anal sphincter, especially given that higher doses of postoperative radiotherapy are required to achieve similar oncologic benefit as compared to neoadjuvant radiotherapy. Chronic inflammation, poor function, stricture, and subacute perforation with abscess/fistula can result. Furthermore, tumoricidal effects of radiation may be diminished when it is administered in the postoperative period, as

the tissues surrounding the operative field are not as well oxygenated as naïve tissues prior to surgery.

The rationale for utilizing postoperative radiotherapy/chemotherapy derives from trials that accrued patients in the 1980s, a time when surgical technique and pathology processing were not standardized and often were what would be considered suboptimal today. The efficacy of adjuvant radiation for stage II/III rectal cancer was established in two studies showing that adjuvant 5-FU-based chemotherapy plus radiation leads to improved local control and decreased distant recurrence compared to radiation or surgery alone [41, 42]. In another prospective randomized trial, 694 patients with stage II/III rectal cancer who went straight to curative surgery were randomized to receive chemotherapy alone or chemotherapy with adjuvant radiation [9]. There were no differences observed in disease-free survival or overall survival, but the cumulative incidence of locoregional relapse at 5 years was significantly lower in the group that received adjuvant radiation (8% vs. 13%, $p = 0.02$). However, all three of these studies were conducted at a time when less attention was paid to maintaining sound oncologic principles of mesorectal excision and ensuring negative circumferential margins. Therefore, it is unclear if adjuvant radiation would confer the same benefits in modern practice with experienced surgeons performing high-quality proctectomy utilizing the principles of "total mesorectal excision" (TME).

NCCN® guidelines for adjuvant therapy after curative resection without neoadjuvant therapy distinguish between low-risk stage II tumors and high-risk stage II/any stage III tumors [33]. For low-risk stage II disease (pT3N0M0, negative CRM), adjuvant chemoradiation followed by 5-FU/leucovorin or capecitabine is preferred, but observation alone is also an option. For high-risk stage II (pT4N0M0 or positive CRM) or any stage III tumor (pT1–4N1–2), adjuvant chemoradiation followed by oxaliplatin-based chemotherapy (FOLFOX or CAPOX) is preferred. Total duration of adjuvant treatment is typically 6 months. However, many experienced surgeons would argue that the benefit of postoperative radiotherapy may be minimal if negative CRM is achieved as compared to the toxicity of therapy and that current chemotherapy regimens are highly effective. Thus, another reasonable strategy is to treat patients with node-positive disease with negative CRM with postoperative chemotherapy only.

Adjuvant Therapy Following Local Excision of Early-Stage Rectal Cancer

The significant morbidity associated with proctectomy makes local excision for low-risk early-stage (cT1–2N0M0) rectal cancers an appealing option. However, beginning in the early 2000s, there was an increased awareness that local excision was associated with significantly worse oncologic outcomes compared to proctectomy. Five separate institutional series published between 2000 and 2009 reported local recurrence rates of 7–23% following local excision compared to 0–9% following proctectomy and 5-year overall survival rates of 70–92% versus 80–96% following proctectomy [43–47]. This has led many to revisit this approach and look to multimodal therapy to try to improve oncologic outcomes while maintaining organ preservation.

Table 30.2 High-risk features of early-stage rectal cancers following local excision

Poor differentiation
Lymphovascular invasion
R1 resection
Tumor fragmentation during local invasion
Margins positive or <1 mm

An improved understanding of high-risk histopathologic features of early-stage rectal cancer has allowed for better patient selection and identification of those at highest risk of recurrence who may benefit from additional treatment following local excision [43, 45, 48, 49]. A list of these features can be found in Table 30.2. If any of these features are present, proctectomy should be considered. However, if the patient is unwilling or unable to tolerate major abdominal surgery, then treatment with adjuvant chemoradiation and possibly chemotherapy could be considered.

The use of neoadjuvant chemoradiation for cT2N0M0 rectal cancers treated with local excision was examined in the ACOSOG Z6041 trial [50]. In this multicenter phase 2 single-arm trial, 79 patients with cT2N0M0 distal rectal cancer were treated with chemoradiation followed by local excision. The 3-year DFS was 87%, which was significantly lower than what would be expected for similarly staged patients who underwent proctectomy. Therefore, this approach should be considered an oncologic compromise for carefully selected patients who are unable or unwilling to undergo proctectomy.

The current NCCN® guidelines recommend proctectomy or chemoradiation with either capecitabine or infusional 5-FU along with radiotherapy for pT2Nx and pT1Nx locally excised tumors with high-risk features [33]. Proctectomy is the preferred option for pT2Nx tumors in otherwise healthy patients.

Figure 30.2 shows treatment options for multimodal treatment of locally advanced stage II or III rectal cancer.

Targeted Chemotherapy Options

Several targeted chemotherapeutic agents have been evaluated in the adjuvant setting, including bevacizumab (anti-VEGF antibody) and cetuximab (anti-EGFR antibody).

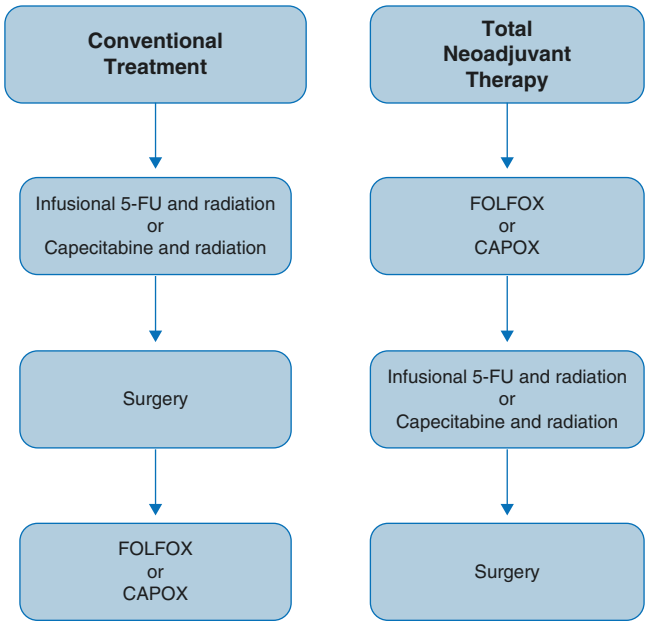

Fig. 30.2 Two treatment options for multimodal treatment of locally advanced stage II or III rectal cancer. Total duration of perioperative therapy should be 6 months

Unfortunately, neither has been shown to be beneficial for routine adjuvant therapy following curative resection. In the AVANT trial, patients with resected stage II/III colon cancer were randomized to either FOLFOX, FOLFOX plus bevacizumab, or XELOX plus bevacizumab [51]. After a minimum follow-up of 60 months, there were no differences in disease-free survival, but there were more grade 3–5 adverse events in the bevacizumab groups, and therefore it was not routinely recommended to use bevacizumab in the adjuvant setting following curative surgery. Similarly, the PETACC-8 and N0147 trials randomized patients with KRAS wild-type tumors to adjuvant FOLFOX with or without cetuximab [52, 53]. Both studies found no difference in disease-free survival with the addition of cetuximab, and the N0147 trial demonstrated increased incidence of grade 3–5 adverse events and lower likelihood of completing the full 12 cycles.

Molecular Profiling

Although a complete understanding of the molecular pathways and genetic mutations that drive the pathogenesis of colorectal cancer remains elusive, significant advances in the understanding of several key pathways have been achieved in recent years [54]. Molecular profiling has now entered routine clinical practice to help identify patients who are at increased risk for tumor recurrence or who may benefit from certain chemotherapy regimens.

DNA mismatch repair proteins (MLH1, MSH2, MSH6, and PMS2) are responsible for the detection and correction of nucleotide pairing errors that occur during DNA replication. Mutations in the DNA mismatch repair proteins may be inherited (i.e., Lynch syndrome) or sporadic [55]. Alternatively, abnormal protein expression may be the result of epigenetic modification, either through silencing by the BRAF (V600E) mutation or through promoter hypermethylation.

Screening for DNA mismatch repair protein expression can help identify patients most likely to benefit from oxaliplatin-based adjuvant chemotherapy. In general, MMR-deficient tumors have a better prognosis and are less responsive to chemotherapy with 5-FU/leucovorin [23]. Therefore, MMR testing can identify patients who will derive little benefit from chemotherapy and who can thus avoid the toxicity of therapy.

Several multigene assays have been developed for risk stratification of colon cancer recurrence. The best studied to date is Oncotype DX®. This is a 12-gene assay used to calculate a recurrence score to predict risk of recurrence following potentially curative resection. Its ability to risk stratify for recurrence has been evaluated in 3 prospective studies and 1 retrospective cohort study including a total of nearly 3000 patients with stage II or III colon cancer [56–59]. However, this test and others like it are unable to accurately predict response to adjuvant therapy, and so their clinical utility is limited.

Surveillance After Curative-Intent Therapy

Introduction

Given the improvements in screening, diagnostics, surgery, and adjuvant therapy, most patients suffering from colorectal cancer will survive, resulting in an ever-increasing survivor population [60]. The 1.3 million adults living with a history of colorectal cancer represent a large group of cancer survivors in which appropriate follow-up and survivorship care is a priority to identify cancer recurrence, treat long-term consequences of therapy, as well as to address the psychosocial needs of survivorship [61]. Unfortunately, there remains little consensus regarding best practice for surveillance and survivorship care [62, 63].

The goal of surveillance is the detection of treatable recurrence or metachronous colorectal primary malignancy while improving the patient's opportunities for curative intervention and survival. For those patients with suspected or known genetic syndromes, appropriate strategies must consider the risk of other associated cancers, as well as address appropriate screening of at-risk relatives. It should be understood that the appropriateness of surveillance must take the patient's age, comorbid conditions, functional status, life expectancy, and goals of care into consideration.

Active surveillance to detect recurrent or metastatic disease should only be performed if the patient is willing and able to undergo aggressive treatment. Otherwise, surveillance is simply an economic and emotional burden that the patient must bear, solely to satisfy the intellectual curiosity of the ordering physician.

Decisions regarding surveillance should be based in part on the demonstrated magnitude of improvement in overall survival, cancer-specific survival, quality of life, and function. Unfortunately, it is difficult to interpret and synthesize the findings of published series on surveillance, as they are plagued with heterogeneity regarding interventions and comparisons, where one trial's "more intensive regimen" may be virtually identical to another trial's "less intensive regimen." In addition, few series have adequate power to detect meaningful differences in survival and other objective measures of outcome.

National organizations, such as the American Society of Colon and Rectal Surgeons, the American and European Society of Clinical Oncology, and the National Comprehensive Cancer Network, have published surveillance testing guidelines for primary colorectal cancer (Table 30.3). In general terms, surveillance includes history and physical examination as well as laboratory testing [carcinoembryonic antigen (CEA) measurement every 3–6 months for 5 years] and image-guided testing [computed tomography (CT) scans of the chest, abdomen, and pelvis every 6–12 months for 3–5 years] along with colonoscopy at 1-, 3-, and then 5-year intervals. Variation in the recommended frequency of tests is common when comparing various society recommendations and those of authors of primary studies on the topic in the published literature.

While historical evidence has suggested intensive follow-up improves the detection of early disease which may be amenable to additional therapeutic and surgical measures, newer evidence is calling this paradigm into question. Historically, improvements in overall survival hinged on the detection of treatable disease. Newer data suggests that less intensive follow-up results in similar overall and cancer-specific survival, suggesting that the previously perceived benefits of intensive surveillance were due to lead-time bias or stage migration. This shift in surveillance recommendations is critical for the third of patients who suffer from recurrence, many of whom undergo salvage resection with a median survival in excess of 3–5 years [61, 64–66]. Throughout this chapter, we will discuss past and current literature regarding the surveillance of patients with colorectal malignancy who undergo curative-intent resection of their primary tumors.

Timing and Choice of Surveillance Modalities

Historical Literature

There have been eight prospective randomized trials addressing outcomes of surveillance after curative resection published from 1995 to 2014 [67–74]. These series are all limited by their heterogeneity of surveillance regimes, diagnostic and therapeutic modalities, and the varying time periods in which the study was conducted [75].

Table 30.3 National organization surveillance testing guidelines for primary colorectal cancer [16, 21, 33, 96, 139, 140]

Organization	History/physical	CEA	CT scan	Endoscopy
ASCO 2013 (stages II–III)	q 3–6 mos. for 5 yrs.	q 3–6 mos. for 5 yrs.	Chest/abdomen/pelvis (if rectal) q yr. for 3–5 yrs.	Colonoscopy at 1 yr., if negative, every 5 yrs. Rectal cancer, proctosigmoidoscopy q 6 mos. for 2–5 yrs. if now pelvic RT
ESMO 2013 (stages I, II, III)	q 3–6 mos. for 3 yrs. and then q 6–12 mos. for 2 yrs.	q 3–6 mos. for 3 yrs. and then q 6–12 mos. for 2 yrs.	Chest/abdomen q 6–12 mos. for 3 yrs.	Colonoscopy at 1 yr., if negative, every 3–5 yrs.
ESMO 2017 (stages I, II, III)	q 6 mos. for 2 yrs.	q 6 mos. for 3 yrs.	2× chest/abdomen/pelvis during the first 3 yrs.	Colonoscopy at 1 yr., if negative, every 5 yrs. till age 75
NCCN 2020 colon	q 3–6 mos. for 2 yrs., q 6 mos. for 5 yrs.	q 3–6 mos. for 2 yrs. and then q 6 mos. for 5 yrs.	Chest/abdomen q 6–12 mos. for 5 yrs.	Colonoscopy at 1 yr., repeat q 1 yr. if adenoma, otherwise repeat 3 yrs. and then every 5 yrs.
NCCN 2020 rectum	q 3–6 mos. for 2 yrs., q 6 mos. for 5 yrs.	q 3–6 mos. for 2 yrs. and then q 6 mos. for 5 yrs.	Stages II and III chest/abdomen/pelvis q 6–12 mos. for 5 yrs.	Transanal: EUS or MRI q 3–6 mos. for 2 yrs. and then q 6 mos. for 5 yrs., colonoscopy at 1 yr. and then 3 yrs. and then repeat q 5 yrs. Stages II–III: q 1 yr., repeat q 1 yr. if adenoma, otherwise repeat 3 yrs. and then every 5 yrs.
ASCRS 2015	q 3–6 mos. for 2 yrs., q 6 mos. for 5 yrs.	q 3–6 mos. for 2 yrs. and then q 6 mos. for 5 yrs.	Chest/abdomen/pelvis q 1 yr. for 5 yrs.	1 yr. after surgery, for rectum, the same or proctoscopy +/- ERUS q 6–12 mos. for those undergoing resection or q 6 mos. for those with local excision for 3–5 yrs.

Tjandra and Chan [76] reviewed seven of the eight studies noted above [67–71, 73] concluding that intensive surveillance resulted in earlier asymptomatic detection of resectable recurrences, as well as a statistically significant improvement in survival during follow-up (78% vs. 74%, $p = 0.01$). This was followed by a systemic review of 11 trials by Pita-Fernandez et al. [77] with more than 4055 patients which demonstrated a small but significant improvement in overall survival, as well as a higher probability of identifying asymptomatic recurrence (RR 2.59), higher rates of curative surgery (RR 1.98), and improved overall survival after recurrence (RR 2.59) [77]. However, the common theme of all of these trials is the finding of no significant difference in cancer-specific survival when compared to less intensive strategies.

FACS Trial

The eighth trial mentioned above is the FACS trial. In this landmark study published in 2014 [74], 1202 patients from the United Kingdom between the years of 2003 and 2009 from 39 national health service hospitals with primary colorectal cancer treated with curative-intent surgery were randomized to 4 combinations of testing. The four groups included minimal (clinical-only) follow-up, CEA only (every 3 months for 2 years and then semiannually out to 5 years), CT only (every 6 months for 2 years, done annually for 5 years), and both CEA and CT. Colonoscopy was performed at 5 years in the group without CT and at 2 and 5 years in the CT group. For those with minimal follow-up, additional testing was utilized only if symptoms occurred. The active surveillance group resulted in more curative-intent salvage operations (7% CEA alone, 8% CT alone, 7% CEA + CT) than the minimal follow-up group (2%, $p = 0.02$); however, there was no improvement in survival (82% active regimens vs. 84% no surveillance). Moreover, the addition of both CT and CEA did not increase detection rates of resectable disease. These findings challenged the notion that intensive surveillance and aggressive treatment of recurrence are of benefit.

Modern Literature

Modern surveillance trials from 2014 to 2018 as well as future trials (PRODIGE, expected to be completed by 2021) [78] have the potential to alter our understanding of these issues. These studies, which will be discussed, present evidence suggesting that more frequent testing or intensive surveillance may not be associated with any clinically meaningful benefit to patients (Table 30.4).

CEA Watch Trial

The Watch trial published in 2015 with follow-up in 2017 [79, 80] was not powered to assess overall survival but is important in terms of the information one can glean about the ability to detect recurrent disease. This randomized multicenter prospective study was designed to transition from a limited follow-up regime to an intensified follow-up for those with resected colorectal cancer. The less intensive protocol included outpatient clinic visits with liver ultrasound and chest x-ray every 6 months and CEA every 3–6 months for 3 years. The intensive follow-up protocol included bimonthly CEA measurements and annual CT imaging of the chest and abdomen for 3 years. As a part of this protocol,

Table 30.4 Colorectal cancer trials [74, 81, 82]

Trial	Setting	Population	Intensive group	Control group	Results
FACS (JAMA 2014)	United Kingdom	1201 stages I–III	Either CEA every 3 mos. for 2 yrs. and then every 6 mos. for 3 yrs., with a single chest, abdomen, and pelvis CT scan at 12–18 months if requested; CT of the chest/abdomen/ pelvis q 6 mos. for 2 yrs. and then q 1 yr. for 3 yrs.; both CEA and CT as above	No scheduled follow-up except single CT of the chest/abdomen/pelvis at 12–18 mos. if requested	No difference in mortality for combined CEA/ CT compared to control
GILDA (Ann Oncol 2016)	Italy	1228 Dukes B2–C (high-risk stages II and III)	CEA, CBC, liver tests, and CA 19-9 q 4 mos. for 2 yrs. and then q 6 mos. for 2 yrs. and then at 5 yrs.; colonoscopy and chest x-ray q yr. for 5 yrs.; liver ultrasound at 4, 8, 12, 16, 24, 36, 48, and 60 mos.	CEA q 4 mos. for 2 yrs. and then q 6 mos. for 2 yrs. and then at 5 yrs.; colonoscopy at 1 yr. and at 4 yrs.; liver ultrasound at 8 and 20 mos.	No difference in overall survival or health-related quality-of-life scores
COLFOL (JAMA 2018)	24 centers in Sweden, Denmark, and Uruguay	2509 stages II and III	CEA and CT of the chest/abdomen at 6, 12, 18, 24, and 36 mos.	CEA and CT of the chest/ abdomen at 12 mos. and 36 mos.	No difference in overall mortality, cancer-specific mortality, and cancer recurrence

additional imaging was obtained if the CEA increased by 20% or more over two consecutive measurements. The more intensive surveillance protocol detected a higher percentage of recurrent disease, 57% versus 43%. This resulted in a greater proportion of recurrences being treated with curative intent in the intensive surveillance group, 42% versus 30%. One potential limitation, which must be discussed, is the low overall recurrence rate of 8%, which is far lower than many published results, which average around 20%. This fact limits the generalizability of these findings.

GILDA

The GILDA trial published in 2016 included 1228 patients with resected stage II/III colorectal cancer from 1998 to 2006 [81]. Patients were randomized to intensive or minimal surveillance. The intensive protocol included annual colonoscopy with ultrasound and chest imaging every 6 months. The minimal follow-up protocol included two ultrasounds within 16 months with colonoscopy performed at years 1 and 4. Despite detecting recurrence an average of 6 months earlier, there remained no statistical difference in disease-free survival or overall survival. Moreover, there were no differences in health-related quality-of-life scores among treatment groups.

COLOFOL Trial

This randomized multicenter trial published in the *Journal of the American Medical Association* in 2018 evaluated 2509 patients [82]. All patients had stage II and III colorectal cancer and were treated at 24 centers in Sweden, Denmark, and Uruguay from 2006 to 2010. These patients were randomized to follow-up testing with chest and abdomen CT scans and CEA every 6 months for 3 years versus the CT and CEA at 12 and 36 months after initial resection. Recurrence rates were equivalent between the intensive and low-frequency testing groups (22% versus 19%). Moreover, disease-specific and overall mortality were equivalent at 11% versus 11% and 13% versus 14%, respectively.

Alliance and CoC Collaboration

A collaborative effort between the Alliance Surveillance Optimization Work Group and the Commission on Cancer in 2018 published a large series comparing surveillance testing intensity within the National Cancer Database [83]. Those patients treated from 2006 to 2007 with follow-up through 2014 were included. 8529 patients were identified and evaluated with the aim to determine if intensity of follow-up was associated with time to detection of CRC recurrence, rate of recurrence, resection of recurrence, and overall survival. Those patients with high-intensity follow-up included a mean of 2.9 imaging tests and 4.3 CEA evaluations during follow-up. Patients undergoing low-intensity treatment underwent a mean of 1.6 imaging tests and 1.6 CEA evaluations during follow-up. Frequency of imaging and CEA surveillance was not associated with differences in recurrence rates [HR 0.98 (95% CI 0.89–1.09) and 1.00 (95% CI 0.90–1.10)], resection of recurrence [HR 0.99 (95% CI 0.89–1.09) and 1.00 (95% CI 0.90–1.10)], or overall survival [HR 1.00 (95% CI 0.94–1.08) and 0.96 (95% CI 0.89–1.03)]. The conclusion of the authors was that there was no perceived benefit to more intensive follow-up.

PRODIGE

This French and Belgium trial will be randomizing 1750 patients with resected stage II and III colorectal cancer to intensive follow-up versus minimal follow-up. The results should be available sometime in the year 2021 [78].

Other Works

Despite the findings of a previous Cochrane collaborative meta-analysis of pre-FACS study findings, which demonstrated improved salvage surgery rates and a 27% reduction in odds of mortality, updated versions of similar analyses reveal alternative findings [75]. A review in 2019 demonstrated no overall survival benefit associated with intensive surveillance [75]. This new analysis of 13,216 patients from 16 previous studies demonstrated no statistical significance in overall survival, cancer-specific survival, or relapse-free survival for intensive follow-up. Moreover, compliance with best practice remains a real-world issue. A recent Canadian study of 408 patients revealed a disturbing fact that only 14%, 33%, and 24% completed their recommended CT imaging, colonoscopy, and CEA testing, respectively. Ultimately only 50% of all patients enrolled received all three follow-up tests at any time. Investigators in the Netherlands [84, 85] and Norway [86] found significant variability in surveillance when providers were compared. There is little consensus regarding who should coordinate cancer surveillance. Two randomized trials have compared surveillance by general practitioners and surgeons. In both series, surgeons were costlier, using intensive diagnostic testing with no associated difference in recurrence, time to recurrence, survival, or quality of life [87, 88]. Patient followed by their primary care doctors also reported a high emphasis on preventive health maintenance over surgical consultation [89]. A recent publication of the Optum®, a database with

180 million patient claim records, 80 million with EHR, and 12 million with deterministically linked claims and EHR, reviewed 6921 patient which demonstrated strikingly low levels of compliance with recommended surveillance examination during follow-up [90]. They concluded that low levels of compliance led to decreasing frequencies of CT imaging in surveillance programs. They also made recommendations to study further why providers are not adhering to aspects of surveillance. In the United States, there is substantial geographic variation in the intensity of surveillance, with both undertreatment in 40% and overtreatment in 23% based on published guidelines [91]. Similarly, a survey of ASCRS (American Society of Colon and Rectal Surgeons) membership concluded that surgeons engage in a variety of surveillance approaches, with only 30% following formal national guidelines [92]. Ultimately, implementing best practice and guideline recommendations from both a provider and a patient perspective remains challenging.

Specific Tests and Recommendations

Eighty percent of recurrence is detected within 2–3 years following initial curative surgical therapy. Therefore, most guidelines include more intensive surveillance during the first 2–3 years, with diminishing intensity over the remaining years of surveillance (typically a total of 5 years of surveillance testing) [65, 93–95]. The data associated with any specific surveillance test are generally of poor quality and often derived from larger trials using different testing at varying frequencies. Substantial variability exists in the use of clinical, laboratory, radiologic, and endoscopic methods to evaluate patients with colorectal cancer as part of "routine surveillance." Therefore, the recommendations within this section reflect that which is presented in Table 30.3 along with the best evidence for such recommendation.

Physical Examination

The American Society of Colon and Rectal Surgeons (ASCRS) recommends physical exam every 3–6 months for 2 years and then every 6 months until 5 years [96]. The physical exam should focus on the abdomen, the wound, the rectal examination, and the perineal wound if an abdominoperineal resection was performed. Not surprisingly, there are virtually no data to support the contention that physical examination provides any benefit to patients undergoing curative-intent resection of intraperitoneal colon cancer. It would seem logical that patients undergoing restorative proctectomy for rectal cancer may benefit from physical examination to detect pelvic recurrence; however, definitive data are lacking. More important may be that patient complaints possibly associated with tumor are voiced during an office visit and investigated appropriately.

Probably more important than detection of recurrence during an office visit is attention to the psychosocial issues that accompany colorectal resection. There are many physical, functional, and emotional challenges that affect patients post resection. A majority (50%) of patients who undergo rectal resection suffer from low anterior resection syndrome and defecatory dysfunction [97, 98]. Moreover, many patients suffer from depression after colorectal resection, and therefore it remains important to address these issues as well as encourage patients to engage in healthy eating and exercise [99–101].

Laboratory Testing

The evaluation of CEA (an oncofetal protein) levels is recommended by most societies and guidelines. CEA alone may detect up to 30–60% of recurrences [16, 33, 65, 102–104]; however, more than 15% of patients will have falsely elevated CEA in the absence of recurrence [105]. CEA elevation may identify disease in the setting of normal conventional imaging in up to 23% of patients [103]. Typically, one third of primary colorectal cancers do not produce CEA, yet overall, CEA elevation remains an independent predictor of recurrence [102]. There remains some controversy about the use of CEA in those patients with normal preoperative CEA levels at diagnosis, although some metastatic tumors will release CEA into the circulation even when the primary tumor did not. Elevations of CEA should be confirmed and then prompt evaluation with physical examination, colonoscopy, and typically CT of the chest, abdomen, and pelvis [96]. If conventional testing is non-diagnostic, then one may consider the use of combined positron emission tomography/CT (PET/CT). If no tumor is detected, CEA and imaging can be repeated every 3 months until levels decline or recurrence is detected [96].

Abdominal Imaging

The most common metastatic site of metachronous colorectal cancer is the liver (50) although the lung is increasing in frequency, particularly in cases of rectal cancer. Past recommendations for routine imaging include ultrasonography and CT imaging. However, current recommendations have reduced their emphasis on ultrasound to diagnose liver disease. In general, ultrasound has been replaced with CT due to its greater sensitivity [96].

Although observational studies [95, 106] have supported the use of frequent advanced liver imaging to improve the opportunity for further salvage surgery, few modern trials

suggest improved survival with such a strategy. In a meta-analysis of five surveillance trials, Renehan et al. [107] concluded that the regimen most consistently associated with improved survival included both CT and frequent CEA testing. This combination of testing is common among consensus recommendations. The routine use of PET/CT or liver magnetic resonance imaging (MRI) has not been endorsed by any current organizations [96]. One fundamental limitation of PET remains its low spatial resolution in combination with low-quality CT imaging without contrast for combined cases. A meta-analysis using PET demonstrated inadequate support for its use in routine surveillance [108].

Colonoscopy

The primary purpose of colonoscopy in surveillance algorithms is to detect metachronous neoplasia. If primary resection was accomplished with negative margins, luminal recurrence should be a relatively rare and late event, only occurring after extraluminal tumor has grown through the wall of the colon or rectum. If surgery was performed skillfully at the initial operation, usually the detection of luminal recurrence portends unresectable disease, as the local recurrence presumably arose from micrometastases beyond the normal planes of resection. Table 30.3 outlines current recommendations for colonoscopy surveillance from multiple societies and guidelines. Anastomotic recurrence is a rare event representing less than 4% of all recurrences [107, 109, 110]. The risk of metachronous cancer found within 2 years after surgery with colonoscopy is also low with an incidence of 0.7% [111–114]. Cone et al. [109] demonstrated an incidence of neoplastic polyps in 18% of patients undergoing first surveillance colonoscopy at a mean of 478 (± 283) days post resection, but only a 3% rate of polyps >1 cm in size. It thus is reasonable to defer colonoscopy to 2–3 years following resection, provided that the patient has a good-quality colonoscopy prior to resection and there is no suggestion of Lynch syndrome. A second primary colorectal cancer is found at 5–10 years in 2–3% of patients [112, 115–117]. It should be emphasized that patients with limited life expectancy should refrain from endoscopic surveillance in the absence of symptoms [118–120].

Special Circumstances

Stage I Colon Cancer

Patients with stage I tumors have been largely excluded from randomized trials of surveillance. Several of the consensus guidelines recommend against routine CEA testing or imaging [16, 21], advising only endoscopic surveillance to look for metachronous neoplasia. In general terms, the number needed to treat for a potential survival advantage to be demonstrated for CEA and imaging testing would not be consistent with healthcare value for patients or society.

Stage I Rectal Cancer

Typically, surveillance is used to identify distant disease. Updated guidelines from NCCN® in 2020 recommend only colonoscopy at 1 year after surgery with repeat at 3 years and then every 5 years after that for those cases with full surgical staging [33]. However, in locally transanally resected rectal cancer, the highest risk component of recurrence is local disease, estimated to be 4–33% [45, 121, 122]. Therefore, an emphasis on local site surveillance takes precedence over traditional modalities. Identification of local recurrence may allow for curative-intent salvage resection, especially if patients were initially treated with local excision. Therefore, surveillance including endoscopic and pelvic imaging is recommended. Endorectal ultrasound (ERUS) has been identified as a sensitive imaging modality for detection of recurrence in expert hands, exceeding other forms of follow-up such as digital exam, endoscopy, CT, and CEA in about 30% of cases in some studies [123–125]. Moreover, ERUS-guided biopsy can obtain histological confirmation of extraluminal recurrence [126–128].

MRI of the pelvis can also be used as a highly accurate diagnostic pelvic modality to detect recurrence [129]. However, its use in routine surveillance did not improve the detection of resectable recurrences in one trial [130], and its cost-effectiveness has not been formally evaluated. Kwakye et al. [131] recently evaluated 114 patients in which 11% suffered from local recurrence. In the series, it was suggested that traditional surveillance methods such as laboratory testing or imaging are actually responsible for a minority of positive findings. On the other hand, ERUS was able to identify the majority of recurrences. Although it is difficult to prove that this more intensive surveillance results in improved outcomes, some have suggested that a novel approach to detect pelvic recurrence following treatment of rectal cancer may be needed. ERUS or MRI every 3–6 months for the first 2 years and then every 6 months for a total of 5 is the recommendation from this series and the new 2020 NCCN® guidelines [33, 131]. In addition, surveillance is recommended to extend beyond the 5-year window because local recurrence has been observed beyond 7 years.

Quality of Life

In addition to cancer-specific outcomes of surveillance, the psychological health and quality of life of patients are of critical significance. Most patients in surveillance report that

the anxieties, which may be potentiated by intensive follow-up, are outweighed by the reassurance of negative results [132]. The randomized trial by Kjeldsen et al. [133] reported that patients had greater confidence in the surveillance process and less worry about test results. Likewise, Stiggelbout et al. [134] reported on 212 patients undergoing surveillance with positive attitude toward surveillance. Although difficult to prove through research, it is likely to assume that patients simply desire a standardized approach, which is known and executed on their behalf.

Cost

Given the myriad of proposed recommendations, the cost of surveillance testing, correlation with patient outcomes, and availability of healthcare resources are of paramount concern. Between 1999 and 2000, the use of CT and MRI scans increased more than 5% annually, with the use of PET scans tripling in the same time period [135]. Among a cohort of Italian patients undergoing surveillance with clinical examination, CEA, abdominal ultrasound, chest radiograph, and colonoscopy, the 5-year cost of surveillance averaged $5400 per patient but more than $100,000 per detected case of potentially curable recurrence [136]. Similarly, Renehan et al. [137] estimate the average cost of surveillance at almost £2500 per patient or about £3000 per year of life saved, within the range of acceptable cost-effectiveness for the United Kingdom's National Health Service. A comparative study in France estimated that intense surveillance cost an additional €3144 for quality-adjusted year of life gained over a minimal surveillance strategy. Wanis et al. [138], using a mathematical Markov model, demonstrated that the effectiveness of routine surveillance and the treatment of recurrent colorectal cancer is on average small.

Overall, assessments of cost-effectiveness for colorectal cancer surveillance would suggest that it provides low value. Current NCCN recommendations for stage II and III colorectal cancer patients promote costly surveillance testing with minimal to no demonstrated improvement in overall outcomes. Therefore, although the cost-effectiveness of colorectal cancer surveillance is within the range of other interventions considered acceptable by many Western cultures, it is highly likely that this intensity of practice leads to an overall elevated utilization healthcare and surgical services, without substantial benefit.

Conclusions

Although surgery remains the mainstay of treatment of non-metastatic colorectal cancer, recurrence following surgery with curative intent remains relatively high. Adjuvant systemic chemotherapy offers clear advantages in terms of reduced risk of recurrence and improved survival following surgery for stage III colon cancer and stage II and III rectal cancer, but its benefits for stage II colon cancer remain unclear. Adjuvant radiotherapy has a role in the treatment of rectal cancer, but it is ideally used in the neoadjuvant setting, and it is rarely used for colon cancer. Molecular profiling can be helpful in predicting risk of recurrence and identifying potential candidates for targeted therapies, but its routine use following curative-intent surgery remains limited.

The optimal frequency and modalities of surveillance testing remain a question. There appears to be a growing consensus regarding the lack of benefit from intensive surveillance for colorectal cancer. Despite the growing array of management options and diagnostic testing, the ability to identify early recurrence appears to provide patients little benefit in terms of cancer-specific survival. It is time to reevaluate US consensus guidelines to more closely reflect current evidence.

Colorectal Cancer: Management of Distant Metastases

31

Traci L. Hedrick

Key Concepts

- Treatment of advanced colorectal cancer has evolved significantly over time, reflecting a shift toward more aggressive therapy recognizing the potential for long-term survival.
- The liver is the most common site of metastatic disease followed by the lung. The brain, bone, ovary, peritoneum, and adrenals make up the remaining less common sites of metastatic disease.
- Treatment options depend on the functional status and primary goals of the patient, site and volume of metastatic disease, as well as the degree of symptoms from the primary tumor.
- Treatment of the patient with metastatic colorectal cancer requires a comprehensive multidisciplinary approach to develop an individualized treatment scheme integrating quality of life and patient needs.

Introduction

The majority of CRC-related deaths are attributable to metastatic disease, with up to 22% of patients exhibiting evidence of metastatic disease at initial presentation [1–4]. The overall 5-year survival rate in the setting of Stage IV CRC is 10–14% [2, 5]. However, this is highly dependent on the extent and site of metastases with 5-year survival ranging from 24% to 58% (averaging 40%) in patients with resectable hepatic metastases. The liver is the dominant site of metastatic disease, accounting for 75% of patients with CRC metastases, followed by the lung in 22% [5]. Over 70% of patients with lung metastases have synchronous liver metastases as well [5]. The brain, bone, ovary, peritoneum, and adrenals make up the remaining less common sites of metastatic disease. Prognosis relates to volume and site of metastases with oligometastases portending a worse prognosis than single-organ metastases. Wang et al. demonstrated a 3-year overall survival (OS) for patients with solitary metastasis to the liver and lung of 26.8% (95% CI, 25.8–27.8%) and 34.0% (95% CI, 29.9–38.1%), respectively, using the Surveillance, Epidemiology, and End Results (SEER) database [5].

Multidisciplinary Evaluation

Treatment of metastatic CRC has evolved over time with a shift toward more aggressive therapy in recognition of the potential for long-term survival. There are innumerable factors to consider in the management of the patient with metastatic CRC. The National Comprehensive Cancer Network (NCCN) and American Society of Colon and Rectal Surgeons (ASCRS) guidelines do not recommend one treatment strategy over the other, particularly in the patient with resectable metastatic disease [6, 7]. Rather, treatment of the patient with metastatic CRC requires a comprehensive multidisciplinary approach to develop an individualized treatment scheme, integrating quality of life and patient needs [6]. Shared decision-making strategies between the patient and the team result in better alignment between medical decisions and patient care preferences [8–10].

Synchronous Metastases

The patient presenting with metastatic disease at the time of initial diagnosis requires a sophisticated individualized approach based on a multitude of factors. Treatment options depend on the functional status and primary goals of the patient, site and volume of metastatic disease, as well as the degree of symptoms from the primary tumor. An algorithm is presented in Fig. 31.1 to guide clinical decision-making in patients presenting with synchronous colorectal primary tumor and liver or lung metastases.

Management of Primary Tumor

Management of the primary tumor requires thoughtful clinical judgment to ascertain the degree of primary tumor-related symptoms during the initial evaluation.

Bleeding Many patients suffer from symptomatic anemia at the time of diagnosis. Given that the ongoing blood loss from the primary tumor is typically low volume, symptomatic anemia can usually be managed non-operatively. Rarely, however, patients exhibit significant blood loss necessitating surgery, particularly in the setting of mandatory chronic anticoagulation (e.g., mechanical valve/pulmonary embolus) or tumor involvement of a mesenteric or surrounding vascular structure (Fig. 31.2). Management of bleeding depends on the location and size of the tumor as well as the rate of bleeding. Radiation provides relatively quick and effective palliation for surface bleeding at the site of the tumor, particularly within the rectum [11, 12]. Resection is the preferred approach, if possible, for more proximal cancers or in the setting of significant hemorrhage. However, this decision will depend on the local invasion of the tumor into adjacent structures, the functional status of the patient, and the volume of metastatic disease. Endovascular procedures (e.g., embolization, covered stent placement) are also available in the palliative setting for bleeding from advanced CRC [13, 14].

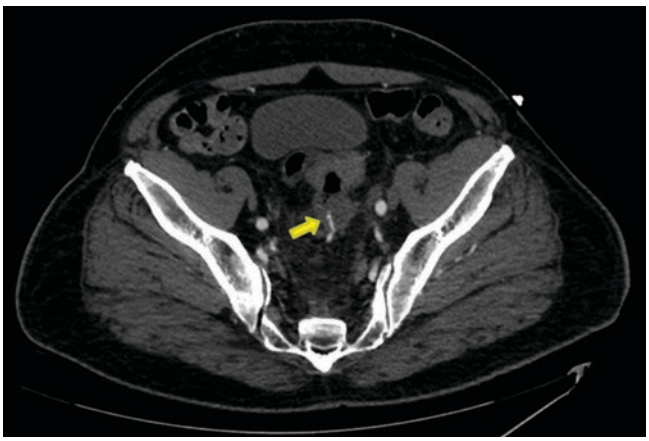

Fig. 31.2 Computed tomography image demonstrating active extravasation from the inferior mesenteric artery (arrow) into a necrotic rectosigmoid tumor causing significant intraluminal bleeding requiring resection

Obstruction Between 8% and 30% of patients with colorectal cancer present with a partial or completely obstructing primary lesion [15]. While recognition of a complete obstruction is straightforward, recognition and management of a patient with an impending obstruction can be more nuanced. Patients may complain of constipation, diarrhea or tenesmus, weight loss, post-prandial colicky abdominal pain, and abdominal distention. Failure to pass the endoscope past the primary lesion is an obvious indicator of pending obstruction. However, many patients (particularly right-sided) remain surprisingly asymptomatic in this situation and do not require immediate intervention. Alternatively, there are patients who will clinically obstruct despite passage of the endoscope through the primary lesion, particularly when the tumor is in the left colon. A stool column proximal to the primary lesion on cross-sectional imaging, and absence of stool distally, can be a subtle harbinger of impending obstruction, even in the absence of colonic dilation.

The size and location of the primary tumor dictate the interventional options for an obstructing tumor. ASCRS guidelines recommend considering decompressive stent insertion prior to colectomy or diversion in patients with an obstructing colon cancer in the setting of incurable metastatic disease. Compared to surgery, colonic stenting reduces short-term morbidity and the interval to chemotherapy initiation with no impact on OS [6, 16–19]. Anecdotally however, institutional capabilities and experience with colonic stenting seem highly variable. The ability to successfully stent an obstructing tumor is also dependent on anatomic considerations, such as acute angulation of the colon or location in the colon. For example, distal rectal tumors are often not amenable to stenting as the distal end of the stent may sit on the anorectal muscular ring and cause severe discomfort. One must also consider the patients' overall life expectancy when contemplating palliative intervention given that the median duration of stent patency is 106 (68–288) days [20, 21]. In addition, stents may ultimately erode through the bowel wall with resultant abscess and fistula.

Resection may be preferable in the patient with an easily resectable primary tumor who is expected to live for at least 6 months. The threshold should be low for fecal diversion with the possibility of staged reconstruction (either Hartman's or primary anastomosis with proximal diversion) in the newly diagnosed patient with obstruction and metastatic CRC. There are significant implications of an anastomotic leak on receipt of chemotherapy [6]. This is not the time nor the place to be cavalier, given that surgical complications are a leading cause of adjuvant chemotherapy delays/omission which could adversely affect oncologic outcomes [22]. Resection should follow oncologic principles to the extent possible [6].

Proximal diversion is a valuable option for locally invasive or rectal lesions that would be difficult to resect. The distal portion of the bowel should always be vented, either as loop stoma or divided end-loop stoma, to avoid closed-loop obstruction and perforation. It is also wise to anticipate the ultimate definitive resection when considering proximal diversion in a patient with potentially resectable disease. A misplaced stoma can significantly interfere with future reconstructive options (e.g., a distal transverse or mid-/proximal descending loop colostomy in the rectal cancer patient). In addition to restricting colonic mobility, damage to the marginal artery can occur during transverse/descending colostomy creation or reversal. This would devascularize the distal colon once a high ligation of the inferior mesenteric artery is performed during a low anterior resection. Therefore, it is best to use the mid-/proximal sigmoid colon (preferably) or the proximal transverse colon just to the patient's right of the middle colic artery for diversion of obstructing rectal tumors. If a sigmoid colostomy is performed, the colon and mesentery can simply be transected distal to the stoma at time of subsequent proctosigmoidectomy. A transverse colostomy placed in the right upper quadrant facilitates access to the splenic flexure during subsequent proctosigmoidectomy, whereas a distal loop transverse colostomy may impede it. A loop ileostomy, which has the least influence on the "next" operation, is another valuable consideration. However, caution is warranted in this scenario. Diversion with a loop ileostomy could create a closed-loop obstruction physiology within the colon if the ileocecal valve is competent and the distal tumor is completely obstructing. In addition, ileostomy carries with it the risk of dehydration, which can be magnified by chemotherapy-induced enteritis.

Perforation Similar to the principles described above, exploration for perforation warrants resection versus diversion based on the feasibility of resection. Resection should follow oncologic principles if possible. However, aggressive en bloc resection of vital structures is rarely indicated in the setting of a perforated tumor and metastatic disease, given the overall poor prognosis [23]. Rather, priority should be placed on obtaining source control of the intra-abdominal infection. This may include simple diversion if the perforation is contained and can be percutaneously or surgically drained.

Unresectable Synchronous Metastases

Survival is closely linked to control and treatment of the distant disease in patients with Stage IV CRC. Therefore, control of metastatic disease should be prioritized [24]. Within this context, early determination of whether the patient has

potentially curable metastases is necessary to determine the appropriate treatment strategy (Fig. 31.1).

In the setting of unresectable synchronous metastases, NCCN and ASCRS guidelines recommend systemic chemotherapy for patients with minimal symptoms from the primary tumor [6, 7]. Surgery is reserved for patients with an imminent risk of obstruction, significant bleeding, perforation, or other significant tumor-related symptoms. This is based on evidence demonstrating that few patients (<20%) with metastatic CRC require palliative intervention of the primary tumor during chemotherapy [25]. There has been a philosophical shift away from prophylactic resection of the primary lesion in asymptomatic patients with unresectable metastatic disease (84% in 2000 vs 52% in 2011) toward upfront systemic chemotherapy [26]. It remains unclear whether resection of the primary tumor ultimately improves survival in patients with unresectable metastatic disease after treatment response to systemic therapy. There are retrospective data suggesting a significant survival benefit from chemotherapy and surgical resection of the primary tumor compared to chemotherapy alone in patients with unresectable synchronous CRC metastases [5, 27, 28]. Improvements in disease-free survival (DFS) and OS ranging from 6 to 14 months have been reported with resection plus chemotherapy compared to chemotherapy alone in patients with unresectable metastatic disease [27, 29–31]. However, all studies are retrospective with regard to the operative decision-making and therefore inherently plagued with selection bias. There are several ongoing prospective clinical trials (JCOG1007, CAIRO4, and GRECCAR 8) which may elucidate the efficacy of resection in the future [32–34]. For now, however, the decision should be individualized based on response to chemotherapy, estimated prognosis, and patient preference.

In the setting of unresectable synchronous metastases, chemotherapy options include FOLFOX or FOLFIRI or CAPEOX or FOLFOXIRI ± bevacizumab [7]. An additional option for KRAS/NRAS/BRAF WT gene left-sided tumors only is FOLFIRI or FOLFOX or FOLFOXIRI ± panitumumab or cetuximab. NCCN recommends reevaluation with cross-sectional imaging to monitor for conversion to resectable disease every 2 months if conversion to resectability is a possibility [7]. In the event of planned operation, a 6-week interval between the last dose of bevacizumab and elective surgery with re-initiation at least 6–8 weeks postoperatively is recommended [7].

Resectable Synchronous Metastases

Approximately 20% of patients with CRC metastases have resectable or potentially resectable disease [35]. There are numerous treatment options involving resection of the primary tumor, resection/ablation of metastases, and 6 months of chemotherapy with varying sequences. Neither NCCN nor ASCRS guidelines recommend one strategy over the other but stipulate that treatment should be individualized and determined by multidisciplinary consensus [6, 7]. This is based on systematic reviews and meta-analysis showing equivalent oncologic outcomes between treatment strategies in the patient with resectable synchronous metastatic disease [6, 7]. FOLFOX or CAPOX are the preferred chemotherapeutic agents over capecitabine or 5-FU/leucovorin alone in the patient with resectable metastatic disease unless the patient cannot tolerate oxaliplatin (7). Surgery should be delayed 4 weeks after the last dose of FOLFOX or CAPOX.

The ideal sequencing of surgery and chemotherapy remains unclear. There are advantages and disadvantages to each approach which must be carefully weighed by the multidisciplinary tumor board. Advantages for the resection-first strategy include elimination of tumor shedding of metastatic cells from the primary tumor during systemic treatment and avoidance of emergent surgery in the event of primary tumor progression while on treatment [25]. Additionally, there are reports of increased perioperative morbidity and liver toxicity (steatohepatitis, sinusoidal obstruction syndrome, noncirrhotic portal hypertension) following neoadjuvant therapy [36–39]. Alternatively, advantages of neoadjuvant chemotherapy include elimination of micrometastatic disease, cytoreduction facilitating R0 resection, or potential conversion from unresectable to resectable disease. An additional advantage is avoidance of potential surgical complications from upfront surgery which could delay initiation of chemotherapy [22, 40]. Finally, initial treatment with chemotherapy may uncover the natural history of the individual's cancer with avoidance of futile surgery in patients with aggressive tumor biology who progress on systemic therapy. Regardless of the specific regimen chosen, NCCN guidelines recommend limiting the duration of neoadjuvant chemotherapy to 2–3 months in the patient with clearly resectable disease. The remaining 3 months of perioperative chemotherapy are then administered after surgery [7].

Although each patient will require individual evaluation by the multidisciplinary team to determine the optimal treatment scheme, the following vignettes are provided to illustrate possible options within the NCCN guideline framework (Fig. 31.3) [7].

Synchronous or staged colectomy with liver or lung resection (preferred) and/or local ablative procedures followed by 6 months adjuvant chemotherapy. Patients with small solitary metastases in the periphery of the liver or the lung are at lowest risk for surgical morbidity and mortality. Assuming the patient is otherwise healthy and the colon resection appears straightforward, the patient with a solitary peripheral liver metastasis would be a candidate for a combined upfront resection followed by adjuvant chemotherapy.

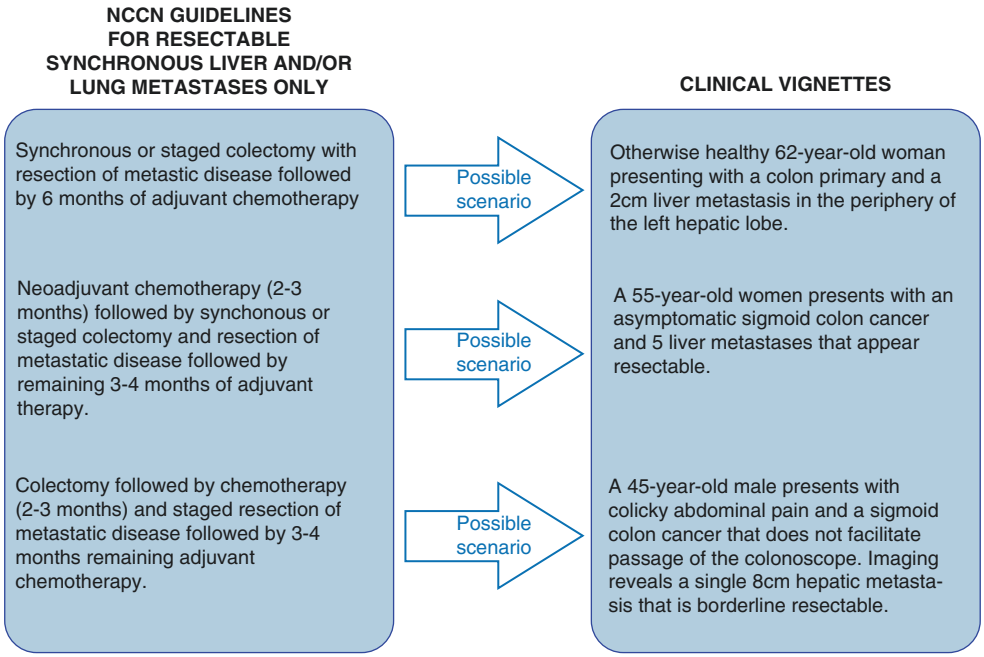

Fig. 31.3 NCCN guidelines for resectable synchronous liver and/or lung metastases with clinical vignettes highlighting possible scenarios

Neoadjuvant chemotherapy [2–3 months] followed by synchronous or staged colectomy and resection of metastatic disease followed by remaining the 3–4 months of adjuvant therapy. The patient with multiple (>4) liver metastases and an asymptomatic primary is an appropriate candidate to start with neoadjuvant chemotherapy. The increasing number of hepatic metastases puts a patient in the high-risk category for recurrence following hepatic resection [41]. Assuming a patient is fit for surgery and the liver lesions respond (or at least fail to progress) to neoadjuvant therapy, this patient may be a candidate for a simultaneous liver and colon resection followed by 3 months additional adjuvant chemotherapy.

Colectomy followed by chemotherapy (2–3 months) and staged resection of metastatic disease followed by 3–4 months remaining adjuvant chemotherapy. A 45-year-old male presents with colicky abdominal pain and a sigmoid colon cancer that does not facilitate passage of the colonoscope. Imaging reveals a single 8-cm hepatic metastasis that is borderline resectable. This patient is not an ideal candidate for combined upfront resection of the colon and hepatic metastasis, given the extent of the hepatic metastasis. Rather, in the setting of a potential impending obstruction, this patient would likely benefit from upfront colon resection and 2–3 months of chemotherapy with reevaluation for resectability. Assuming he is medically fit and the tumor responds to chemotherapy, the patient could then undergo hepatic resection followed by additional adjuvant chemotherapy. Alternatively, an endoscopic stent could also be used to alleviate the obstruction while the patient receives neoadjuvant chemotherapy.

Rectal Cancer

The patient with locally advanced rectal cancer and synchronous resectable metastases is further complicated by the possible addition of pelvic radiotherapy to the treatment armamentarium. Treatment options include upfront chemotherapy followed by short-course radiotherapy or long-course chemoradiotherapy and then resection (synchronous or staged) or upfront short-course radiotherapy or long-course chemoradiotherapy followed by chemotherapy and then resection. If radiotherapy is given first, short-course radiotherapy is an attractive option as it allows institution of multi-drug chemotherapy much sooner than if long-course chemoradiotherapy is utilized. Giving radiotherapy first allows for more accurate assessment of response of the primary tumor [42]. There may be patients with resectable metastases (particularly those facing an abdominoperineal resection) who would choose a "wait-and-watch" approach for the primary tumor in the event of a complete clinical response. It is important to recognize however that prior studies evaluating the "wait-and-watch" approach exclude patients with Stage IV disease [43–45]. Therefore, the oncologic outcomes of a "wait-and-watch" approach in the setting of synchronous resectable metastatic disease have not been evaluated. This further exemplifies the need for shared decision-making based on an in-depth discussion with the patient about their goals of treatment [8–10].

There is some concern that delaying hepatic resection until completion of, and recovery from, systemic chemotherapy may worsen chemotherapy-induced liver changes and increase the risk of postoperative liver failure. If pelvic

radiotherapy is planned after chemotherapy, then short-course radiotherapy after chemotherapy, followed by immediate surgery, is the preferred option to shorten the time to resection in this setting [7].

Another appropriate option in this case is to the treat the patient with 2–3 months of neoadjuvant chemotherapy followed by liver resection. After recovery from the liver resection, the patient would then receive the additional 3 months of perioperative chemotherapy and chemoradiation or short-course radiation prior to resection of the rectal primary. A further consideration is the risk of abdominal adhesions and radiation enteritis. As such, another option is to administer short-course radiotherapy prior to liver resection in the above algorithm. This would allow radiotherapy to occur prior to any surgical intervention and also allow for better assessment of the clinical response of the primary tumor to radiotherapy.

Metachronous Metastases

Roughly 20% of patients with CRC present with synchronous metastases at the time of initial diagnosis. Another 20% of patients go on to develop metachronous metastases after initial curative treatment [37, 46]. Over 85% of metachronous metastases are diagnosed within 3 years of initial curative treatment, and the most common site of disease is the liver (60%), followed by the lungs (39%), extra-regional lymph nodes (22%), and peritoneum (19%) [46, 47]. Predictors of metachronous metastases include male gender (HR = 1.2, 95%CI 1.03–1.32), advanced primary T-stage (T4 vs. T3 HR = 1.6, 95%CI 1.32–1.90) and N-stage (N1 vs. N0 HR = 2.8, 95%CI 2.42–3.30 and N2 vs. N0 HR = 4.5, 95%CI 3.72–5.42), high-grade tumor differentiation (HR = 1.4, 95%CI 1.17–1.62), and a positive (HR = 2.1, 95%CI 1.68–2.71) and unknown (HR = 1.7, 95%CI 1.34–2.22) resection margin [47]. Many of the same treatment principles apply in the setting of metachronous disease, depending on whether or not the disease is resectable and adjuvant therapy was received within the previous 12 months [7]. In general, patients with metachronous disease have a better prognosis than patients with synchronous metastases. [48]

Liver Metastases

Resection

Surgical resection is associated with the highest cure rates of the available treatment modalities in patients with hepatic metastases. Five-year survival ranges from 24% to 58% (averaging 40%), and 30-day mortality rates are less than 3% [39]. This compares to 5-year survival rates of 10–11% for patients who received systemic chemotherapy alone, although, obviously, this finding is heavily influenced by selection bias [49]. Approximately 20% of patients with hepatic metastases are considered resectable at the time of initial presentation. Another 10% may become resectable after induction chemotherapy [35].

What constitutes "resectable disease" has broadened significantly over time through adoption of a more aggressive surgical approach [50]. Initially, criteria for resection was limited to small, easily resectable, low-volume (<4) lesions in the absence of extrahepatic disease [41]. However, criteria have expanded to include multiple/bilobar metastases of varying size in the setting of extrahepatic disease (particularly the lung) (Fig. 31.4). Close margins and difficult-to-reach lesions can be managed with ablation (cryosurgery or radiofrequency ablation) or en bloc vascular resection with reconstruction to achieve an R0 resection. Additionally, the use of three-dimensional (3D) imaging technology, portal vein embolization, and liver partition and portal venous ligation for staged hepatectomy (ALPPS) have expanded resection possibilities through more precise assessment and optimization of the future liver remnant [51]. In the modern environment, patients are considered resectable if they are fit enough to tolerate surgery, and an R0 resection can be achieved with preservation of enough viable hepatic parenchyma to sustain life [50].

Future liver remnant (FLR) volume and the degree of hypertrophy achieved after portal vein embolization (PVE) can be measured through a variety of imaging modalities, serving as important predictors of surgical outcomes in

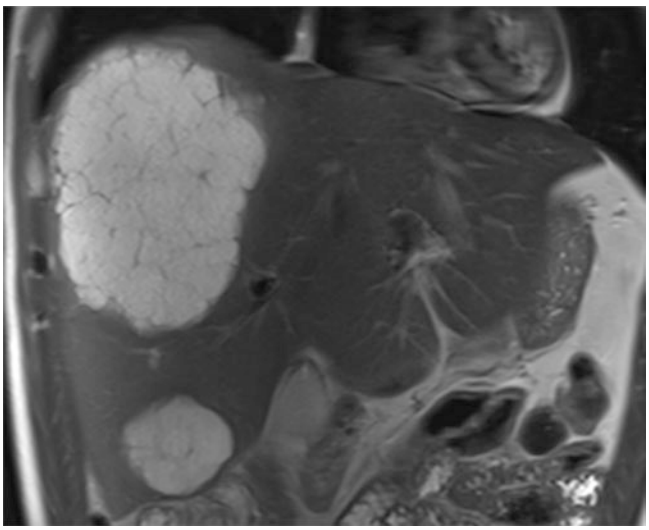

Fig. 31.4 Magnetic resonance imaging demonstrating multiple large hepatic CRC metastases that previously would have been considered unresectable. Criteria for resection have expanded with neoadjuvant chemotherapy, three-dimensional imaging technology, and portal vein embolization facilitating more precise assessment and optimization of the future liver remnant

patients undergoing major liver resection. 3D reconstruction of computed tomography (CT) images is one of the most common techniques for measuring the future liver remnant. A FLR >30% of the total hepatic volume is generally regarded as the minimum FLR volume for patients who have received chemotherapy for longer than 12 weeks [52].

The patient with extensive bilobar hepatic metastases presents an additional challenge given the risk of hepatic failure with resection. Previously, these patients were considered unresectable. However, resection criteria have expanded over time to include a select group of these patients in which an R0 resection can be achieved. This is accomplished with portal vein occlusion, either via embolization or ligation, resulting in hypertrophy within the liver remnant to reduce the risk of hepatic failure. In the patient with extensive bilobar disease, resection may be undertaken in stages. In the first stage, partial hepatectomies are performed to clear the FLR of disease in conjunction with portal vein ligation. This can be performed with resection of the primary tumor in the case of synchronous disease. Formal anatomic resection of the remaining diseased lobe is undertaken in a second-stage operation after the FLR has achieved adequate hypertrophy in the absence of metastatic progression. Alternatively, portal vein embolization is performed up front with a single-stage hepatectomy after adequate hypertrophy is achieved [53]. Embolization/ligation of the portal vein can expand functional liver volume by 39% over 4–8 weeks, although occasionally it can take longer to achieve adequate hypertrophy [54]. The risks of this method include cancer progression during the waiting period and insufficient hypertrophy. Not surprisingly, there are a substantial number of patients (25–38%) who progress and fail to undergo the staged hepatectomy [53–55].

Associating liver partition and portal venous ligation for staged hepatectomy (ALPPS) is an emerging technique in the treatment of CRC metastases [56]. With the ALPPS procedure, the portal vein is occluded either operatively with portal vein ligation or through percutaneous embolization. In the first stage, the liver is incised (partitioned) at the site of the future transection which theoretically produces much more rapid regrowth of the liver compared to portal vein occlusion alone. The patient undergoes 3D reconstruction and volumetric analysis within 1–2 weeks of the first stage to ensure adequate hepatic parenchyma. Staged hepatectomy is performed when adequate volume in the FLR is achieved (as soon as 7–10 days). The initial clinical series suggested increased liver growth rate and volume, rendering more patients resectable in a quicker amount of time [56]. However, there was significant morbidity and mortality, which has limited widespread adoption of the technique. The LIGRO Trial was a Scandinavian multicenter randomized controlled trial randomizing 100 patients with advanced colorectal liver metastases to ALPPS versus conventional two-stage hepatectomy with either portal vein ligation or embolization. ALPPS was associated with both a higher resection rate (92% vs 80%, $P = 0.091$) and estimated median survival (46 months vs 26, $P = 0.028$) compared to conventional staged hepatectomy [57]. There were no differences in complication rates or 90-day mortality between groups. Interestingly, the ALPPS procedure has been coined the "hepatobiliary controversy of the decade," testifying to the polarizing view of the procedure by many leaders of the field [58]. Further studies are needed to fully evaluate the efficacy of the technique. For now, portal vein embolization remains the standard care in patients with resectable liver metastases and FLR of less than 30%.

The majority of liver resections are performed via an open approach. However, the randomized OSLO-COMET trial demonstrated shorter hospital stays (2 days vs 4 days; $P < 0.001$), lower complication rates (19% vs 31%; $P = 0.021$), and better quality of life in patients with CRC metastases undergoing laparoscopic compared to open liver resection. Long-term oncologic outcomes were similar between groups with median overall survival (OS) of 80 months (95% CI, 52–108) in patients who underwent laparoscopic surgery compared with 81 months (95% CI, 42–120) in patients who underwent open surgery ($P = 0.91$). Therefore, a laparoscopic approach should be considered when anatomically feasible.

Locoregional Therapies

Per NCCN guidelines, resection is preferred over locoregional therapies in the management of CRC metastases given better DFS and OS [59]. However, approximately 80% of patients will have unresectable disease and may benefit from alternative locoregional therapies including percutaneous ablative treatments (radiofrequency ablation, microwave ablation) and transcatheter intra-arterial therapies [transarterial chemoembolization (TACE), and radioembolization with yttrium-90 (^{90}Y)]. Many of these image-guided ablative therapies can also be used in conjunction with resection to improve resectability. Table 31.1 provides an overview of the available locoregional treatment modalities in comparison with resection and systemic chemotherapy.

Radiofrequency Ablation

Radiofrequency ablation (RFA) causes thermal damage through high-frequency alternating current (375–500 kHz) from monopolar or bipolar radiofrequency systems inducing cytotoxicity within the few millimeters of the surrounding thermal zone. As the surrounding tissue reaches 100 °C, cells die and irreversible coagulation ensues. However, water evaporation causing desiccation results in electrical impedance which limits the volume of thermal transmission. Thus,

Table 31.1 Treatment options in patients with hepatic CRC metastases

Modality	Mechanism	Indication	Adv/dis	Survival	Risks
Resection	Partial hepatectomy, lobectomy, PVE, ALLPS	R0 resection can be achieved, pt fit for surgery	Only 20% of pts resectable	5-yr OS 24–58%	Morbidity <15%, Mortality <3%
Radiofrequency Ablation (RFA)	Thermal damage via high-frequency alternating current	Unresectable, peripheral lesions <3 cm, pt not surgical candidate	Not effective near vascular structure or lesions >3 cm	OS 28–53 mo, 5-yr OS 43%	Morbidity <2%, Mortality <1%, post ablation syndrome
Microwave Ablation (MWA)	Electromagnetic signal generates heat via molecular friction	Unresectable, pt not surgical candidate	Effective for larger and more central lesions than RFA	5-yr OS 37%	Morbidity <2%, Mortality <1%, post ablation syndrome
Transarterial chemoembolization ± drug eluding beads (TACE)	Delivers chemotherapy into hepatic arteries supplying tumor	Unresectable, not candidate for ablation, failed chemotherapy	Toxicity, limited efficacy	OS 8–14 mo, 5-yr OS 6%	Post-embolization syndrome in 60–80%
Transarterial radioembolization (TARE) or Selective internal radiotherapy (SIRT)	Microspheres loaded with radioisotope (^{90}Y) deliver high dose radiation to tumor	Unresectable, not candidate for ablation, failed chemotherapy	Toxicity, limited efficacy	OS 8–14 mo, 5-yr OS 4–7%	Better tolerated than TACE
Stereotactic body radiation therapy (SBRT)	Precise external beam radiation using 4D imaging	Unresectable, pt not surgical candidate	Unclear advantage over ablation or chemo	OS 24–27 mo	20% hepatic toxicity
Chemotherapy	FOLFOX or FOLFIRI or CAPEOX or FOLFOXIRI ± bevacizumab	Unresectable, pt not surgical candidate	Noninvasive	5-yr OS 20%, OS 23 mo	Neutropenia, neuropathy; perforation and bleeding (bevacizumab)

Abbreviations: *Adv* advantages, *Dis* disadvantages, *PVE* portal vein embolization, *ALLPS* liver partition and portal venous ligation for staged hepatectomy, *pt* patient, *OS* overall survival, *yr* year, *mo* month

RFA is limited to a relatively small-size treatment zone. Additionally, flowing blood within large vessels adjacent to the target causes a cooling effect, thereby reducing the ablation volume and lowering the efficacy near large vessels (heat sink effect) [60]. Generally, RFA is well tolerated with major complication rates ranging from 6% to 9% and mortality rates <2% [61]. RFA may be performed through an open, laparoscopic, or percutaneous approach and can be combined with surgical resection [62]. RFA is most effective for peripheral lesions less than 3 cm in diameter [63]. Median OS following RFA ranges widely throughout the literature between 28 and 53 months and seems superior to treatment with chemotherapy alone but inferior to surgical resection [59, 64–66].

Microwave Ablation

Microwave ablation (MWA) utilizes electromagnetic signal to general heat via molecular friction with frequencies between 900 and 2450 MHz resulting in cellular death via coagulation necrosis. MWA has gain acceptance as an alternative to RFA with faster heating over larger volumes of tissue and resistance to heat sink effect. Therefore, as opposed to RFA, MWA can be used to treat tumors larger than 3 cm and those near hepatic vessels with similar to improved recurrence rates [60]. Given these technical advantages, in addition to ease of use and shorter ablation time resulting in less procedural pain, there has been a shift from RFA toward MWA over the past few years [60]. In a recent meta-analysis, median 5-y OS was 43% for RFA versus 55% for MWA compared to 20% for chemotherapy alone [59].

Transcatheter Intra-arterial Techniques

Transcatheter intra-arterial techniques are reserved for patients with unresectable oligometastatic disease who are not candidates for ablative therapy and have failed systemic chemotherapy [7]. Transarterial chemoembolization (TACE) delivers chemotherapeutic agents (mitomycin, doxorubicin, cisplatin) emulsified with lipiodol, followed by delivery of an embolic agent, (traditionally polyvinyl alcohol or gelfoam) into the hepatic arteries supplying the liver tumors. Pioneered initially in the treatment of hepatocellular carcinoma, it is considered a salvage option for patients with liver-limited mCRC who fail systemic chemotherapy. Not surprisingly, OS rates are low with median survival between 8 and 9 months [59, 67, 68]. Side effects include fever, right upper quadrant pain, nausea, and vomiting known collectively as "post-embolization syndrome."

Recently, drug-eluting beads (DEBs) have replaced polyvinyl alcohol or gelfoam as embolic agents, allowing a slower and more sustained release of chemotherapeutic drugs directly

into the liver tumors, theoretically reducing systemic drug exposure and side effects (DEB-TACE) [59, 69]. Irinotecan-loaded DEBs (DEBIRI) are the most widely studied for the treatment of liver metastases in CRC. Toxicity rates average 10% with OS of 16 months [69]. Martin et al. [70] randomized 70 chemo-naïve patients with unresectable CRC hepatic metastases to FOLFOX+bevacizumab vs FOLFOX+bevacizumab+DEBIRI (FOLFOX-DEBIRI). Higher response rates were demonstrated in the FOLFOX-DEBIRI group at 6 months (P = 0.05) with a significant improvement in downsizing to resection in the FOLFOX-DEBIRI arm (35%) versus the FOLFOX-alone control arm (6%; P = 0.05). However, there was no difference in progression-free survival and no data presented on OS. Further studies are needed to define the role of DEB-TACE in the treatment of patients with hepatic CRC metastases.

Transarterial radioembolization (TARE), also known as selective internal radiotherapy (SIRT), utilizes microspheres loaded with a radioisotope to deliver high doses of radiation to liver tumors through an intra-arterial, catheter-based technique. The commonly used radioisotope is ß emitter yttrium-90 (^{90}Y). TARE was one of the initial transcatheter techniques utilized as a salvage option for patients who failed systemic chemotherapy. Response rates vary between 35% and 40% with a median survival between 8 and 14 months [59]. Recent analysis of three RCTs (FOXFIRE, SIRFLOX, and FOXFIRE-Global) demonstrated higher toxicity and no difference in OS with the addition of SIRT ^{90}Y compared to FOLFOX alone in 1103 patients with liver-only and liver-dominant metastatic CRC [71]. As such, the exact role of this technique in the armamentarium of treatment modalities for patients with metastatic CRC remains to be seen.

Stereotactic Body Radiation Therapy

Stereotactic body radiation therapy (SBRT) is an extremely precise form of external beam radiation that utilizes sophisticated 4D CT imaging to deliver intense doses of radiation (Fig. 31.5). In the case of hepatic metastases, patients are immobilized in a thermoplastic body mask using a Styrofoam block for abdominal compression and receive 25Gy in three consecutive daily fractions for a total dose of 75Gy to the target [72]. Five-year follow-up from a Phase II trial on SBRT for unresectable liver metastases demonstrated median OS of 27.6 months with 5-yr survival rates of 18% [72]. Recently published data from two large international registries including over 400 patients with hepatic CRC metastases demonstrates median OS between 24 and 27 months after SBRT [73, 74]. These results are comparable to a median OS of 23.3 months demonstrated with oxaliplatin-based chemotherapy alone in patients with unresectable CRC metastases [71]. Therefore, it is unclear whether SBRT contributes to better survival over modern chemotherapeutic regimens in patients with unresectable hepatic CRC metastases.

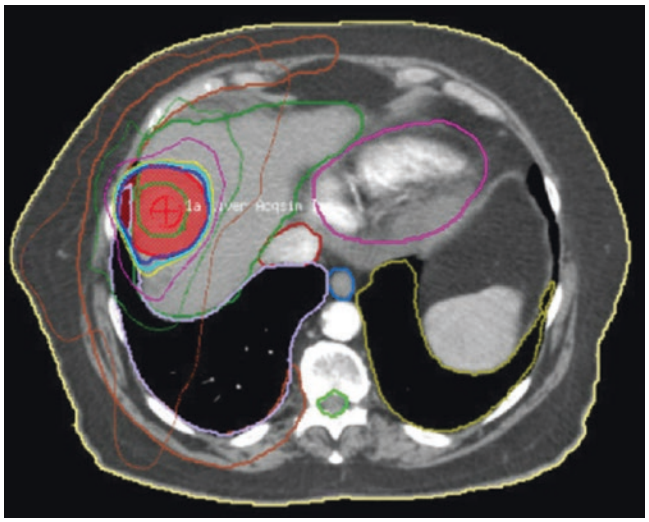

Fig. 31.5 Computed tomography image demonstrating the planning field for stereotactic body radiation therapy (SBRT) in a patient with hepatic metastases unfit to tolerate surgical resection

Lung Metastases

The lung is the second most common site of CRC metastatic disease, accounting for 22% of CRC metastases. In general, isolated lung metastases are associated with a better prognosis than isolated liver metastases with 5-yr OS up to 68% [5, 75]. Many of the same treatment modalities utilized with hepatic metastases are available for the treatment of pulmonary metastases including resection, ablative techniques, radiotherapy, and chemotherapy. Similarly, multidisciplinary input is essential.

Surgical resection of pulmonary metastases is a common practice. However, surprisingly there has not been a single prospective trial to evaluate the effectiveness of pulmonary metastasectomy (PM). Instead, practice patterns have been defined through retrospective series and several international registries, which are limited by selection bias, inconsistent systemic treatment, variable follow-up length, and a lack of comparative survival analyses [76]. There is an ongoing trial in patients with metastatic CRC randomizing patients to resection or surveillance (PulMiCC trial) [77]. Management decisions will depend on expert consensus and retrospective series until data from this and other prospective trials are available.

The Society of Thoracic Surgeons (STS) put together an Expert Consensus Task Force on Pulmonary Metastasectomy, which published a consensus document with treatment recommendations utilizing the modified Delphi method [76]. In addition, NCCN guidelines provide specific recommendations pertaining to pulmonary resection [7]. The goal of PM is complete resection based on the location and extent of the tumor with preservation of adequate functional lung. Most

pulmonary tumors are amendable to metastasectomy as opposed to formal lobectomy, while pneumonectomy is generally discouraged in the context of metastatic disease. There is no defined contraindication to PM based on the number of pulmonary metastases as long as an R0 resection can be achieved. Re-resection is appropriate in select patients assuming extrapulmonary disease is manageable [78].

Minimally invasive techniques for PM are preferred over the open approach [76]. The minimally invasive thoracoscopic technique presents a challenge for localization of small lesions. There are many different techniques for localization including finger or instrument palpation through port sites, percutaneous coils, wire localization, agar injection, and dyes. However, there does not seem to be a demonstrable difference between techniques [79].

Mediastinal LN metastases occur in up to 44% of patients with pulmonary metastases and are associated with worse survival [80]. Some advocate for routine LN sampling/dissection at the time of PM to provide prognostic information and influence decision-making with regard to systemic therapy following surgery [80]. STS guidelines suggest consideration of LN sampling/dissection at the time of PM. However, there was no uniform agreement with this recommendation [76].

PM is associated with low rates of morbidity (11%) and mortality (1.1%), with average LOS between 4 and 7 days in properly selected patients [81, 82]. As is the case with hepatic metastasectomy, chemotherapy can be administered before or after surgery based on multidisciplinary input.

STS guidelines suggest that ablative techniques and SBRT are both reasonable therapy for patients with oligometastases, particularly for high-risk patients or those who refuse resection. Compared to hepatic metastases, NCCN guidelines are not as definitive in recommending resection over other locoregional modalities in the management of pulmonary metastases. Rather, it is suggested that ablative techniques may be considered alone or in conjunction with resection for resectable pulmonary metastases [7].

Other Sites of Metastases

Ovarian Metastases

Approximately 5–10% of women with CRC develop ovarian metastases, with preponderance toward younger patients. The development of ovarian metastases is associated with a median survival of 19–27 months. Ovarian metastases can reach significant size before becoming symptomatic and are disproportionately unresponsive to chemotherapy compared to other sites of disease [83].

The term Krukenberg tumor has been loosely (and incorrectly) applied to all metastatic tumors of the ovary. However, true Krukenberg tumors are secondary carcinomas of the ovary that contain >10% mucin-filled signet-ring cells and are most commonly gastric in origin [84]. Hematologic spread accounts for the most common route of metastases in CRC as evident by the association of ovarian metastases with vascular invasion and low rate of lympho-angio invasion [85]. Primary ovarian metastases spread by transcoelomic dissemination, the spreading of tumor cells across the peritoneal cavity [86]. However, this does not seem to play a role in the majority of CRC metastases as evident by the smooth capsular surface of affected ovaries in the absence of surface tumor deposits.

It can be difficult to distinguish ovarian CRC metastases from a primary ovarian malignancy given that both ovarian primaries and CRC ovarian metastases tend to be large and unilateral. On histopathology, mucinous adenocarcinomas can be misinterpreted as ovarian primaries. Immunohistochemistry can help elucidate the diagnosis with ovarian adenocarcinomas typically exhibiting CK7+, CA 125+, CK20−, CEA−, and CDX2−, while the converse immunophenotype (CK20+, CEA+, CDX2+, CK7−, and CA 125−) is observed in metastatic CRC [87].

Synchronous ovarian metastases are more commonly encountered than metachronous ovarian metastases [88]. The indication for oophorectomy in the synchronous setting includes grossly abnormal ovaries or contiguous extension of the colorectal cancer into the ovarian capsule. While prophylactic oophorectomy of normal appearing ovaries was traditionally advocated to remove potential microscopic "undetectable" synchronous disease, this practice is no longer recommended. Specifically, NCCN guidelines state that "routine prophylactic oophorectomy is not necessary" [7]. It is reasonable to consider reoperation for oophorectomy in the metachronous setting given that ovarian metastases are less responsive to chemotherapy than other sites of disease and can grow quite large and symptomatic. This will, of course, depend on the performance status of the patient and the tumor burden elsewhere. The majority of patients with ovarian metastases will have extraovarian metastases, and residual disease after surgery is associated with worse survival. As with all other sites of metastases, overall survival is improved if an R0/R1 resection can be achieved [83].

Brain Metastases

Approximately 1–4% of patients with CRC will develop brain metastases, which are generally seen in the context of diffuse widespread metastases. Rarely, patients can present with isolated brain metastases. Given the infrequency of brain metastases, brain imaging is not routinely performed on initial staging or during metastatic workup in the absence of neurologic signs or symptoms. Treatment options for patients with

brain metastases include a combination of surgery, whole-brain radiation therapy (WBRT), and stereotactic radiosurgery (SRS). Surgery is preferred in the case of an isolated brain metastasis. However, surgical resection of a single brain metastasis is associated with a 50–60% risk of local recurrence within 1 year [89]. SRS has replaced WBRT in the adjuvant setting to reduce the risk of local recurrence due to its improved side effect profile [89, 90]. SRS is also indicated for small unresectable solitary tumors or in patients with a limited number of brain metastases that are <3 cm in diameter. WBRT is an option for patients with multiple intracranial metastases who are not candidates for surgery or SRS. However, it is associated with significant side effects (fatigue, alopecia, neurocognitive decline), and does not improve OS [91]. Palliative options include steroids to reduce peritumoral edema and anticonvulsants for seizure prophylaxis.

Adrenal Metastases

Adrenal metastases are uncommon in the setting of metastatic colorectal cancer and usually develop late in the course of the disease. Surgery is rarely an option, although there are case reports of prolonged survival following resection of isolated adrenal metastases [92].

Surveillance

There is a paucity of data to guide posttreatment surveillance in patients with metastatic CRC who were treated with curative intent. NCCN guidelines suggest utilizing the same strategy as for Stages II and III CRC with the exception of more frequent cross-sectional imaging [7]:

- History and physical every 3–6 months for 2 years and then every 6 months for a total of 5 years
- CEA every 3–6 months for 2 years and then every 6 months for a total of 5 years
- Chest/abdominal/pelvic CT scan every 3–6 months for 2 years and then every 6–12 months for a total of 5 year
- Colonoscopy 1 year after surgery

Conclusion

Treatment of advanced colorectal cancer has evolved significantly over time reflecting a shift toward more aggressive therapy recognizing the potential for long-term survival. The complexity involved in managing patients with advanced colorectal cancer relies on multidisciplinary collaboration to develop an individualized treatment scheme that takes into account the patient's goals and objectives.

Locally Recurrent Rectal Cancer

32

Michael J. Solomon

Key Concepts

- Local recurrence of rectal cancer is an extra-total mesorectal excision (TME) pathology and differs inherently to advanced primary rectal cancer with respect to treatment planning and management, as well as surgical training.
- Surgery for recurrent rectal cancer requires meticulous planning and is based on magnetic resonance imaging (MRI) and requires multidisciplinary team (MDT) interpretation and collaboration.
- Surgeons embarking on recurrent rectal cancer operations must be adept at resecting the anterior, lateral, and posterior pelvic compartments.
- Circumnavigate the involved pelvic compartment—operate in virgin planes.
- Gain proximal and distal control of organs, vessels, and nerves prior to final resection.
- If recurrence abuts an organ, vessel, nerve, or structure, then resect it, and avoid "close shaves," which risks an involved margin. R0 resection predicts both survival and quality of life.
- Posteriorly the pelvic floor is the site of recurrence. It arises from the sacrum (S3 down) and the sacrospinous ligament out to the ischial spine and abuts the piriformis muscle laterally and the obturator internus muscle anteriorly.
- When considering surgical anatomy, the ischial spine is the center of the lateral pelvic compartments, while the urethral orifice (as it passes through the pelvic floor) is the center of the anterior compartment.
- En bloc common and external iliac artery and vein excisions can be performed with R0 rates and survival comparable to more central recurrences and with good arterial graft patency but high rates of venous graft thrombosis. Consideration should be given to venous ligation without reconstruction after excision.

Introduction

Dozois and Colibaseanu performed an excellent review of the management of locally recurrent rectal cancer (LRRC) in the previous edition of the *ASCRS Textbook of Colon and Rectal Surgery* (2016) [1]. The aim of this review is to provide an update on progress made in the past few years, discuss ongoing controversial issues, as well as provide a practical guide to the surgical approaches to LRRC to be used as a complement to the previous detailed review. Despite the worldwide adoption of the principles of total mesorectal excision (TME) and a more expanded usage of preoperative neoadjuvant therapy in lower and more advanced rectal cancers, the reported rate of local recurrence is still about 10% in most unselected series [2–5]. In the last decade, there has been an increasing experimentation with minimally invasive techniques for primary rectal cancer such as laparoscopic and robotic surgery and transanal TME (taTME), as well as organ-sparing techniques such as transanal endoscopic microsurgery (TEM), transanal minimally invasive surgery (TAMIS), and "watch-and-wait" nonoperative approaches to rectal cancer, which arguably may produce a significant increase in the need for radical salvage surgery in the immediate future [6–9]. While these various approaches are admirable, none have demonstrated benefit in randomized trials where small but clinically significant differences in local recurrence remain important.

Exenterative surgery is now well established as the treatment of choice for patients with LRRC and represents the only chance of cure for this group of patients. In patients who undergo radical surgery with clear resection margins, 40–50% overall survival at 5 years can be expected, which is comparable to the outcomes of patients with primary colorectal cancer who undergo excision of hepatic or pulmonary metastases [10–13]. Patients who do not undergo surgery may develop malignant fistulae and obstruction and neuropathic pain due to nerve, muscle, and bone infiltration. Palliative resectional surgery, including exenteration, has yet

S. R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, https://doi.org/10.1007/978-3-030-66049-9_32

to be shown to actually palliate symptoms in terms of return to baseline quality of life despite modest survival advantages and should only be offered selectively [14].

General Considerations

The previous iteration of the ASCRS textbook proposed quite accurately that several centers around the world were achieving excellent results in situations that were previously believed to be absolute contraindications for curative surgery. They also put forward that lateral neurovascular resection and composite sacrectomy should only be undertaken at these higher-volume specialized centers. In 2020, we would argue that pelvic exenterative surgery for LRRC is fundamentally a different operation to exenteration for advanced primary rectal cancer and that all centers who embark on recurrent rectal cancer surgery should not only be competent but also expert in the lateral and posterior pelvic compartments.

Advanced primary rectal cancer sometimes breaches the mesorectal fascia, extending into the surrounding pelvic compartments and organs (T4). In contrast, almost by definition, local recurrence that develops following adequate proctectomy develops in the extra-mesorectal planes of the pelvic floor muscles, the presacral fascia, and the lateral compartment, including the iliac vessels and piriformis muscle, and deeper neurovascular structures posterolaterally including the sacrospinous and sacrotuberous ligaments. The pelvic floor continues anteriorly, and more laterally the obturator internus muscle and ischial and pubic bones become the important anatomical landmarks for dissection and resection for the recurrent rectal cancer surgeon. These are the most difficult surgical planes of the pelvis, and with the added complexity of redo surgery and post-radiotherapy fibrosis, pelvic exenteration for LRRC can be the most challenging of pelvic operations. Complete soft tissue pelvic exenteration for an advanced primary rectal cancer, while having obvious implications for the patient's quality of life with two stomas, remains a relatively straightforward procedure for an experienced exenteration surgeon and may be taken on by a colorectal surgeon trained in advanced rectal cancer surgery in combination with a urological colleague. These procedures, based on the central and anterior compartments, only become more challenging when a more radical perineal resection is required with complete vaginectomy, perineal urethrectomy with or without penectomy in males, or pubic bone resection.

While isolated iliac nodal and anastomotic recurrences are the simplest to excise, they are much less common in our experience and are perhaps still operated upon by the original "TME surgeon." The mindset of the "TME surgeon" exploring focally outside their realm in LRRC is fundamentally a flawed surgical plan in 2020. While this approach is often adequate in advanced primary rectal cancer, it will undoubtedly lead to low R0 resection rates in LRRC. This is contrasted by the increasingly radical approach by surgeons at specialized centers, where the R0 resection rates for LRRC have climbed from well below 50% in the mid-2000s to 70% as we approach the end of the current decade [13, 15–17]. In a recent review of well over 200 recurrent rectal cancer exenterations at our unit, 49% required total cystectomy, 58% required sacrectomy, and 73% involved the lateral compartment (defined as at least complete excision of the internal iliac vasculature) [17]. Major lumbosacral or complete sciatic nerve excision was performed in 38% of the cohort.

Patterns of Local Recurrence and Anatomical Considerations

Multiple classification systems have been proposed by various groups worldwide for exenteration, and these are often derived from the individual unit's current surgical expertise and opinions as to what is a contraindication to surgery, and none work truly well for LRRC [2, 18–22]. Confusion with the historical gynecological concept of exenteration, which was based on the uterus as the central component of the classification, leads to further disparity between what is considered the anterior and posterior pelvic compartments and indeed the definition of a pelvic exenteration. For the colorectal surgeon, an exenteration usually focuses on the rectum or previous rectal site (neorectum, anastomosis, or central pelvic floor scar post abdominoperineal excision) as the anatomical center of all classifications. None of these current systems have been universally adopted, and perhaps a different classification for advanced primary to recurrent rectal cancers should be considered. Classification systems for LRRC need to incorporate the important technical considerations in exenterative surgery: the extent of local invasion into adjacent organs and involvement of the neurovascular structures of the pelvic sidewall and the bony pelvis. These considerations influence the technical difficulty of achieving R0 resection and the functional consequences that will be envisaged for the patient, as well as the need for urological, perineal, vascular, and orthopedic reconstruction.

The pelvic floor and its bony attachments are the core determinants of our current classification system for LRRC and the extent of exenterative surgery [15, 23]. The five pelvic compartments can be subdivided into a supra- or infralevator section with reference to the pelvic floor. The anatomical compartments of the pelvis are illustrated in Fig. 32.1. Understanding, as most colorectal surgeons do well, the structures that abut the original TME plane of dissection allows the exenteration surgeon to conceptually plan the subsequent resection. Historically, 50% of recurrent

tumors operated upon are located in the center of the pelvis and are generally peri-anastomotic recurrences of the neorectum or arise from the rectal scar (after previous abdominoperineal resection) [10]. In our experience, true isolated anastomotic recurrences are unusual. Central tumors may involve the vagina and uterus in women or the prostate and seminal vesicles in men as well as the urinary bladder (i.e., extend into the anterior compartment) and are generally resectable by complete or total "soft tissue" exenteration. In the infralevator anterior compartment of the male, one must understand the anatomy of the membranous urethra as it exits the prostate and that this plane will be encroached upon when a routine cystectomy is performed. This should be considered when planning a soft tissue exenteration for LRRC, particularly after previous abdominoperineal excision [24, 25]. Where the tumor extends to the anterior boundary of the pelvis (the pubic rami and symphysis), radical anterior bone resection may be necessary (Fig. 32.2a) [24, 25]. Posterior recurrences sit on and usually infiltrate the presacral fascia, the sacrum, and its nerve roots and often necessitate en bloc sacrectomy in order to achieve clear resection margins (Fig. 32.2b). Lateral compartment recurrences require radical resection of the iliac vasculature, lumbosacral trunk, or sciatic nerve, sidewall muscles, and ligamentous structures (Fig. 32.3).

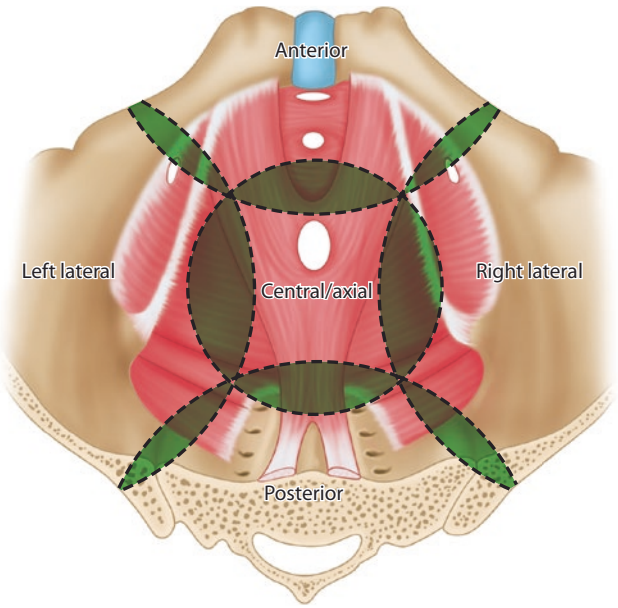

Fig. 32.1 The anatomical compartments of the pelvis

Patient Selection and Treatment Planning

The detection and confirmation of LRRC are often more difficult than expected, as in many patients, there is no luminal component of the recurrent tumor that would be readily identified at endoscopy and symptoms, if present, are often nonspecific. Confirmation is best done with biopsy of abnormal areas identified on radiographic imaging, but in some cases, it is difficult or potentially dangerous due to the biopsy path crossing vessels and bowel loops. In these cases, a combination of radiological changes with ^{18}F-fluorodeoxyglucose uptake on positron emission topography (PET) may be the best available evidence of recurrence and sufficient to initiate treatment. Once local recurrence is confirmed and the patient

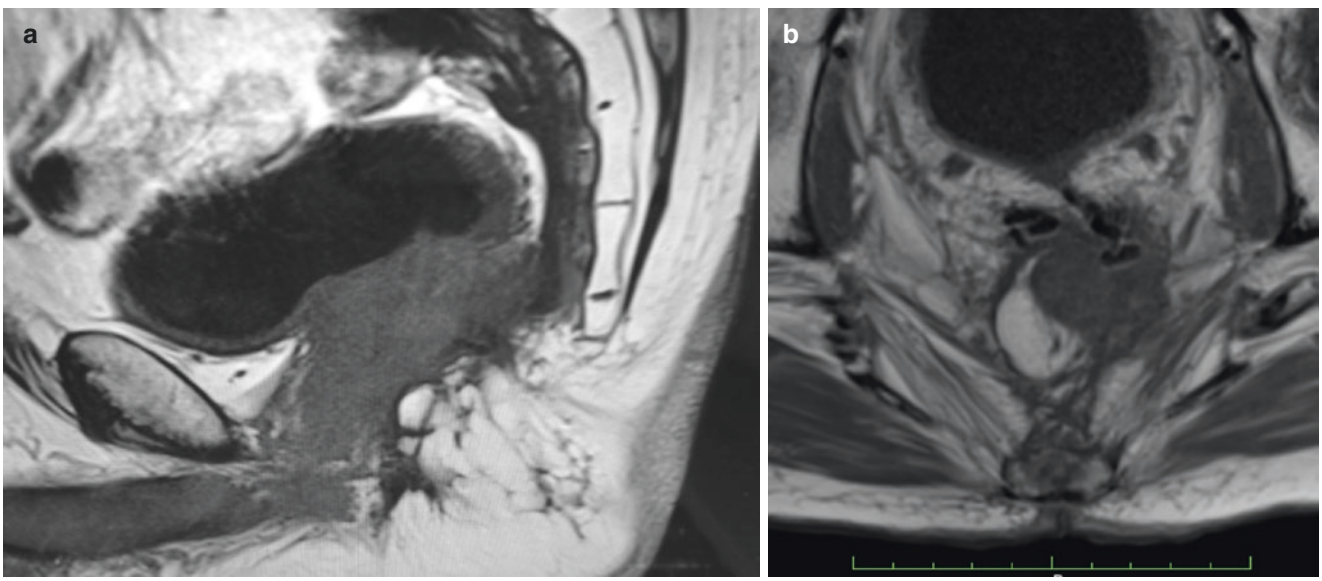

Fig. 32.2 (**a**) Recurrent rectal cancer after previous abdominoperineal resection, encasing membranous urethra extending to the base of the penis and posteriorly along pelvic floor to presacral fascia. (**b**) LRRC extending from the sacrum in posterior compartment along the left sacrospinous ligament approaching the ischial spine and invading the left seminal vesicle

is considered a potential candidate for exenteration and if metastatic disease is either absent or resectable, then discussions with the patient and family should commence in order to ensure their wishes for radical treatment are appropriately considered. In patients with true isolated pelvic recurrence referred for MDT assessment at our unit, about one in five patients will choose to pursue only palliative approaches despite being deemed suitable for attempt at curative exenteration.

Imaging

PET-CT combined with MRI is undoubtedly the mainstay of assessment of LRRC at the initial diagnosis, for excluding metastatic disease and for meticulous surgical planning [12, 26–28]. PET can be helpful in the identification of metastatic disease as it may detect small lesions not seen on CT [29], and it is also useful when post-radiation changes cannot be differentiated from tumor on MRI. MRI is important in not only confirming recurrence but in surgical planning. MRI has high positive (100%) and negative (89%) predictive values for the diagnosis of LRRC [30], and while it can accurately identify tumor invasion of major central pelvic organs, its accuracy declines when delineating infiltration of the smaller pelvic sidewall structures [31, 32]. In our recent review of preoperative MRI in patients with LRRC, predicted involvement of either the high sacrum or lateral compartment was associated with involved resection margins. On this basis, a more extensive resection should be planned when there is the possibility of posterior or lateral compartment involvement on MRI, rather than trying to "shave" a tumor off an involved structure which may result in R1 resection [33].

Multidisciplinary Team Assessment

Patient assessment for radical salvage surgery should be conducted by a dedicated multidisciplinary team (MDT). A major aim of any oncological MDT is to select appropriate patients for surgery. This exercise will hopefully minimize non-curative (R2) resections as well as operations which are aborted intraoperatively due to occult metastases or an unexpectedly unresectable tumor. Assessment of MDT decisions and referral patterns at our center have confirmed the determinant of resectability was about 70:30 in patients referred for consideration of exenteration and was not changed whether the exenteration surgeon had consulted with the patient before or after the MDT. This implies the MDT process is discriminatory and validates the importance of the multiple experts who have input at an exenteration MDT [34]. In a review of R1 resections for recurrent rectal cancer, we found perioperative miscommunication between the various involved physicians could negatively influence R0 resection rates [35].

A dedicated MDT is optimally attended by specialist colorectal, urological, orthopedic, vascular, and plastic surgeons, medical and radiation oncologists, a radiologist, psycho-oncologist, pain specialist, and palliative care and various allied health staff including care coordinators, stomal therapy nurses, dietitians, psychologists, physiotherapists, and research/audit officers. The availability of these personnel would depend on the number and extent of resections undertaken and local availability. Patient access to referral pathways and pelvic oncology MDTs remains a major issue, with recent data from Sweden indicating that fewer than one third of patients with LRRC nationally were discussed at an MDT prior to exenterative surgery [10]. These studies collectively confirm the importance of the MDT process in recurrent rectal cancer and the benefit of communication derived from the MDT.

Resectability

The definition of "resectable" LRRC has changed significantly in recent decades and continues to evolve [27, 36, 37]. In 2020, the indication for extended radical resection for

LRRC is a predicted R0 resection with acceptable anticipated morbidity in an appropriately consented and motivated patient.

LRRC infiltrating the lateral pelvic compartment and in particular the iliac vessels and major nerves of the pelvic sidewall had been considered unresectable until recently [20, 22, 27, 38, 39]. Development of a more radical approach to the lateral compartment in the last decade has led to significant improvements in R0 resection rates for tumors which invade the major neurovascular structures of the pelvic sidewall. By ligating and dividing the internal iliac vessels close to their origin, the surgeon can enter the undissected plane lateral to the vessels on top of piriformis fascia which allows the vessels to be readily excised en bloc with the recurrent tumor. Recent data from our unit shows an R0 resection rate of 69% in the lateral compartment (compared to 21% in 2008) [40, 41], and similar findings have been reported by the Karolinska Institute [42]. En bloc resection of the common and external iliac vessels is feasible in selected patients where deemed necessary due to tumor effacement or invasion, with R0 resection rates reported at 38–58%. Excellent long-term vascular arterial graft patency following vascular reconstruction can be achieved, but venous graft patency has been suboptimal [43, 44]. Consideration of ligation of the common or external iliac vein after resection without insertion of interposition grafts should be considered due to the high occlusion rate and risks of thrombosis and pulmonary embolism and is our current policy. In many cases of venous involvement with LRRC, there are established collaterals which both contribute to the resultant graft thrombosis and fortuitously limit the venous leg swelling when only ligation is performed.

En bloc resection of the sciatic nerve and/or lumbosacral trunk for tumors which extend more laterally into the piriformis muscle has R0 resection rates similar to central pelvic tumors and functional outcomes better than anticipated [45–48]. Radical resection of the sciatic nerve (partial or complete) with or without resection of the sciatic notch can be done either through the abdominal perineal access or transgluteal/prone access championed in London [45]. Partial or complete sciatic nerve resection can be more easily performed by these approaches. Almost all patients (96%) who require a complete sciatic nerve resection are able to mobilize postoperatively with intensive physiotherapy and orthotics input [45]. Patients mobilize by fixation of their resultant foot drop using ankle orthotics and raising of the ipsilateral hip followed by locking of the knee joint with the quadriceps (femoral nerve) on landing (the so-called rolling gait of sciatic nerve palsy). While an initial temporary reduction in the patient's physical quality of life can be expected after surgery for sciatic nerve involvement, this returns to preoperative baseline within 12 months.

Posterior pelvic compartment tumors generally involve or efface the sacrum and require en bloc sacrectomy for tumor clearance. Low sacrectomy (below S3) is now performed routinely by exenteration surgeons with relatively low complication rates, whether performed prone or in the abdominolithotomy position [49]. High sacrectomy (transection above S2/S3) remains controversial; however, several units have developed experience with this composite technique [50–53]. A recent international multicenter collaboration demonstrated that high sacrectomy can be performed without compromising rates of R0 resection and cancer-specific or overall survival [54]. High sacrectomy was, however, associated with higher blood loss, increased risk of complications, and obviously more sacral neurological impairment [55]. High sacrectomy should therefore no longer be considered a contraindicated procedure, although it does require consideration of the added morbidity during the consent process.

Metastatic Disease

Up to 40% of patients with LRRC will also have metastatic disease detected at the time of diagnosis [56, 57]. Salvage pelvic surgery is generally not pursued in the setting of unresectable metastases. Where isolated metastases are resectable, metastasectomy may be performed before or after local salvage surgery, but synchronous metastasectomy is generally avoided. Liver and/or lung surgery should typically occur before the exenteration due to the longer surgical recovery after pelvic exenteration. Delays prior to metastasectomy are associated with greater risk of cancer mortality.

Neoadjuvant and Intraoperative Treatment

Long-course neoadjuvant chemoradiotherapy is recommended prior to surgery for all patients with LRRC who did not undergo neoadjuvant therapy for treatment of their primary rectal cancer. Re-irradiation, intraoperative brachytherapy, and adjuvant chemotherapy remain contentious issues in recurrent rectal cancer and are the focus of international collaborative efforts and have been dealt with in the extensive review in the previous ASCRS textbook [1]. The appropriate balance between additional morbidity and improved local control has yet to be determined [58, 59].

Technical Considerations

While pelvic exenteration represents a heterogeneous and varied group of procedures, all salvage operations for LRRC can be considered in three phases: an initial *dissection phase* beginning with abdominal exploration to exclude metastatic disease, including extensive adhesiolysis of the small bowel with a meticulous "patience" to minimize the risk of

enterotomy and subsequent enteric fistulae, followed by ureterolysis and operative drainage of ureters with catheters if a conduit is planned, proximal and distal vascular control for planned resection of vessels, or just control of hemorrhage during lateral and posterior resections. Obliterated planes in the pelvis can be expected due to previous dissection of the mesorectal plane and fibrosis secondary to radiotherapy, so wider virginal planes to circumnavigate the most difficult compartment(s) are the safest approach to a hostile pelvis. Once the dissection has proceeded as far as possible, with proximal control of the bowel, ureters, and vessels, a *resection phase* begins where the tumor is excised with all contiguously involved structures. The final phase is the *reconstruction phase* which involves hemostasis, urinary and fecal conduit construction, or ureteric and/or bladder repair. Mesh reconstruction of soft tissue and bone defects as well as myocutaneous soft tissue reconstruction may be necessary in the reconstruction phase. The three-phase plan for exenteration involves a "6 C philosophy" coined by previous fellows in our unit: coherent plan, clear exposure, control (proximal and distal), circumnavigate the tumor, constantly reassess progress, and at all times be calm (additional latter "c" depending on surgeon personality!).

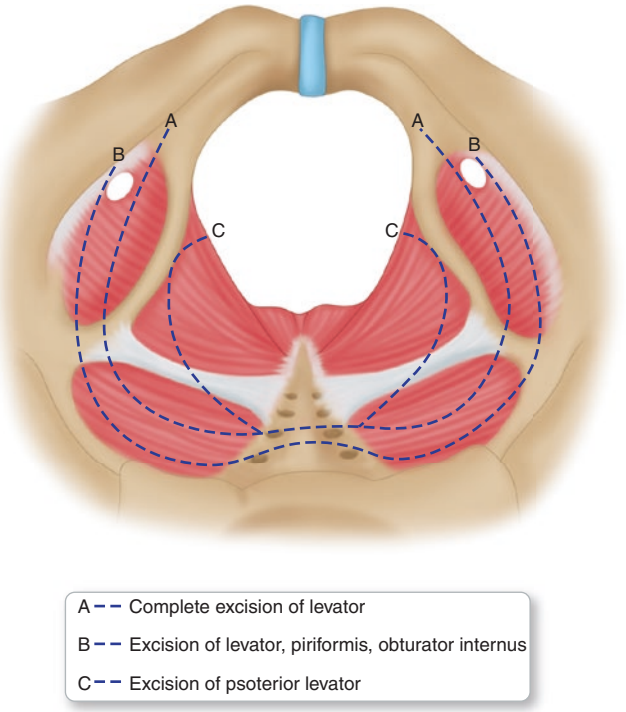

Fig. 32.4 Planned resection planes of the posterior and lateral compartments

Preparation

Safe and effective exenterative surgery relies on intra- and interdisciplinary teamwork. At our unit, two consultant colorectal surgeons are present for all cases where long procedures are expected and particularly for synchronous abdominal and perineal resection involving bone and/or lateral neurovascular structures. In 50% of recurrent rectal cancer, a urological surgeon is required for a conduit, and in a further 5–10%, the urologist is involved for reconstruction of the ureter with bladder re-implantation during the reconstruction phase. Support from orthopedic, plastic, and vascular surgeons is arranged in advance if their need is anticipated. Timing and planning are critical for surgical collegiality and anesthetic planning. Preoperatively the operative team reviews the imaging and revisits the operative plan developed at the MDT. This ensures there is a coherent plan which has been communicated to all members of the operative team (Fig. 32.4).

Positioning

The patient is placed on a nonslip gel mattress in the modified Lloyd-Davies position. The gel mattress distal end is rolled back over 10 cm, or a rolled towel is placed under the patient in the lumbar curve in order to raise the pelvis free of the operating table when an abdomino-lithotomy sacrectomy is planned [45]. The gel mattress provides security from slippage when in steeper Trendelenburg and allows for perineal reflection of the gluteus muscles free of the sacral bone posteriorly without compression of the skin on the sacrum ready for transection. This maneuver provides support of the lumbosacral curvature during operative anesthetic paralysis and limits low back pain postoperatively. In order to limit fecal contamination, any existing intestinal stomas are covered with gauze and a sterile occlusive dressing, and the anus, if present, is sutured closed. Stoma site markings by the stomal therapist are reinforced, and the skin is marked by a plastic surgeon for harvest of a vertical rectus abdominis myocutaneous (VRAM) flap if the need for perineal reconstruction is anticipated. The anticipated new stoma marked sites after VRAM harvest need to be marked accordingly (Fig. 32.5). The lower limbs are prepped down to the knees if vascular reconstruction may be required, to allow access to the groin and thigh for harvesting of autologous vein grafts.

Exploration and Preparing the Pelvis

A midline laparotomy and meticulous adhesiolysis are performed in order to avoid inadvertent enterotomies. After unanticipated peritoneal and hepatic metastases are excluded, the small bowel is excluded from the pelvis. If the tumor involves a small bowel loop(s), the bowel is transected

Fig. 32.5 Operative markings of potential vertical or horizontal rectus abdominis myocutaneous flaps and the expected repositioning of stoma sites after harvest of flaps

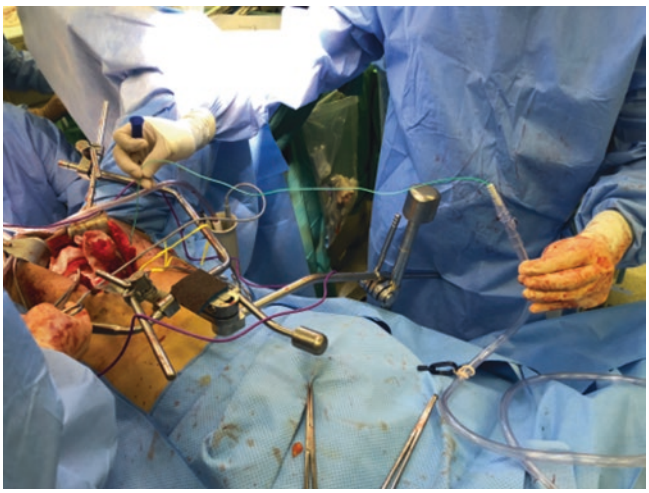

Fig. 32.6 Insertion of ureteric catheters during resection phase of exenteration prior to conduit fashioning in reconstruction phase

proximally and distally and excised en bloc. The ureters are identified proximally and dissected distally, over the pelvic brim, leaving a cuff of tissue surrounding each ureter to preserve their blood supply. If total cystectomy or ureterectomy is required, the ureters are divided as distal as possible, ensuring that only non-irradiated ureter is preserved for reconstruction. Infant feeding catheters are inserted into the proximal cut end of the ureter to allow monitoring of urine output during the resection phase and prevent back pressure on the kidney as acute tubular necrosis can occur during long operative times (Fig. 32.6).

Central Recurrences

Centrally located tumors, which do not involve the pubic bone anteriorly, lateral nerve or iliac vessels of the pelvic sidewall, or sacrum, may be completely excised by complete "soft tissue" exenteration. The posterior dissection commences first above the neorectum, if present, which is dissected free from the presacral fascia. Proceeding in an anterolateral direction, dissection continues in the extra-TME plane, and, after the peritoneum over the iliac vessels is incised, the vas deferens in males and round ligament in females need to be transected. The ureter is immediately deep to the peritoneum and can be retracted medially to give the surgeon access to the internal iliac vessels. The anterior division of the internal iliac artery gives rise to the named visceral branches (including the uterine artery and the superior and inferior vesical arteries) which are ligated and divided with their corresponding venous tributaries. After these vessels have been divided, the genitourinary organs can be retracted away from the pelvic sidewall to expose the obturator fossa including obturator internus muscle. Sidewall branches and tributaries of the internal iliac vessels are now accessible including the obturator vessels with the obturator nerve traversing the fossa to exit through the obturator canal. Care is taken if excising the obturator internus muscle with vessels and nerves, to ligate the vein carefully as the vein is friable post radiotherapy and retracts into the canal with potential venous oozing deep into the bony canal which can be difficult to access and control. The endopelvic fascia and the levator ani are exposed and are easier to resect abdominally under direct vision than the traditional approach from the perineum (Fig. 32.7). Anteriorly the bladder is mobilized by dissection in the prepubic plane, and the dorsal venous complex is ligated and divided. The dorsal venous complex and urethra may be transected during the abdominal phase if well clear of the recurrent tumor. Alternatively, this may be approached transperineally at the base of the penis (Fig. 32.2) [24]. Perineal urethrectomy allows a wider excision of the membranous urethra as well as minimizes bleeding from the dorsal venous complex which is always difficult in the abdominal radiated cave of Retzius (Figs. 32.1 and 32.7a, b).

Total cystectomy in the female with LRRC invariably coincides with extensive vaginal involvement. Preserving a functioning vagina that is radiated can be difficult once the anterior vaginal wall is resected with the urethra. An interlabial radical vaginectomy and cystectomy dissection plane

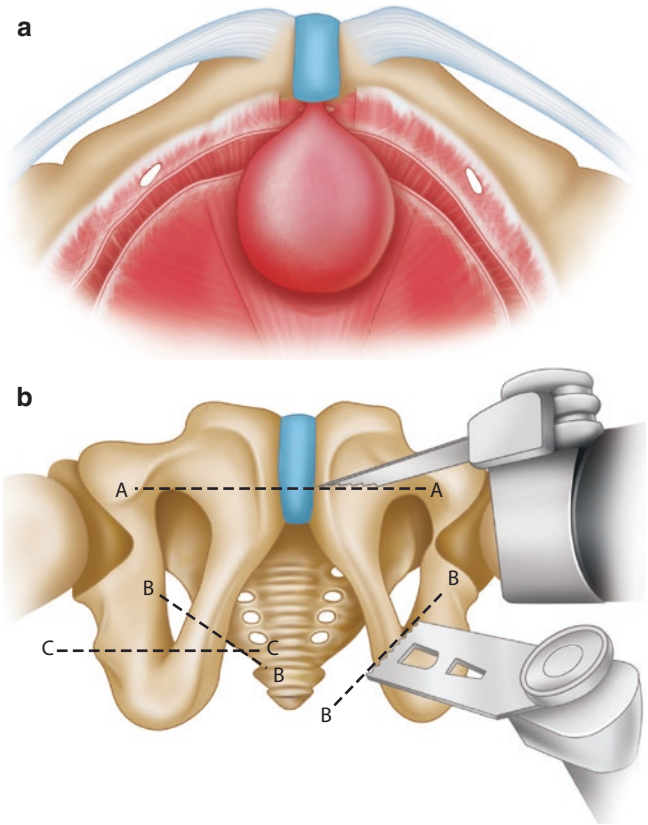

Fig. 32.7 (**a**) Incision of endopelvic fascia over levator and obturator internus muscle laterally. (**b**) Lines of transection of the pubic bone with oscillating saw

(Fig. 32.8a) provides a more radical margin and decreases the vaginal venous bleeding often encountered with subtotal radical vaginectomy. Preservation of the labia majora allows primary closure with no need for a myocutaneous flap (Fig. 32.8b) and arguably a much more cosmetic appearance than a flap (Fig. 32.8c). Neovaginal plastic surgical reconstruction (e.g., using the bowel) can be considered at the time of exenteration or in the future with utilization of the preserved labia majora. If the anterior vaginal wall remains with bladder preservation, then a myocutaneous flap is utilized to restore the posterior half of the vagina (Fig. 32.8d).

The perineal dissection is commenced by making an elliptical incision around the anus or old abdominoperineal resection perineal scar and extending the incision to the base of the scrotum or to include the introitus in females. Wide skin excision is not needed in tumors confined to the supralevator compartments and is usually only necessary if there is skin involvement by infralevator tumors. This is more commonly required in recurrent urogenital or anal SCC. After skin incision, however, a wide dissection through the ischiorectal fossae is carried toward the bony periphery of the pelvis. The bony landmarks of the coccyx, ischial tuberosities, and inferior pubic rami are the key to radical soft tissue planes. Soft tissue excision on the periosteum with high-powered diathermy in conjunction with assistance from the abdominal surgeon allows disconnection of the pelvic floor at the bony attachments of the levator plate defined by the preoperative MRI (Fig. 32.4). The perineal surgeon should approach this dissection anatomically rather than be guided by the abdominal surgeon to ensure predetermined MRI surgical margins are delivered. As a rule, the more pelvic floor, ligaments, and bone that can be disconnected and resected under direct vision by the abdominal surgeon, the clearer the margin is defined and improves the final combined resection. For tumors extending anterolaterally, the levator is released at its attachment to the inferior pubic rami with or without obturator internus more deeply. The abdominal and perineal surgeons continue dividing the pelvic floor until it is released circumferentially allowing delivery of the specimen. The extent of lateral and posterior resection, e.g., ischial bone, lateral neurovascular bundles, and sacrum, is defined by the preoperative plan and discussed below.

Composite Pubic Bone Resection

LRRC centered in the anterior compartment tends to be problematic following previous abdominoperineal excision for low rectal tumors in men and can involve the periosteum and fascia overlying and involving the pubic bone (Fig. 32.2b). Clear resection margins may only be achieved by radical pubic bone excision in this situation. This technique requires both en bloc pubic bone resection and perineal transection of the urethra at the base of the penis. In combination, these maneuvers allow an anterior margin beyond the pubic bone and membranous urethra [24, 25]. If pubic bone resection is not required, then dissection anterior to the bladder in the space of Retzius proceeds as usually but stops short of the inferior aspect of the pubic symphysis, without transection of the dorsal vein complex (Fig. 32.7a). Where pubic bone resection is required, the dissection stops above the point of tumor involvement (Fig. 32.4, line A). If total pubic bone resection is required, then the prepubic space is not entered but resected en bloc.

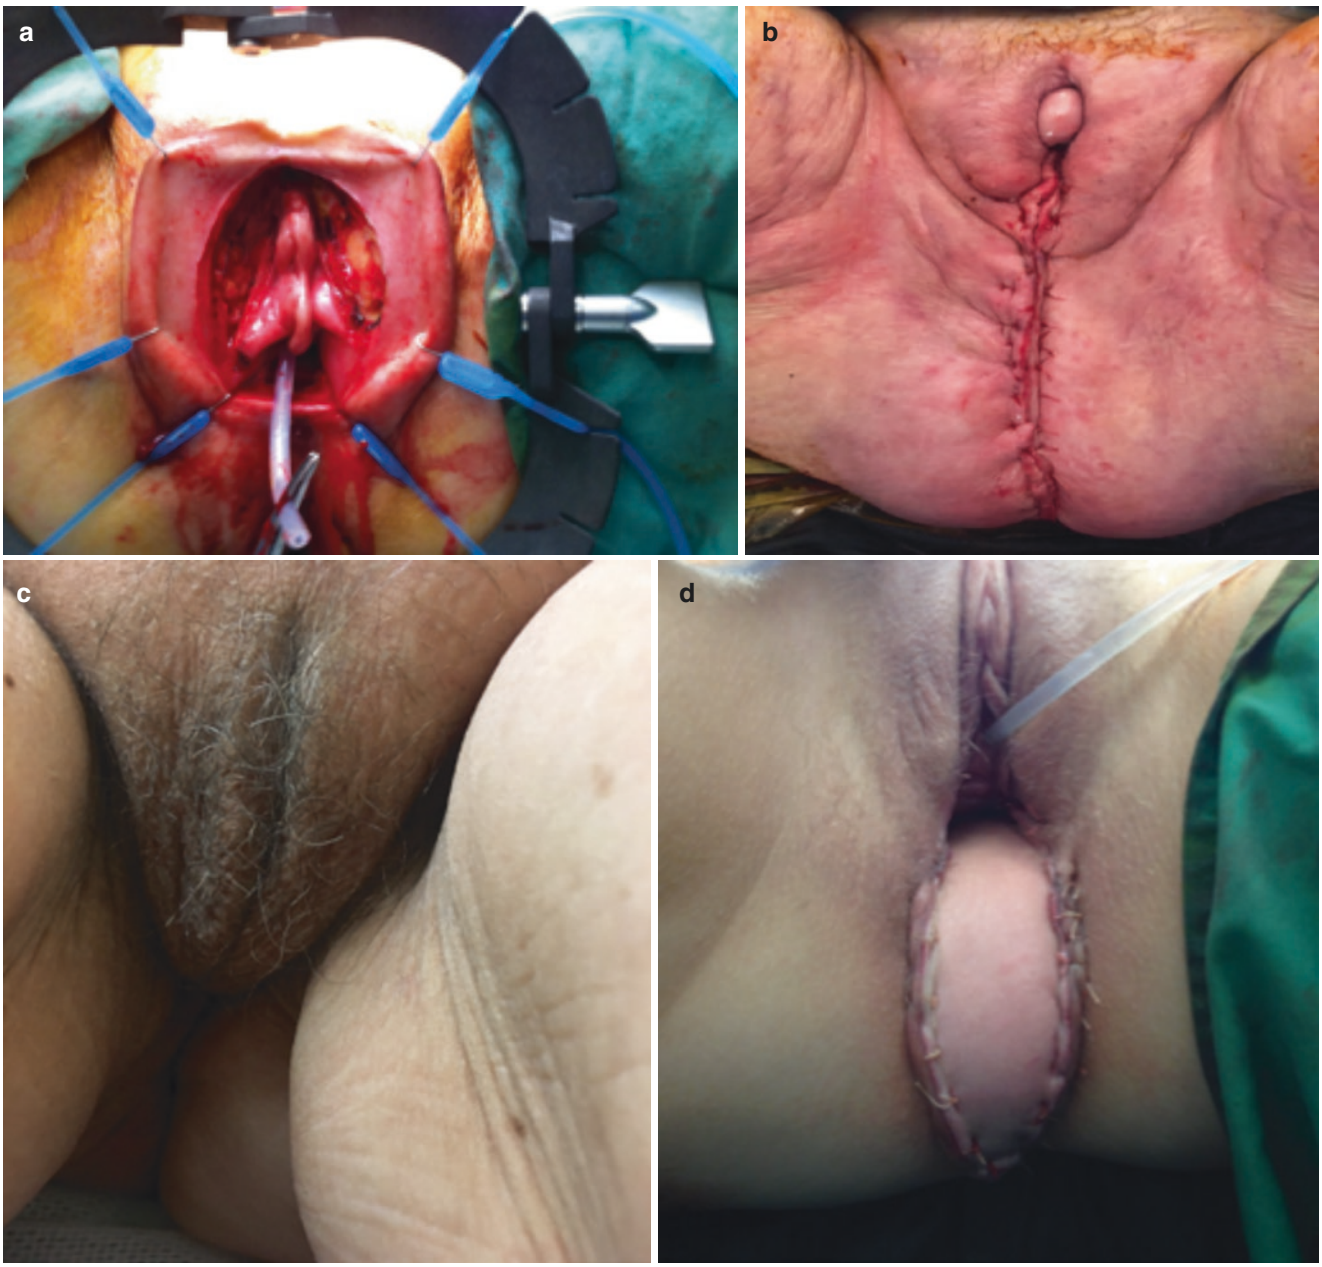

Fig. 32.8 Interlabial approach for radical vaginectomy with total cystectomy. (**a**) Incision between labia majora and minora. (**b**) Postoperative completed wound with clitoris preserved. (**c**) Long-term cosmetic appearance of healed wound. (**d**) VRAM flap posterior vaginal reconstruction

The perineal surgeon extends the skin incision toward the base of the scrotum, and the wide excision of the pelvic floor includes complete exposure of the inferior pubic rami out to the ischial tuberosities. With the base of the penis identified, the bulbospongiosus muscle, the dorsal venous complex, and the urethra (with the urinary catheter) are individually ligated and divided. This exposes the pubic symphysis, and, if required, a complete or partial pubic bone resection can be performed using an oscillating saw (Fig. 32.7b) [24].

Lateral Neurovascular Resection

En bloc internal iliac vascular resection is necessary for oncological clearance for laterally infiltrating tumors but is also required during high sacrectomy to "float" the common iliac vessels out of the pelvis and protect them during sacral transection from the prone approach and to minimize bleeding. For radiated and fibrosed vessels, starting the dissection of the common and external iliac vessels laterally in the

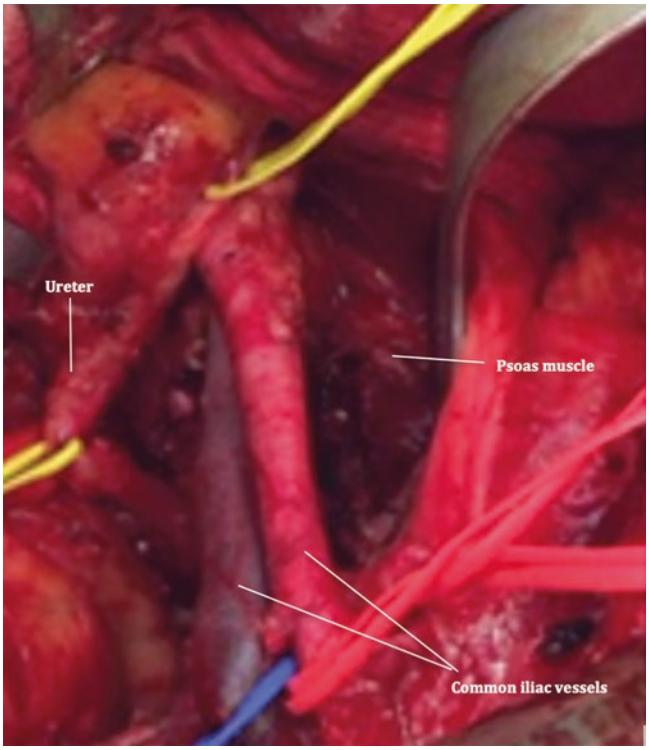

Fig. 32.9 The exposure of left lateral pelvic sidewall with left lateral compartment excision and common and external iliac vessels dissected free of psoas muscle laterally and ureter medially

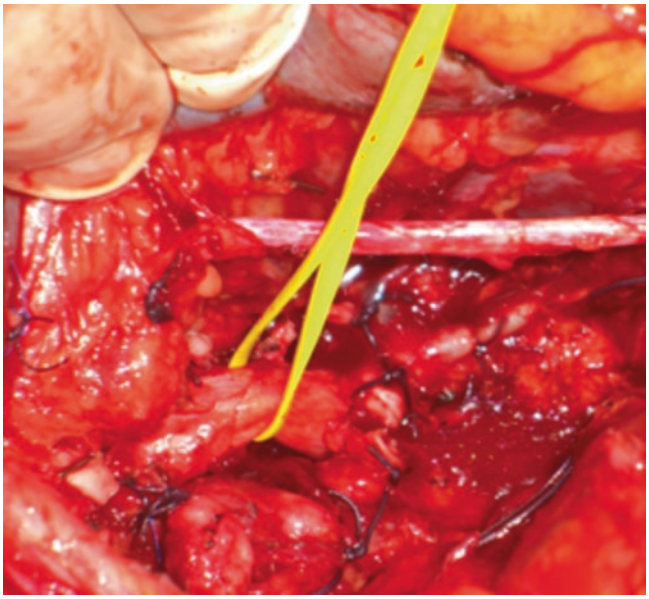

Fig. 32.10 A patient with locally recurrent rectal cancer: the left common and external iliac vessels have been "floated" out of the true pelvis (under surgeon's fingers), and the internal iliac vasculature has been excised en bloc with tumor. The piriformis muscle and fascia have been excised exposing the L5 nerve root with the exposed obturator nerve

plane medial to the psoas muscle on the bone similar to a lateral pelvic node dissection allows mobility in a virgin surgical plane (Fig. 32.9). Ligation and division of the internal iliac vessels close to their origin from the common iliac allows the lateral branches and tributaries (i.e., gluteal and ascending lumbar vessels) to be ligated and exposes the piriformis muscle, the lumbosacral trunk, and the sacral nerve roots which lie on the piriformis muscle. Care must be taken to identify and ligate these lateral internal iliac branches and tributaries, which can cause major bleeding which can be difficult to control if they retract back into the pelvic sidewall. The nerves lie deep to the piriformis fascia which needs to be incised to dissect the nerve roots and eventually leads down the ischial spine with the sciatic nerve exiting the pelvis posterolateral to this bone landmark. The obturator internus and piriformis muscles can be excised en bloc. If required to achieve a clear margin, the ischial spine can be excised en bloc using an osteotome with care taken not to go deeper into the sciatic nerve unnecessarily (this can also be performed using a Gigli saw). Once exposed, complete or partial sciatic nerve resection can be performed (Fig. 32.10) [45].

Extension of tumors outside the true lateral compartment can involve excision of the psoas muscle and dissection and/or resection of the femoral nerve. Identifying the femoral nerve is easiest just above the inguinal ligament lateral to where the external iliac artery becomes the common femoral artery. Incising the fascia overlying the iliopsoas muscle just above and parallel to the inguinal ligament will expose the femoral nerve. Superiorly at the origin of the psoas muscle at or above the L4–L5 vertebra level, the femoral nerve can be found between the larger anterior and smaller posterior muscle heads of the psoas muscle (Fig. 32.11).

Tumors that infiltrate or encase the common or external iliac vessels necessitate resection of the vessel with reconstruction [44]. Proximal vascular control must first be achieved by dissection at or just below the bifurcation of both the aorta and inferior vena cava as well as control of the distal external iliac vessels before transection (Fig. 32.9). Vessel reconstruction using autologous venous grafts is preferred due to concerns about graft infection after use of synthetic materials. Bovine pericardium is another alternative material used for interposition grafting.

Posterior Recurrences

LRRC involving the posterior compartment generally involves the presacral fascia, the sacrum, and its nerve roots, and composite distal sacrectomy is generally required to ensure a clear posterior resection margin. The nature of the previous posterior plane of the proctectomy dictates this close relationship to the sacrum above S3 and to the pelvic floor muscle as it originates from the S3 vertebra down. Abdomino-lithotomy sacrectomy is feasible if the level of sacral amputation is below S3 [49]. This allows the entire

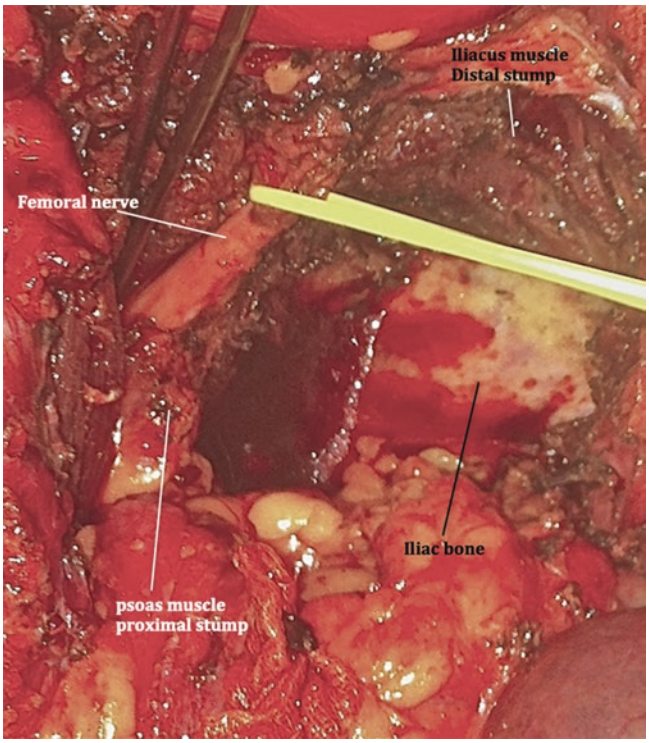

Fig. 32.11 Right femoral nerve identified in the psoas muscle after resection of iliopsoas muscle during extended lateral pelvic compartment resection

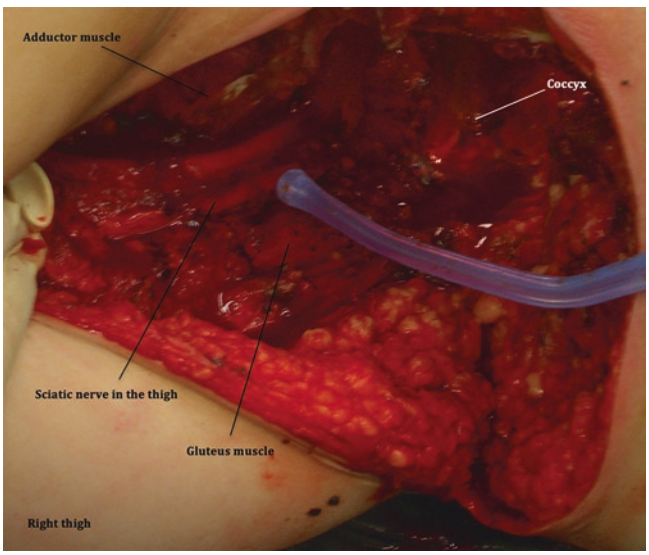

Fig. 32.12 Dissection of right sciatic nerve out from the pelvis into the thigh after excision of the ischial tuberosity in the abdomino-lithotomy position

operation to be performed in the abdomino-lithotomy position and does not require a prone phase. This preserves vascular control via access to the iliac vessels and allows better access to the sciatic nerve as it exits the pelvis more laterally than in the prone position (Fig. 32.12).

In preparation for sacrectomy, circumnavigation of the point of posterior bony fixation is required. This is achieved by circumferential dissection of the anterior and lateral compartment from the abdominal and perineal approaches, leaving the tumor attached only at the sacrum. For the abdominal surgeon, the posterior dissection between the neorectum or bladder after previous abdominoperineal resection and the presacral fascia stops above the level of tumor involvement according to the preoperative MRI. The level of sacral amputation is scored using high-powered diathermy and, if a prone sacrectomy is required, can be marked using a metallic sacral pin. Lateral dissection out to the ischial spine is necessary by following the sacrospinous ligament (Fig. 32.2) and transecting the ligament from the spine to free the sacrum prior to transection. Identification of the lumbosacral trunk, upper sacral nerve roots, and sciatic nerve as it starts in the thigh is critical at this stage. The perineal dissection is in the plane posterior to the coccyx and continues cephalad on the bone releasing the fibrous attachment of gluteus muscle to periosteum up to the level of S2. During this phase, all ligamentous and muscular attachments to the sacrum and coccyx are dissected free. The support of the lumbar groove on a rolled edge of a gel mattress or rolled towel allows the sacrum to be free posteriorly and is essential at this point; otherwise the gluteus muscle, sacral skin, and subcutaneous fat are compressed against and inseparable from the sacrum and coccyx due to the weight of the patient directly on the operating table [49]. After freeing the gluteus and overlying skin from the bone, the perineal surgeon places an osteotome posterior to the sacrum to protect the post-sacral skin, before the sacrum is transected transversely by the abdominal surgeon using an osteotome and mallet, allowing delivery of the specimen through the perineal wound.

Where high sacrectomy (i.e., sacral transection at or proximal to the S2/S3 junction) is required, the patient is turned prone in the jackknife position. With the assistance of an orthopedic spinal surgeon, a longitudinal incision is made over the sacrum which may be continuous with the perineal incision. The remaining attachments of the gluteal muscles are disconnected posteriorly, and after the level of sacral transection is confirmed by intraoperative fluoroscopy, a laminectomy is performed. Transverse osteotomies are made, and the sacrospinous and sacrotuberous ligaments are transected in order to allow delivery of the specimen. The sciatic nerve is preserved where possible although identifying the nerve roots is difficult in the prone position even with fluoroscopic confirmation of the vertebral level. Prior abdominal dissection of the lumbosacral trunk on the piriformis muscle and vessel looping the L5 and S1 nerve roots prior to the prone phase help confirm their identity prone and protect them from inadvertent injury or transection.

Where a central recurrence involves the presacral fascia and sacrum at a high level but centrally between the foram-

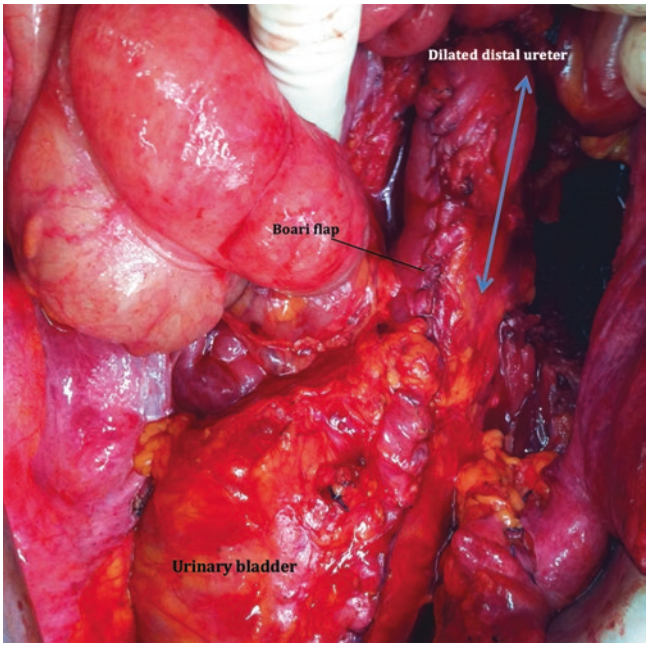

Fig. 32.13 Boari flap (arrow) ureterocystostomy reconstruction post left distal ureterectomy and partial cystectomy

ina (L5, S1, and S2) and without deep infiltration well into the vertebral body on MRI, anterior cortical sacrectomy is possible by making partial-thickness osteotomies around the point of involvement and allows the sacral nerve roots to be preserved [60, 61]. This central high cortical resection can be continued caudad with full-thickness bone transection en bloc below the level of the sacroiliac joint (S3) while remaining in the abdomino-lithotomy approach.

Reconstruction

The extent of reconstruction required depends on the organs, vessels, and soft tissues that require resection during the resection phase. Vascular surgery input may be required for interposition graft reconstruction if complete resection of the common or external iliac artery or vein was necessary [43, 44]. In an attempt to reduce limb ischemia time, vascular reconstruction is performed as soon as possible after vessel transection with a view to reduce the risk of thrombosis and compartment syndrome during long surgery time particularly with the legs elevated in lithotomy. Ureteric re-implantation with or without a Boari flap is necessary following partial cystectomy (Fig. 32.13). There are four options for urinary diversion following total cystectomy: the isolated ileal conduit, isolated colonic conduit, in-continuity colostomy and conduit ("wet colostomy"), and separated colonic colostomy and conduit with communal exit (Fig. 32.14a–d). The choice of conduit formation can depend on the radiation effects on the small bowel as well as previous bowel resections but usually follows local urological preferences. Colonic conduits have the advantage of avoidance of intestinal anastomosis and risk of subsequent anastomotic leak. Urinary reconstruction can be performed at the same time as primary perineal closure, or after a VRAM flap is harvested if required, while it is being inset.

Postoperative Management

Patients undergoing exenterative surgery at our center are routinely admitted to the intensive care unit postoperatively. All patients commence total parenteral nutrition on postoperative day 0 due to the high rate of malnutrition in patients with advanced pelvic malignancy and the risk of prolonged ileus in this patient population. Limb observations are necessary every 4 hours for the first three postoperative days in patients with arterial resection and reconstruction, and these patients also require compression stockings. In patients with urinary conduits, the creatinine level in the abdominal drain fluid is checked on days 1 and 5 in order to detect early urine leaks [62], and ureteric catheters through the conduit are removed on days 10–14 with or without a prior fluoroscopic contrast imaging to rule out subclinical urine leaks.

Outcomes

The PelvEx Collaborative is an international collaboration between specialist exenteration centers, and the most recent pooled data for patients undergoing surgery for LRRC included 1184 patients [16]. On average, the length of hospital stay was 15 days, and the rates of major postoperative complications and reintervention were 32% and 10%, respectively. The rate of R0 resection was 55% in the PelvEx study and 58% in a recent systemic review [16, 63]. Overall survival at 5 years after surgery between 40% and 50% can be expected, provided clear resection margins are achieved [10–13]. Recent data from our center demonstrated that, while a microscopically clear resection margin predicts lower rates of local recurrence and higher overall survival, margins wider than 0.1 mm did not convey an additional survival benefit [17]. This finding challenges the prevailing definition of R0 as a 1 mm margin, which is based on primary rectal cancer data.

Approximately 55% of patients who undergo radical salvage surgery for LRRC will develop disease recurrence. While a small number of patients (14–21%) will have locally re-recurrent tumor for which further radical surgery may be feasible, more will recur systemically with distant metastatic disease [12, 13, 64, 65]. There are no data reporting the outcomes of neoad-

juvant chemotherapy in patients undergoing resection of LRRC; however, chemotherapy may be considered, with the intent of reducing the rate of systemic failure [12].

Conclusions

Exenterative surgery represents the only potentially curative option for patients with LRRC. Careful patient selection, meticulous planning, and interdisciplinary teamwork are required to provide patients with the best possible outcome. When approaching the previously dissected and irradiated pelvis, gain proximal and distal control of organs, vessels, and nerves before circumnavigating the most advanced and involved pelvic compartment. Where there is a question about tumor involvement, radically resect the structure in question in order to avoid a "close shave" and involved margin. Surgeons who operate on LRRC should be comfortable applying this concept to the lateral and posterior compartments of the pelvis. Systemic failure remains the most common form of recurrence after radical salvage surgery, and methods to reduce recurrence and lower morbidity require further investigation.

Appendiceal Neoplasms

33

Sanda A. Tan and Luca Stocchi

Key Concepts

- Appendiceal neoplasms are rare and typically present as incidental findings upon pathologic examination following appendectomy.
- Right colectomy should be considered for appendiceal adenocarcinoma, except for tumors limited to the submucosa.
- Benign mucinous neoplasms are adequately treated by appendectomy provided resection margins are clear.
- A perforated appendiceal tumor associated with peritoneal mucin should be treated with excision of the perforated lesion, peritoneal washings for cytology, and biopsy of any suspicious peritoneal lesions. Formal cytoreductive surgery should be delayed and performed by a specialized surgeon.
- Neuroendocrine tumors smaller than 2 cm are adequately treated with appendectomy alone.
- Neuroendocrine tumors larger than 2 cm, or those having high-risk features (incomplete resection, location at the base of the appendix, Ki 67 > 2%, lymphovascular or perineural invasion, mesoappendix invasion, grade 2 or greater) should be considered for right hemicolectomy.

Introduction

Appendiceal neoplasms are rare and most often present clinically as appendicitis [1]. Based on the histologic subtypes identified in a Surveillance, Epidemiology, and End Result (SEER) analysis, the individual incidence rates of appendiceal tumors between 1973 and 2001 ranged from 0.15 signet ring adenocarcinomas per 1,000,000 people per year to 1.3 mucinous tumors per 1,000,000 people per year. Appendiceal adenocarcinoma, "carcinoid" tumors, and goblet cell carcinoma were associated with intermediate incidence rates within this range [2]. While the definition of malignancy is often difficult to assess in administrative data, it has been reported as 0.12 age-adjusted cases per 1,000,000 people per year in an earlier review of SEER data [3].

The differential diagnosis of an appendiceal mass or thickening is quite extensive, and includes appendiceal mucinous neoplasms and adenocarcinoma subtypes, melanoma, leiomyoma, lipoma, fibroma, neuroma, lymphangioma, metastatic spread from other primary tumors (particularly ovarian) and cecal tumors involving the base of the appendix. Non-neoplastic causes of abnormalities of the appendix include Crohn's disease, neutropenic enterocolitis, tuberculosis, actinomycosis, mesenteric cystic disease, nonsteroidal anti-inflammatory drugs (NSAIDs)-induced damage, and, perhaps most importantly, appendicitis.

Appropriate diagnosis, and often times definitive treatment, requires appendectomy. A preoperative biopsy may be inconclusive and carries the risk of perforation, mucin extravasation, and increased risk of recurrence.

Epithelial Neoplasms

Epithelial neoplasms comprise different clinical entities, including invasive adenocarcinomas and benign mucinous neoplasms of variable histology, including low-grade appendiceal mucinous neoplasms (LAMNs) and high-grade appendiceal mucinous neoplasms (HAMNs). Goblet cell adenocarcinomas (GCAs), which were previously termed "goblet cell carcinoids" and "adenocarcinoids" and classified as neuroendocrine tumors, are now more appropriately classified as epithelial tumors [4].

Adenocarcinoma

The histologic subtypes of this invasive malignancy include mucinous adenocarcinoma, non-mucinous adenocarcinoma, and, less commonly, signet ring cell adenocarcinoma. The latter is considered the most aggressive of the three subtypes. Adenocarcinomas of the appendix most commonly present as an incidental finding following appendectomy for suspected acute appendicitis. A recent SEER analysis of Medicare data indicated that 29% of patients older than 65 having an appendiceal cancer or neuroendocrine tumor first received an incorrect diagnosis of appendicitis between 2000 and 2014 [5].

Mucinous adenocarcinoma is associated with a propensity for local invasion and tumor perforation, leading to extravasation of mucin into the peritoneal cavity. This can lead to the development of pseudomyxoma peritonei, which will be covered in separately (see Chap. 35).

Staging of appendiceal adenocarcinoma is similar to staging for colorectal cancer. Computed tomography (CT) scan of the chest, abdomen, and pelvis is helpful to exclude distant metastases. In patients who cannot undergo CT, magnetic resonance imaging (MRI) of the abdomen and pelvis combined with chest radiograph is a reasonable alternative. Colonoscopy is recommended to rule out synchronous tumors. Carcinoembryonic antigen (CEA) should be measured, as it is useful in select cases to facilitate detection of recurrence. Measurement of other serum tumor markers such as cancer antigen 125 (CA-125) and carbohydrate antigen 19-9 (CA 19-9) is only indicated if the primary tumor site is unclear.

The prognosis of appendiceal adenocarcinoma is strongly affected by locoregional lymph node metastasis, distant metastatic disease, and tumor differentiation [6, 7]. Surprisingly, tumor perforation does not seem to be an obvious adverse prognosticator [8]. An additional determinant in the prognosis of appendiceal adenocarcinoma is the histologic subtype: signet ring type being associated with the worst prognosis; mucinous and intestinal type with an intermediate prognosis; and goblet cell with a more favorable prognosis [9]. A recent analysis of SEER data indicates that both overall survival and cancer-specific survival were comparable between mucinous and non-mucinous adenocarcinoma [10].

The treatment of appendiceal adenocarcinoma can be limited to simple appendectomy for tumors not extending beyond the submucosal layer; most of the remaining cases have been considered for right hemicolectomy. However, the recommendation for right hemicolectomy is controversial, as current data suggest comparable survival after appendectomy alone, and a relative rarity of nodal metastases in mucinous adenocarcinoma [11–13]. On the other hand, there are advocates of formal right hemicolectomy for all cases of appendiceal adenocarcinoma [14, 15]. We feel that the risks associated with right hemicolectomy are acceptable when balanced with the risks of lymph node metastasis. We therefore recommend right hemicolectomy except in cases of well-differentiated T1 tumors, or in patients with prohibitive co-morbidities. A particularly challenging scenario is the spontaneous perforation of an appendiceal tumor associated with the release of mucin into the peritoneal cavity. In the acute setting, the surgeon should remove the perforated lesion through either an appendectomy or right hemicolectomy, obtain peritoneal washings for cytology, and biopsy other suspicious peritoneal lesions. Formal cytoreductive surgery should be delayed to a later date and referred to specialized surgeons and/or centers. Prophylactic oophorectomy is not thought to be helpful.

Adjuvant therapy is largely modeled after colon cancer, as data specific for appendiceal adenocarcinoma are limited. Chemotherapy combinations include either infusional 5-fluorouracil, oxaliplatin, and leucovorin (FOLFOX) or oral capecitabine and oxaliplatin (CAPOX). Data from the National Cancer Database (NCDB) suggest that patients with either stage II or III adenocarcinoma benefit from adjuvant chemotherapy [7]. As overall survival is the only endpoint assessed in these datasets, it is unclear whether chemotherapy would have a similar effect when examining cancer-specific outcomes. In the absence of definitive data clarifying this issue, it is generally accepted that adjuvant chemotherapy should be considered for all patients with Stage III disease and select patients with Stage II disease, specifically those with T4 tumors, poor tumor differentiation, tumor perforation, or fewer than 12 evaluated lymph nodes in the surgical specimen. Patients suffering from metastatic disease (Stage IV) might also benefit from combination chemotherapy including irinotecan and bevacizumab. Second- and third-line treatment options similar to those available for colon cancer may also be attempted. The use of cytoreductive surgery for peritoneal carcinomatosis associated with advanced mucinous adenocarcinoma, with or without heated intraperitoneal chemotherapy (HIPEC), is reviewed in Chap. 35.

Surveillance following treatment of appendiceal adenocarcinoma mimics the recommendations and guidelines for resected colon adenocarcinoma.

Other Mucinous Lesions

The nomenclature of mucinous lesions has been clarified by the renewed classification proposed by the Peritoneal Surface Oncology Group International (PSOGI) [16, 17]. A *serrated polyp of the appendix* largely resembles its equivalent in the colon. A simple *mucocele* is the result of the distention of a mucin-filled appendix without evidence of mucosal hyperproliferation or neoplastic changes. Mucinous appendiceal

neoplasms are classified as *low-grade appendiceal mucinous neoplasms (LAMNs)* and *high-grade appendiceal mucinous neoplasms (HAMNs)*. Both are histologically dysplastic but lack an infiltrative growth pattern. LAMN and HAMN can be distinguished based on their degree of epithelial dysplasia. While HAMNs are staged using the same system as invasive adenocarcinoma because of its higher recurrence risk relative to LAMN, there is no conclusive evidence to support this designation [4]. It is widely accepted that HAMN is not associated with distant metastatic potential. When infiltration and invasion are present, the lesion is described as mucinous adenocarcinoma (see above). The term adenoma is not used to describe mucinous lesions and currently designates only those rare cases of appendiceal neoplasms having the same histology as their counterparts in the colon and rectum.

As mentioned in the Introduction, mucinous neoplasms are rare. They are frequently identified incidentally when performing diagnostic testing for unrelated reasons. This includes colonoscopy, where they may manifest as a raised, circumferential lesion with a central umbilication referred to as the "volcano sign" (Fig. 33.1). When symptoms are present, they can be limited to vague abdominal pain, bowel obstruction, or symptoms arising from tumor compression of an adjacent structure. A palpable mass indicates a larger neoplasm and is relatively uncommon. Mucinous neoplasms of the appendix are frequently identified as incidental findings on abdomino-pelvic CT. CT should also be considered as a diagnostic and staging test when an appendiceal tumor is suspected on colonoscopy. Sometimes, it is possible to identify peritoneal deposits of mucin or masses, which can be indicative of advanced and/or metastatic disease. Thickened or irregular appendiceal wall and concurrent calcifications are suggestive of a neoplasm and/or malignancy (Fig. 33.2). In general terms, a larger mass is more likely to be malignant than a smaller one, although there is no definitive size cutoff. Regardless, in most cases, it is difficult to accurately characterize the abnormal appendiceal mass as benign or malignant based on radiographic imaging. Abdominal ultrasound has been described as a useful imaging modality. In particular, the lesion's layered appearance has led to the term "onion skin sign," which has been described as pathognomonic for mucinous neoplasm [18]. However, ultrasound for this indication is rarely performed in the United States. Colonoscopy can also be used to assess the extent of the lesion in the cecum and can therefore be helpful in planning surgical intervention (appendectomy/cecectomy vs right colectomy). Colonoscopy is also indicated preoperatively to assess for synchronous colorectal neoplasia. The use of endoluminal ultrasound at the time of colonoscopy has been described, although this is not generally considered part of standard evaluation algorithms.

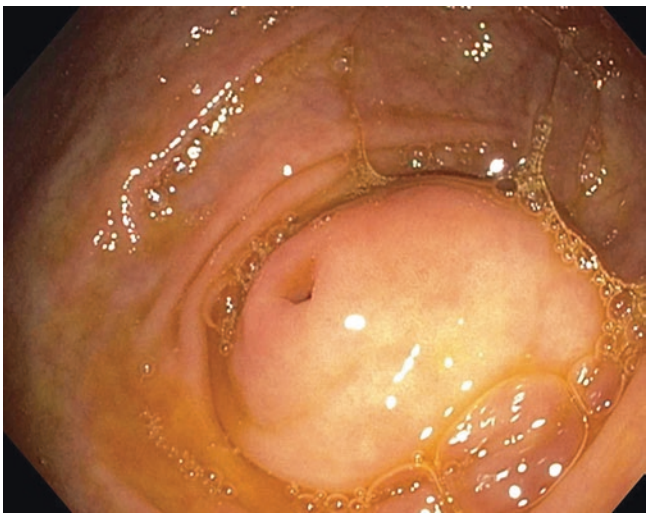

Fig. 33.1 Colonoscopy demonstrating a raised circumferential lesion with central umbilication referred to as the "volcano sign"

Fig. 33.2 Appendiceal dilatation with calcification suspicious for appendiceal neoplasm. The pathology after appendectomy revealed simple mucocele

Appropriate diagnosis, and often times definitive treatment, requires appendectomy. A preoperative biopsy may be inconclusive and carries the risk of perforation, mucin extravasation, and increased risk of recurrence. Depending on the specific location of the lesion within the appendix, it may be safer to excise in continuity the portion of the cecum surrounding the base of the appendix to ensure clear resection margins. In other cases, which may be possible to anticipate based on preoperative imaging, there can be direct involvement of the mesentery, mesocolon, and/or bowel.

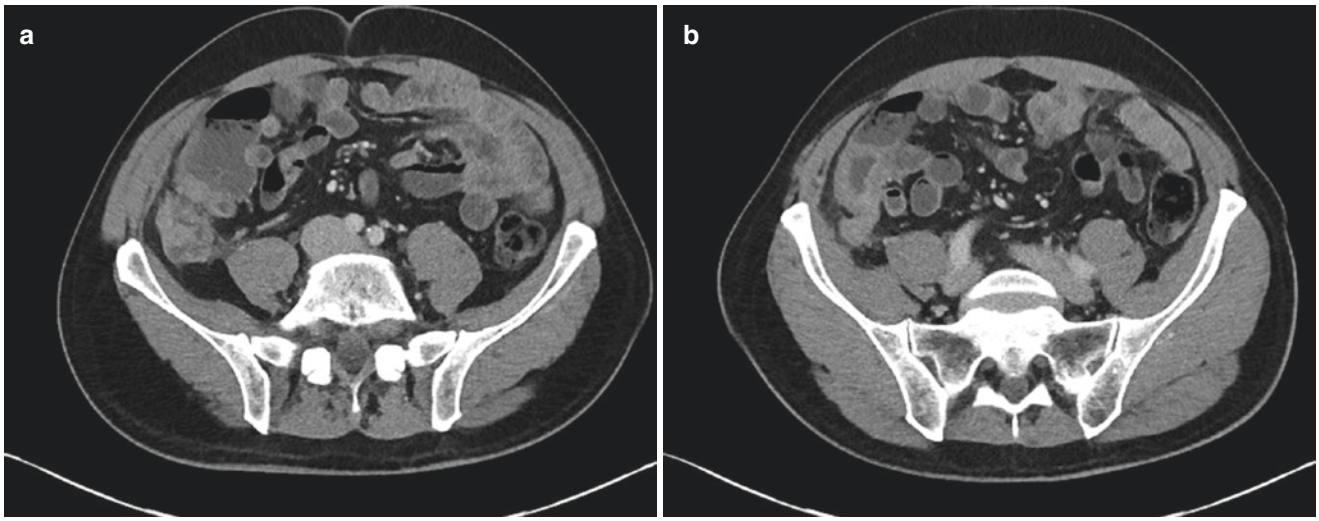

Fig. 33.3 Computed tomography scan showing replacement of the mid and distal portions of the appendix by a heterogeneous mass (**a**) associated with thickening of the adjacent cecal wall (**b**). This patient underwent right hemicolectomy. The pathology report indicated low-grade appendiceal mucinous neoplasm forming a 4 cm mass adherent to the cecum. Acellular mucin extended into the mesoappendix (T4a) and through the muscularis into the submucosa of the adjacent cecum

This finding typically prompts radical resection (Fig. 33.3a, b). An intraoperative frozen section has limited ability to accurately characterize mucinous tumors and will rarely lead to changes in operative treatment. More often, a pathologic diagnosis based on permanent specimen is necessary to dictate definitive management.

Patients having LAMN or HAMN limited to the appendix without perforation do not require any additional surgical treatment beyond appendectomy, provided there are clear resection margins. It is also questionable whether a completion right hemicolectomy is necessary when the appendectomy margins are histologically positive or have mucin on the resection margin [19]. There is agreement that the finding of mucin deposits on the serosal surface of the resected appendix (T4a) is a risk factor for peritoneal recurrence and subsequent pseudomyxoma peritonei (PMP). In particular, it is the identification of tumor cells outside of the appendix that is most closely associated with recurrence.[16] In two separate, comparative studies, the peritoneal recurrence rates associated with acellular mucin outside of the appendix were 4% and 7% at follow-up, compared with 33% and 75% in cases of cellular mucin, respectively [20, 21]. In this context, there is no evidence that a right hemicolectomy is associated with a reduction of PMP risk. Therefore, the general recommendation in these cases is surveillance with sequential imaging—generally performed with CT scans—although the specific intervals have not been established. Several authors have recommended CT intervals of 3–6 months during the initial 2 years of surveillance, and yearly afterward to 5 years [22, 23]. An alternative approach that may lead to earlier detection and optimized treatment is the use of diagnostic laparoscopy following index appendectomy in cases of either radiographically detected disease or empirically at 12 months postoperatively [24]. An even more aggressive, and controversial, approach for advanced stage neoplasms is what is referred to as "preemptive" cytoreductive surgery and HIPEC [25, 26]. Patients found to have peritoneal deposits of mucin should be referred to centers specializing in the treatment of peritoneal malignancies.

When LAMN is limited to the appendix, the prognosis is excellent. Even in cases of spread beyond the appendix, the prognosis remains relatively favorable with 5-year survival between 79% and 86% [27, 28]. The data regarding the prognostic implications of acellular mucin on the appendiceal surface are still limited but risk of recurrence is estimated to be between 5% and 20% [28, 29].

Neuroendocrine Tumors

Following the small bowel and rectum, the appendix is the third most frequent site for gastrointestinal neuroendocrine neoplasms (GI-NENs) [3, 30, 31]. The incidence of these tumors has been reported to be increasing in recent years, although it is unclear whether this is simply a reflection of changes in classification system, and/or increase in incidental detection at colonoscopy or operation for other pathology. Relatively speaking, appendiceal neuroendocrine neoplasms (aNENs) have a low prevalence in some cancer registries because they are often considered benign and cases are therefore not entered by all registrars [3]. In pediatric patients, aNEN is the second most common tumor of the bowel [32–34]. GI-NENs are frequently diagnosed during surgery for appendicitis or other abdominal treatments [35,

36]. In particular, aNEN discovered during appendectomy occurs at a rate of 0.3–2.3% [37–41]. The prevalence of aNEN among primary malignant tumors of the appendix ranges between 43% and 57% [1]. The most common histologic subtype of this tumor is giant cell carcinoma (GCC) at 59.6%, followed by malignant aNEN at 32.1%.

Many studies have shown a higher incidence of aNEN tumors among women as compared to men [42]. A review of the available studies also reveals that women predominantly present with initial tumor in the appendix, while men present initially with tumor in the small bowel. These findings may be the result of gynecological surgical intervention in female patients during which incidental appendectomy is performed [43]. aNEN displays an unusually early onset profile, with a maximum incidence in ages 15–19 years in women and 20–29 years in men [44]. In patients aged less than 35 years, the appendix represents the most frequent site for the tumor and there is some evidence indicating that patients with larger tumors and metastatic disease were younger than those with smaller and clinically benign tumors. The median age of patients with tumors greater than 2 cm was 31 years, and those with metastasis was 29 years, as compared to a median age of 42 years in patients with non-metastatic tumors [45].

The clinical presentation of aNEN is indistinguishable from that of appendicitis in over 54% of patients and obstructive features are present in 25% of cases [14, 46, 47]. The majority of aNEN occurs at the tip of the appendix, thus it is not surprising that obstruction of the lumen is relatively uncommon. However, non-appendicitis-like symptoms, such as intermittent abdominal pain in the right lower quadrant may be due to intermittent partial obstruction of the appendiceal lumen caused by the tumor. Because aNEN originates from neuroendocrine cells, one would think carcinoid syndrome is common. However, this is extremely rare as the hormones produced by the tumor are usually degraded in the liver. Symptoms of carcinoid syndrome are usually only present in the case of liver metastases.

Primary GI-NEN tumors typically evade standard radiographic detection until they are large enough to be evident on CT [48]. Cross-sectional radiographic studies (CT and MR) with both intravenous and luminal contrast have been reported to exhibit high sensitivity in identifying primary neoplasms of the small bowel [36]. However, luminal contrast is typically unhelpful in identifying tumors of the appendix, and therefore appendiceal tumors may be more difficult to detect until of relatively large size. Somatostatin receptor imaging (SRI) has been used successfully in staging GI-NEN [36, 49]. However, in a small retrospective study, it was not found to be reliable in pre-operative localization of aNENs [50]. SRI with Indium-111 pentetreotide imaging (octreotide) has been found similarly ineffective in identifying small tumors, especially aNEN <1 cm size [51]. However, this modality can be used to locate extra-hepatic and extra-abdominal tumor spread [52]. Octreotide studies with Ga-DOTATOC radiolabeling provide better spatial resolution and are now gaining support in staging of GI-NEN, but its usefulness in preoperative localization of small aNEN is not yet proven [49, 53].

Chromogranin A (CgA) is currently the most useful biomarker in the diagnostic algorithm for aNEN. CgA levels will not be elevated until the tumors are larger than 2 cm. Consequently, it is not a useful screening tool for aNEN [54, 55]. However, trending the levels of CgA regularly after initial treatment could help detecting recurrence or metastasis before these lesions can be detected radiographically [56]. Routine screening for 5-HIAA excretion is only recommended when the patient is suspected of having carcinoid syndrome [54].

Almost all primary endocrine tumors will exhibit CgA immunoreactivity [57]. While aNEN has some characteristics in common with tumors expressing cancer germline gene (CGG), it shows a stronger CgA and a weaker Ki67 marker [58, 59]. Additionally, a small proportion of aNEN tumors demonstrate abundant lipid accumulation and will need to be distinguished from giant cell carcinomas or signet ring adenocarcinomas [60].

Tumor size has traditionally been considered the most reliable indicator of malignant potential for aNEN. Tumor size greater than 2 cm in any dimension represents one of the most valuable predictive factors for lymph node metastases [36]. Over 95% of aNENs are less than 2 cm in size, with 60–85% being less than 1 cm in diameter and only 2–17% are greater than 2 cm [45, 46]. The risk of lymph node metastasis for tumors less than 1 cm is very low [61, 62].

The most reliable predictor for recurrence is location of the tumor. The majority of aNENs are located at the tip of the appendix, with 5–21% occurring in the body of the appendix and some 7–10% located at the base of the appendix [46, 47, 63]. Because incomplete resection is most likely to occur near the resection margin at the base of the appendix, such lesions are more likely to develop locoregional recurrence following a simple appendectomy compared to those located at the tip [55, 64]. Additionally, Grozinsky-Glasberg reported in 2013 that 33% of tumors located at the base of the appendix have metastases [54].

Mesoappendix invasion represents an extension of the tumor from the serosa into the pericolic fat. Despite the fact that serosal involvement alone is not usually considered an aggressive feature of the tumor, mesoappendix invasion is a strong predictor of worse prognosis and is considered an indication for right hemicolectomy. In 1979, Syracuse et al. reported that a small number of patients who had undergone right hemicolectomy for ≤1 cm aNEN had nodal metastasis when mesoappendix invasion was identified [65]. A study published in 2011 by Alexandraki found in 12 patients, 50% had mesoappendix invasion and 17% of those had one posi-

tive lymph node [55]. There is no correlation between mesoappendix invasion and tumor size or recurrence [35, 36].

Tumor proliferation markers may also predict potential metastases [36, 55]. A high Ki67 proliferation index or mitotic index has been demonstrated to predict aggressive biological behavior and decreased survival in aNEN [66, 67]. However, there is no correlation between high Ki67 index and tumor size or metastasis [68]. Vascular invasion is another indicator of potential aggressiveness. Sixty percent of patients with this invasion also exhibit lymph node metastases [54]. Similarly, patients with peritoneal invasion are also at increased risk for harboring lymph node metastases [54].

The American Joint Commission on Cancer (AJCC) staging system for aNEN is shown in Table 33.1. Stratification is primarily based on the size of the tumor and does not account for tumor grade or the other histologic features mentioned above which are associated with an increased risk of metastasis. The European Neuroendocrine Tumor Society (ENETS) staging does include tumor grade [36].

Treatment and prognosis are highly dependent on the size and degree of extension of the primary lesion. In the majority of cases, appendectomy is sufficient, as these tumors are usually small. No further staging or postoperative surveillance is necessary [36, 69]. Patients with Stage I tumors require only appendectomy, and while it is true that tumors at the base of the appendix are more likely to be insufficiently removed during appendectomy, this does not appear to be associated with a significantly worse prognosis [70]. For patients who have undergone an appendectomy when aNEN was present, it is recommended that the rest of the small bowel be examined prophylactically on a regular basis by visualization and palpation to ensure no other lesions are missed [36]. Right hemicolectomy is recommended for both stage II tumors of less than 2 cm diameter and for tumors up to 3 cm with serosal or mesoappendix invasion. For patients with aNEN greater than 2 cm but with no lymph node metastasis, there is no clear consensus regarding follow-up or surveillance recommendation. However, long-term follow-up is recommended for those with nodal, resected locoregional, or distant metastasis [71].

Table 33.1 American Joint Commission on Cancer (AJCC) staging system for aNEN

T Stage	TX	Primary tumor cannot be assessed
	Tis	Carcinoma in situ
	T1	Invades submucosa
	T2	Invades muscularis propria
	T3	Invades through muscularis propria
	T4a	Invades visceral peritoneum
	T4b	Invades all adjacent organs
Nodes	N0	No regional lymph node involvement
	N1	Metastasis to 1–3 regional nodes
	N2	Metastasis to ≥4 regional nodes
Metastasis	M0	No distant metastasis
	M1a	Intraperitoneal-only metastasis
	M1b	Extraperitoneal distant metastasis
Grade	GX	Cannot be determined
	G1	Well-differentiated
	G2	Moderately differentiated
	G3	Poorly differentiated
	G4	Undifferentiated
Stage	0	Tis, N0, M0
	I	T1/2, N0, M0
	IIA	T3, N0, M0
	IIB	T4a, N0, M0
	IIC	T4b, N0, M0
	IIIA	T1/2, N1, M0
	IIIB	T3/4, N1, M0
	IIIC	Any T, N2, M0
	IVA	Any T, N0, M1a, G1
	IVB	Any T, N0, M1a, any G
	IVC	Any T, any N, M1B, any G

In cases of incomplete resection of tumor at the base of the appendix, right hemicolectomy may be recommended. Patients should be informed about surgical complication rate and perioperative risk. No guidelines currently exist for the management of aNEN associated with perforated appendicitis. For those who present with distant metastasis at the time of presentation, it would seem reasonable to consider right hemicolectomy if the metastasis is considered resectable for cure. There are multiple systemic therapies that may be useful in treatment in combination with metastasectomy [55].

In conclusion, the appendix is the third most common location for neuroendocrine tumors of the GI tract. These tumors usually present as appendicitis and the majority are found after appendectomy on histologic review of the resected specimen. The prognosis of aNEN is significantly better than other neoplasms of the appendix [2]. For carcinoid tumors at the tip of the appendix and those tumors less than 2 cm in diameter, appendectomy is adequate treatment. Right hemicolectomy is recommended for larger tumors or when high-risk features are identified. However, there is little demonstrable difference in outcome between those offered only an appendectomy when compared to a right hemicolectomy and this may be due to the less aggressive nature of the tumor and a high 5-year survival rate [43, 72]. For the minority of patients who present with more extensive disease, or if surgery is not an option, treatment with somatostatin analogues has been shown to improve progression-free survival [36, 73]. There are scant reports of recurrence following a long postoperative interval in patients with tumors larger than 2 cm with local metastasis or with high risk features [63, 74]. Chromogranin A level can be used for surveillance, as these tumors are indolent. Yearly CgA level surveillance may be of benefit [54, 55]. Local recurrence or metastasis cannot easily be detected using

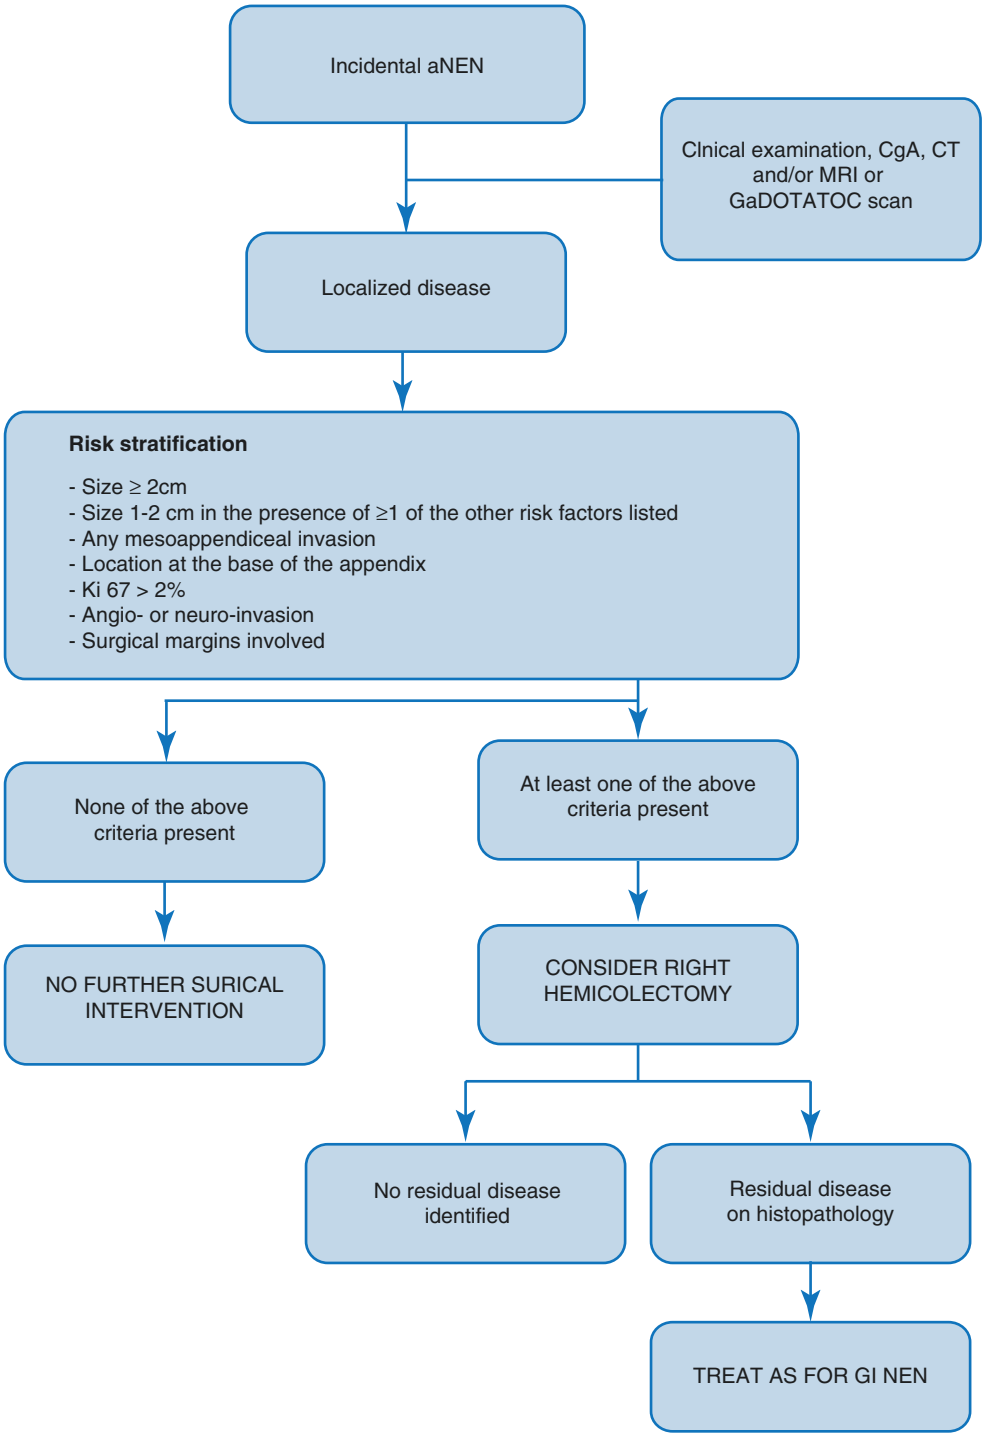

Fig. 33.4 Management of appendiceal neuroendocrine neoplasm. *aNEN* appendiceal neuroendocrine neoplasm, *CgA* Chromagranin A

current radiographic modalities. Usefulness of Ga-Octeotide PET studies needs to be evaluated in this regard. Yearly MRI and blood CgA may be useful in surveillance when there is residual disease after colectomy[68]. The algorithm in Fig. 33.4 shows the management of appendiceal neuroendocrine neoplasia.

Other Neoplasms

Goblet cell carcinoid tumors (GCC) are no longer considered aNENs but exhibit characteristics of both neuroendocrine tumors and appendiceal adenocarcinomas, differing in respect to their natural history, prognosis, and treatment [36].

They are composed of cells with secretory phenotypes including goblet cells, endocrine cells, and Paneth cells [75]. GCC can co-exist with high-grade adenocarcinoma, with the high-grade component dictating the treatment and prognosis.

Clear cell carcinoid tumors have been described only in case studies as they are exceedingly rare [76]. These tumors are filled with clear cells and abundant amounts of lipid. They may have a superficial resemblance to GCC or they may represent an appendiceal metastasis from clear cell carcinoma of non-appendiceal origin [60, 77].

Gastrointestinal Stromal Tumors, Neuroendocrine Tumors, and Lymphoma

34

Karim Alavi and Marylise Boutros

Key Concepts

- The majority of gastrointestinal stromal tumors (GISTs) stain positive for CD117 and have an alteration in *c-kit* proto-oncogene.
- Surgical excision with a 1–2 cm margin is the preferred treatment for GISTs located in the rectum.
- Treatment of midgut neuroendocrine tumors (NETs) is segmental resection with lymphadenectomy.
- Somatostatin analogs control the symptoms of carcinoid syndrome and help limit the progression of disease.
- Rectal NETs less than 1 cm in diameter may be treated by endoscopic or local excision, while tumors greater than 2 cm should be considered for radical resection.
- Patients with symptomatic colonic lymphomas are best treated with surgical resection prior to chemotherapy.

Gastrointestinal Stromal Tumors (GISTs)

Introduction

Gastrointestinal tumors (GISTs), originally thought to have originated from mesenchymal cells, actually arise from the interstitial cells of Cajal, the pacemaker cells of the gastrointestinal (GI) tract [1]. These cells are located within the muscular layer of the GI tract and coordinate autonomic movements [2]. GISTs comprise 20% of soft tissue sarcomas with an annual incidence of approximately 10 per million [3]. All GISTs are thought to have malignant potential, with 10–30% progressing to malignancy [4].

Histology and Molecular Biology

The diagnosis of GIST is confirmed by both histopathology and immunochemistry. There are three different histologic subtypes, including spindle (70%), epithelioid (20%), or mixed type (10%). It is not uncommon for GISTs to be mischaracterized as leiomyoma or leiomyosarcomas prior to immunohistochemical analysis [5]. The majority of GISTs stain for CD117, a marker for type III receptor tyrosine kinase KIT (95%) [6] and anoctamin-1(DOG-1; 98%) [7]. Approximately 60–70% stain positive for CD34, a hematopoietic progenitor cell antigen. However, they do not stain for smooth muscle biomarkers such as desmin. These features help differentiate GISTs from leiomyomas which stain positive for desmin, S100, and smooth muscle actin [8].

The *c-kit* proto-oncogene encodes KIT. Alterations in the gene result from point mutations, deletions, and insertions in exons 11 and 9. KIT alterations are present in 70–80% of GISTs [9]. While mutations in exon 11 are responsible for the longest duration of response to imatinib and improved survival, mutations in exon 9 are responsible for a shorter duration of response to imatinib and overall poorer survival in advanced disease [9]. A mutation in platelet derived growth factor receptor A (PDGFRA), in exons 18, 12, and 14 on chromosome 4, is present in 10–20% of GISTs. With few exceptions, mutations in PDGFRA are associated with a similar response rate and overall outcome to medical therapy, as KIT mutations [10].

Previously, patients without a mutation in either KIT or PDGFRA were considered to harbor wild-type (WT) GISTs. More recent evidence suggests they may have a mutation in succinate dehydrogenase (SDH) complex gene, an enzyme involved in the Krebs' cycle, which leads to failed DNA methylation [11]. Mutation analysis of KIT and PDGFRA is mandatory for optimal care of GIST patients. In the absence of KIT or PDGFRA mutations, tumor immunostaining for SDH is recommended, as the absence of staining indicates a possible SDH mutation. These patients may subsequently

S. R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, https://doi.org/10.1007/978-3-030-66049-9_34

need genetic counseling as the presence of SDH mutation suggests a heritable condition, in which patients present at a younger age and are prone to be afflicted with multifocal disease [8].

Incidence and Distribution

The majority (97%) of GISTs present sporadically at a median age of 65 (range, 10–100) with a 1:1 male to female ratio [5]. There are no known risk factors unless they present as part of tumor familial syndromes, including neurofibromatosis type 1, Carney–Stratakis syndrome, and Carney triad. Neurofibromatosis type 1 presents with multifocal intestinal GISTs that harbor mutated NF1 gene. The Carney–Stratakis syndrome harbors a germline mutation in the SDH complex genes. These patients present at a young age and have a high risk of gastric GIST and paragangliomas. The Carney triad, a possible variant of multiple endocrine neoplasia, consists of multiple gastric GISTs in young females, paraganglioma, and pulmonary chordoma. Esophageal leiomyomas, pheochromocytomas, and adrenocortical adenomas have also been described as part of this condition. Patients with Carney triad or Carney–Stratakis syndrome do not have KIT or PDGFRA mutations but may harbor a mutation in the SDH gene [12].

GISTs are most commonly found in the stomach (56%), followed by the small bowel (32%). Tumors of the colon and rectum account for 5–10% of GISTs with the majority arising in the rectum. GISTs may also arise in extragastrointestinal locations, principally in the mesentery, omentum, and retroperitoneum [13].

Clinical Presentation

GISTs are slow-growing tumors, which are often discovered incidentally during endoscopy, on abdominal cross-sectional imaging, or during surgery for other conditions. Presenting symptoms are variable and are largely dependent on location and behavior of the tumor. In the GI tract, GISTs can erode through the mucosa into the lumen, presenting with bleeding, or outward through the serosa, presenting with peritonitis. Symptomatic patients may present with nonspecific symptoms of nausea, vomiting, abdominal distension, early satiety, abdominal pain, and rarely as a palpable abdominal mass. Large tumors may cause intrinsic or extrinsic compression of the GI tract with presenting symptoms largely dependent on location, such as constipation or large bowel obstruction for distal colon or rectal GISTs [5, 14].

Approximately 20% of patients have overt metastases at diagnosis. The most common location is the liver followed by the peritoneal cavity. Metastases to the lungs, bone, and lymph nodes are rare. Increased likelihood of metastasis is associated with GISTs >5 cm and > 5 mitosis per 50 high power field (HPF), and GISTs >10 cm with any mitotic rate [15]. Studies have shown that tumor location is an important prognostic indicator. Miettinen and colleagues demonstrated that a non-gastric tumor of the same size and mitotic index has a higher risk of recurrence than a gastric tumor [4]. Joensuu and colleagues created the modified National Institutes of Health (NIH) classification, which determined that tumor rupture is a negative prognostic indicator. In sum, a GIST is considered high risk if the tumor is >10 cm with any mitotic index, the tumor is >5 cm with a mitotic count >5/50 HPF, or if it has ruptured. Following resection of a nonruptured GIST, the mitotic rate is the most important prognostic factor and determines the need for further adjuvant therapy [3].

Diagnosis

Definitive diagnosis of GIST is often made based on histopathologic evaluation of the excised tumor. However, the submucosal location of the lesion often makes pre-operative diagnosis challenging. Without mucosal ulceration, the diagnostic yield from mucosal biopsy is low. The diagnostic yield of endoscopy can be enhanced with the addition of endoscopic ultrasound (EUS) and fine needle aspiration (FNA) [16, 17]. Percutaneous biopsy is an option for tumors deemed inaccessible by endoscopy. CT-guided percutaneous biopsy of large GISTs is not without risk as these lesions are highly vascular and biopsy may be associated with hemorrhage [18]. Biopsy also risks tumor rupture and dissemination, and should generally only be performed in the setting of metastatic disease, unresectable tumor, or suspicion for lymphoma [19, 20].

Contrast-enhanced computed tomography (CT), specifically CT enterography, and magnetic resonance imaging (MRI) are often the initial imaging modalities and may aid in determining tumor location, perforation, invasion to nearby structures, and distant metastasis [17]. GISTs typically involve the muscularis propria and radiographically have the appearance of a well-circumscribed mass. MRI is preferred when evaluating rectal or duodenal GISTs, and can be performed serially without risk of radiation exposure, when evaluating tumor response to chemotherapy [21, 22]. Finally, positron emission tomography (PET) is not typically thought to be useful in the diagnosis of GIST but may have utility in evaluating response to treatment [5].

Treatment

Surgery

Surgical excision remains the gold standard for localized GIST. The goal is to completely excise the lesion with a 1–2 cm margin avoiding tumor rupture or violation of the accompanying pseudo-capsule, which leads to tumor seeding (Fig. 34.1). Given the absence of spread to draining lymph nodes, lymph node dissection is not necessary [23, 24]. Tumor location will dictate the extent of resection. Tumors of the small bowel or colon dictate a segmental resection using either a minimally invasive or open approach. Tumors of the rectosigmoid junction or upper rectum often necessitate an anterior resection. Management of GISTs of the mid to low rectum is largely dependent on size, distance to anal verge, rectal anatomy, and involvement of the sphincter complex. GISTs in this location can be managed by either a full thickness excision using any of a variety of available transanal platforms, such as transanal endoscopic microsurgery (TEM), transanal endoscopic operation (TEO), or transanal minimally invasive surgery (TAMIS). Regardless of the approach, several studies have shown that the local excision of rectal GIST is associated with higher recurrence rates as compared with radical resection. Changchien et al. reported outcomes on a series of patients who underwent local excision for rectal GISTs. Despite a smaller mean tumor size in the local excision group as compared to the radical resection group (4.5 cm vs. 7.2 cm), the local excision group experienced a higher local recurrence rate (77% vs. 31%) [25]. Low anterior resection or abdominoperineal resection may be necessary for large, bulky tumors of the lower rectum that are unresponsive or minimally responsive to neo-adjuvant therapy. However, many of these tumors are now treated with neo-adjuvant chemotherapy, which may limit the need for radical resection.

Medical Therapy

Imatinib mesylate (Gleevec; Novartis Pharmaceuticals, Basel, Switzerland) is a tyrosine kinase inhibitor (TKI) which works by binding Adenosine triphosphate (ATP) binding sites on CD117 and PDGFRA, blocking signal transduction. Since its introduction in 2000, imatinib has become the first-line agent for GIST therapy and is currently used in the neo-adjuvant, adjuvant, or palliative setting. Imatinib is currently recommended in the neo-adjuvant setting to shrink GISTs with the hope of limiting the extent of resection and associated morbidity. Cavnar et al. [26] reviewed their single-center experience of 47 patients with rectal GISTs, 17 patients in the pre-imatinib era and 30 patients in the imatinib era. In patients identified as high risk, organ preservation and negative margins were more common among the 13 patients treated with neo-adjuvant imatinib than among the 13 patients treated with surgery alone. An additional study reported on 19 patients with primary rectal GISTs. Imatinib used in the neoadjuvant setting in 15 patients significantly reduced tumor size from 7.6- to 4.1 cm ($p < 0.001$). Of the nine patients who underwent surgical resection, seven patients were able to undergo sphincter-preserving surgery who would have otherwise required a more radical approach [27].

Imatinib has been more extensively studied in the adjuvant setting following surgical excision to reduce the risk of recur-

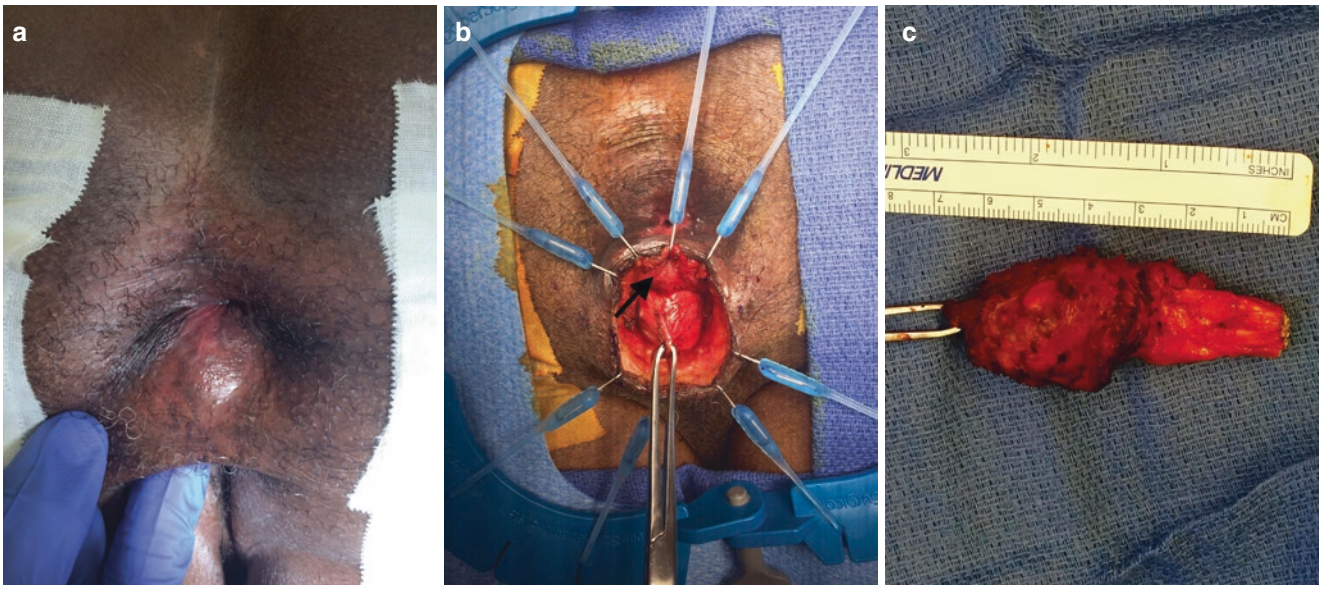

Fig. 34.1 Intraoperative photos of a perianal GIST (**a**), local excision with tumor in close proximity to sphincter mechanism (arrow) (**b**), and GIST completely excised with intact (**c**), Final specimen

rences. The American College of Surgeons Oncology Group (ACOSOG) Z9001 trial evaluated the impact of 1 year of adjuvant imatinib administration at 400 mg/day versus placebo and demonstrated an improved recurrence-free survival (RFS) compared to placebo (HR, 0.6; 95% CI 0.43–0.75) [28]. The European Organization for Research and Treatment of Cancer (EORTC) 62024 phase III trial also demonstrated an improved RFS following 2 years of administration of imatinib versus observation [29, 30]. The Scandinavian Sarcoma Group VVIII/German phase III trial randomized patients receiving imatinib at 400 mg/day between 1- and 3-year arms. With a median follow-up of 7.5 years, patients receiving 3 years of imatinib had a longer RFS and overall survival (OS) compared to those receiving Imatinib for 1 year [31]. The PERSIST-5 (Postresection Evaluation of Recurrence-free Survival for Gastrointestinal Stromal Tumors with 5 years of imatinib) prospective, single-arm, phase II clinical trial evaluated the impact of longer duration of therapy following macroscopically complete resection. This study estimated a 5-year RFS of 90% (95% CI, 80–95%) and an overall survival of 95% (95% CI, 86–99%). Of the 91 patients enrolled, there were 7 recurrences with the majority recurring after discontinuation of the drug. Approximately half of the patients discontinued treatment, mostly due to patient choice [32]. The optimal duration of treatment remains unknown. Patients with an elevated risk of recurrence should be treated for at least 3 years with imatinib and followed closely long term. A reasonable strategy may be to perform surveillance history and physical combined with cross-sectional imaging of the abdomen every 6–12 months for the first 10 years after surgery. More frequent imaging at 3–4 month intervals may be considered for 2 years following discontinuation of imatinib given the increased risk of recurrence during this time period [8].

In the setting of recurrent, progressive, or metastatic disease, the primary treatment modality remains imatinib. Sunitinib and regorafenib, both multitargeted tyrosine kinase inhibitors with activity against KIT, PDGFR, VEGFR, and FLT-1/KD, are alternative options approved for treatment of imatinib-resistant or intolerant GISTs [17]. The role of metastasectomy in the setting of stabilized disease while on imatinib is unclear. Du et al. [33] demonstrated in a small RCT that resection of residual disease on imatinib treatment improves overall survival (OS). In a small retrospective review, Bauer et al. demonstrated longer OS with debulking that achieved R0 or R1 status compared to those where surgery left gross tumor behind [34]. Finally, less invasive approaches may have a role in the management of GISTs. A small, single institution case series demonstrated tumor regression in all but seven patients following radiofrequency ablation of hepatic metastases. There were no GIST associated deaths and the OS was 85.7% at 30.6 months [35]. Gunter et al. reported on endoscopic ultrasound guided injection of 1.5 ml of 95% ethanol into 4 cm gastric GISTs in a patient with significant operative risks. Seven weeks following injection, a 1.5 cm ulcer was noted at the injection site with no evidence of residual tumor. Follow-up evaluation at 2 years demonstrated complete remission [36]..

Neuroendocrine Tumors (NETs)

Introduction

NETs of the GI tract were first described in 1888 in two patients with multiple small bowel tumors. In 1907, Siegfried Oberndorfer, a German pathologist, coined the term *karzinoide*, or "carcinoma-like," to describe the unique features of behaving like a benign tumor but having a malignant appearance microscopically [37]. While "carcinoid tumor," and other names reflecting the secretory nature of a specific tumor such as "insulinoma" or "glucagonoma," is a term used to describe tumors of neuroendocrine origin, "neuroendocrine tumor (NET)" more accurately represents the varied behavior of this family of tumors. NET is the preferred description by the North American Neuroendocrine Tumor Society (NANETS) and the European Neuroendocrine Tumor Society (ENETS) [38].

Histology and Biomarkers

Neuroendocrine cells are differentiated epithelial cells found throughout the GI tract which, depending on the organ of origin, secrete a variety of peptides and hormones. These cells are derived from adult GI stem cells and store peptides and proteins, such as Chromogranin A (CgA) and synaptophysin, in secretory vesicles within their cytoplasm [39].

Classification and terminology of GI NETs has evolved significantly over the past several decades. As noted above, classic terminology was based on the organ of origin or the specific peptide secreted. Two major categories of NETs of the GI tract have since emerged: well-differentiated NETs (WDNETs, which include carcinoids) and poorly differentiated neuroendocrine carcinoma (PDNETs) [40]. Grossly, WDNETs appear as smooth, round, polypoid lesions with normal overlying mucosa. Microscopically, WDNETs are characterized by proliferation of uniform, round to ovoid cells with enlarged nuclei and eosinophilic cytoplasm. Cells grow in a variety of patterns, including nested, solid, trabecular, pseudoglandular, and gyriform. The cytoplasm contains secretory vesicles that contain chromogranin and synaptophysin. PDNETs of the GI tract are high-grade carcinomas, which appear grossly as larger tumors with invasion into surrounding normal tissue. The tumor borders are infiltrative, with associated necrosis and hemorrhage. PDNETs are classified as small cell or large cell carcinomas. NANETS has published a "mini-

mum pathology dataset," which includes variables such as location, tumor/node/metastasis (TNM) staging, margin status, mitotic rate or Ki-67 index, and lymph node metastasis, and highlights the information that should be included on a pathology report for midgut and hindgut NETs [41]. The systems of nomenclature used to describe NETs have continued to evolve over time, although not all practitioners have adopted the new terminology, and thus confusion persists due to the continued use of traditional nomenclature.

NETS are further classified by grade. The grading system for NETs classifies tumors into three categories that are determined by the proliferative rate reflected by either mitotic rate or use of Ki-67 labeling. Grade 1 (G1), or low grade, tumors have fewer than 2 mitoses per 10 HPF, grade 2 (G2), or intermediate, tumors have 2 to 201 mitoses per HPF, and grade 3 (G3), high grade, have greater than 20 mitoses per HPF [38]. In virtually all systems of nomenclature, a sharp division is made between well-differentiated and poorly differentiated tumors. Well-differentiated NETs can include both low- and intermediate-grade groups. Poorly differentiated tumors are designated as "high grade" neuroendocrine carcinomas, which have a more aggressive biologic behavior compared to their well-differentiated counterpart [41].

Incidence and Distribution

NETS of both the midgut and hindgut are quite rare, accounting for ~1% of all new cancers diagnosed in the USA [42]. Overall, it is estimated that 52–58% of all NETs originate in the gastrointestinal tract and 21–32% originate in the bronchopulmonary tree. The most common primary sites for NETs are the rectum, lungs, bronchus, appendix, and small intestine followed by stomach, pancreas, and colon [43]. The true incidence of rectal NETs is unclear. In a retrospective study of 170 patients with GI carcinoids at the Oschner Clinic, Jetmore and colleagues demonstrated the rectum to be the most common location for GI NETs. However, this finding may not be representative of true disease distribution but a reflection of more vigorous screening measures [44]. The incidence of appendiceal/cecal NETs is similar between males and females, but slightly higher for males with respect to jejunal/ileal NETs. Hindgut NETs have a slight male preponderance, with a male-to-female ratio of approximately 1.1 [45]. Black patients are more likely to be diagnosed with NETs of the jejunum, ileum, and cecum than their white and Asian counterparts. White patients are more likely to be diagnosed with appendiceal NETs than their black counterparts [42]. In the hindgut, black patients are more likely to be diagnosed with rectal NETs than their white or Asian counterparts [45].

The median age of diagnosis of midgut NETs is 64 (SD 15.5) years with appendiceal NETs presenting at a younger age (median 47 years, SD 18). The true age at diagnosis of appendiceal lesions may actually be lower as most of the tumors found incidentally at appendectomy are benign and not reported to cancer registries. The mean age of diagnosis of colonic and rectal NETs is 65 and 56, respectively [46].

Clinical Presentation

Midgut NETs are usually small, slow growing tumors with symptoms that are vague and insidious in onset; leading to long delays in diagnosis. Patients may present with bloating, cramping, and mild episodic diarrhea; often being labeled with irritable bowel syndrome. Advanced locoregional disease may present as acute obstruction, caused by either the primary tumor or mesenteric fibrosis, or ischemia due to mesenteric vascular involvement. These tumors can metastasize to lymph nodes at the root of the mesentery triggering a significant desmoplastic reaction that shortens, distorts, and occasionally kinks the mesentery. In fact, occult NET should be considered in the differential diagnosis of patients with chronic bowel complaints or postprandial pain suggestive of ischemia. Systemic signs are rare and if present, are generally due to the presence of bioactive peptides that have bypassed metabolism in the liver. Serotonin, secreted by NETs, enters the portal circulation and is metabolized by the liver. In the setting of metastatic disease with heavy disease burden, specifically in the liver or outside the portal circulation, serotonin can bypass the liver and lead to symptoms of carcinoid syndrome (discussed in the next section) [38, 41].

The majority of appendiceal NETs are diagnosed on pathology after appendectomy for appendicitis and the majority are located at the tip of the appendix. A more detailed discussion of appendiceal carcinoids is presented in Chap. 32. Rectal NETs are often found incidentally on endoscopy in patients presenting for routine screening evaluations. These tumors rarely, if ever, present with the carcinoid syndrome. Colonic NETs generally have a worse prognosis as they typically present with more advanced locoregional disease and frequently with distant metastases [46]. Rectal NETs are indolent, slow-growing tumors with the majority being confined to the rectum. Symptomatic patients often present with hematochezia masquerading as hemorrhoids. Larger lesions with locoregional invasion can present with tenesmus and pain.

Carcinoid Syndrome

Primary colorectal NETs rarely exhibit symptoms of hormone secretion, as the liver is capable of metabolizing and inactivating most of the peptides secreted by these tumors. However, in the setting of advanced liver metastases (which

occurs in <10% of colorectal NETs) [47], secreted peptide hormones may enter the circulation, causing "carcinoid syndrome," with systemic consequences such as cutaneous flushing and gut hypermotility [47–49]. Carcinoid syndrome occurs most frequently (up to 90%) in patients with metastatic NETs, as it is these tumors that can produce high levels of serotonin [50]. However, it should be noted that hindgut NETs rarely produce serotonin, thus even when metastatic, these tumors rarely produce carcinoid syndrome [47].

The classic symptoms of carcinoid syndrome are flushing of the skin, watery diarrhea, abdominal pain, palpitations and wheezing. Patients usually experience intermittent symptoms with aggravating factors such as stress, ingestion of certain foods, caffeine, or alcohol. Flushing is the most common symptom, occurring in up to 85% of patients with the syndrome and may involve the face or the entire body. Secretion of a protease called kallikrein is thought to be responsible for these symptoms [51]. Abdominal symptoms are also common, occurring in up to 80% of patients, and include watery diarrhea and cramping. These symptoms are due to the excess serotonin secretion. Similarly, the surplus of serotonin causes accelerated fibroblast proliferation, increased vascular tone, bronchoconstriction, and platelet aggregation resulting in right-sided heart failure with pulmonary hypertension, tricuspid and pulmonary valve stenosis, and right ventricular hypertrophy and fibrosis [52]. Interestingly, the left side of the heart is spared from these effects as the lungs are capable of inactivating serotonin [52]. Many other symptoms, such as vague abdominal pain, weight loss, bleeding, obstruction, and constipation can occur. These may also be related to the mass effect of the primary tumor and mesenteric fibrosis.

Diagnostic Tests

Endoscopy and Imaging

Guidelines delineate the workup of NETs according to the site of origin [41]. Workup for all midgut NETs should include a complete colonoscopy to assess for any synchronous lesions. To assess for local invasion and distant spread, computed tomography (CT) scans of the thorax, abdomen, and pelvis with early and delayed phases should be performed [53]. Since NETs are hypervascular tumors, an early arterial phase (at 40 seconds) and washout during the delayed portal venous phase can be informative. To assess for indeterminate liver lesions identified on CT, magnetic resonance imaging (MRI) can be used, and would usually demonstrate a high signal on T2-weighted images for metastatic lesions [54]. NANETS recommends somatostatin receptor scintigraphy (SRS) or octreotide scans as part of the initial workup for midgut lesions in order to identify occult metastases. Since the majority of these NETs express receptors that have an affinity for somatostatin, SRS has an 80–90% sensitivity [55]. If metastases are identified on SRS, the patient is likely to respond to treatment with octreotide [56]. Positron emission tomography [^{18}F]-fluorodeoxyglucose (PET) imaging is generally not useful for WDNETs because of their low proliferative nature; however, PET can be used when SRS is equivocal and for PDNETs [41]. In cases where a midgut primary NET is suspected but not directly identified (e.g., a mesenteric fibrosis or mass in the ileal mesentery), a CT enterography, also performed in the arterial phase, can be used to locate the primary tumor. A newer PET modality using 68-Gallium-DOTA peptides (DOTATATE, DOTATOC, DOTANOC) combined with CT has been shown to be an accurate imaging modality for the detection of NETs. In a systematic review including 22 studies, ^{68}Ga-DOTA PET/CT was found to have excellent diagnostic accuracy, with a sensitivity and specificity of 93% and 96%, respectively [57]. Due to its sensitivity, authors suggest that ^{68}Ga-DOTA PET/CT may be used for WDNETs that are at higher risk of having occult metastases such as midgut NETs [58].

Although metabolic imaging tests may improve detection of occult tumor as compared to conventional imaging and clarify equivocal findings, it remains unclear whether any of the metabolic imaging tests would likely alter initial treatment if the patient has no evidence of metastatic disease on staging CT. If the patient would benefit from resection of the primary tumor irrespective of whether micrometastases were present, it may be preferable to proceed directly to operation.

Hindgut (distal colon and rectum) NETs are usually identified incidentally during colonoscopy. The endoscopic features of these neoplasms include a smooth, round, polypoid appearance, with a yellow color due to the presence of CgA and normal overlying mucosa (Fig. 34.2) [59–64]. The workup for hindgut NETs also begins with a complete colonoscopy. For lesions that are <1 cm that are completely resected during colonoscopy, no additional workup or follow-up is required as these tumors have a very good prognosis and low risk of regrowth or lymph node metastases [49]. For hindgut NETs that are 1–2 cm, an endoscopic ultrasound (EUS), endorectal ultrasound (ERUS), or rectal MRI is useful to assess tumor size, depth of invasion, and the presence or absence of lymph node metastases [65]. Using EUS or ERUS, very small tumors can be detected with excellent sensitivity [66]. For locally advanced tumors (T2 to T4), a CT of the abdomen and pelvis (as described above for midgut NETs) should be performed to rule out metastatic disease. SRS is not recommended in the initial workup of hindgut NETs; however, it can be used for investigation of metastatic NETs or rare PDNETs [67, 68]. Ga-DOTA PET/CT may be useful for the rare presentation of locally advanced hindgut NETs.

The TNM staging of NETs reflects depth of invasion, tumor size, and disease spread (Tables 34.1 and 34.2) [69].

Biochemical Workup

NETs have been linked to the production of multiple bioactive compounds. The most important of these biomarkers, CgA, is a 49-kd acidic polypeptide that is abundantly present in the secretory granules of neuroendocrine cells. Depending on the extent of disease, plasma CgA is elevated in 60–100% of patients with either functioning or nonfunctioning NETs. The sensitivity and specificities of CgA for detection of NETs ranges between 70% to 100% [70]. CgA may correlate to overall tumor volume; however, caution is necessary in the interpretation of the results as proton pump inhibitors, renal or liver failure, and chronic gastritis can spuriously elevate serum levels [41]. Urinary 5-hydroxy-indole-acetic-acid (5-HIAA) (24-hour collection) is a useful laboratory marker for well-differentiated NETs or carcinoids. It is a surrogate marker for serotonin metabolism that is tightly linked to the presence of carcinoid syndrome. Serotonin is derived from tryptophan and is stored and transported in platelets. Tryptophan is diverted away from protein (vitamin B_7 and B_3) synthesis in the presence of carcinoid tumors. Serotonin is first metabolized in the liver and then in the kidney to produce 5-hydroxy-indole-acetic-acid (5-HIAA), which is excreted in the urine. The specificity of urine 5-HIAA has been reported to be 88% [71, 72]. However, certain foods rich in serotonin and some medications can alter the metabolism and increase urinary levels of 5-HIAA and should be avoided for at least 24 hours prior to the testing (Table 34.3). Other biomarkers secreted by NETs include neuron-specific

Table 34.1 AJCC TNM staging of colon and rectal NETs

Stage	Primary tumor (T)
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor invades lamina propria or submucosa and size ≥ cm^2
T1a	Tumor size <1 cm in greatest dimension
T1b	Tumor size 1–2 cm in greatest dimension
T2	Tumor invades muscularis propria or size >2 cm with invasion of lamina propria or submucosa
T3	Tumor invades through muscularis propria into subserosa or into non-peritonealized pericolic or perirectal tissue
T4	Tumor invades peritoneum or other organs
Regional lymph nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastases
N1	Regional lymph node metastases
Distant metastases (M)	
M0	No distant metastases
M1	Distant metastases

enolase, substance P, neurotensin, and chromogranins B and C. Only a small fraction of hindgut NETs (<1%) produce and secrete serotonin or other biomarkers making routine measurement of urinary 5-HIAA not necessary. Serum CgA can be a useful marker for monitoring patients with metastatic disease or resected stage II or III disease.

Treatment

Once the diagnostic workup is complete, patients with midgut and hindgut NETs should be discussed at multidisciplinary tumor boards [41, 46, 49]. Surgical considerations differ for midgut and hindgut NETs due to differences in disease presentation and prognosis (Table 34.4).

Most midgut NETs remain asymptomatic and are only discovered when they become advanced, with the exception

Table 34.3 Foods, beverages, and medications that may falsely elevate urinary 5-HIAA levels

Foods and beverages	Medications
Alcoholic beverages	Cough and cold remedies containing expectorants

Table 34.4 Surgical considerations by tumor site

Primary tumor	Factor	Extent of resection
Midgut	Limited disease	Resection of primary with lymphadenectomy and metastatic tumors
	Extensive disease	Resection with lymphadenectomy or bypass of primary tumor
		Debulking of metastasis
Colon		Colectomy with lymphadenectomy
Rectum	<1 cm	Endoscopic or local excision
	1–1.9 cm	Local excision or proctectomy
	>2 cm	Proctectomy

of small NETs of the appendix (covered in Chap. 33). NETs of the jejunum and ileum have greater malignant potential compared to other NETs, with even sub-centimeter NETs reported to present with advanced disease [41]. Of these small midgut NETS under 1 cm, 20–30% have been reported to have lymph node involvement [73]. Oncologic resection with wide lymphadenectomy is the preferred treatment. Since these NETs may be associated with bulky mesenteric nodes that can cause obstruction, ischemia, or fibrosis, oncologic resection should be considered even in the context of metastatic disease to prevent these complications (Fig. 34.3). During small bowel resection, the mesenteric resection should be performed or mapped out prior to resecting bowel, with the goal to preserve bowel length when possible. One-third of midgut NETs may be multicentric, thus it is important to examine the entire small bowel to rule out synchronous lesions [73]. NETs of the cecum and ascending colon often present as large bulky tumors that require a formal right hemicolectomy with adequate lymphadenectomy [41, 47]. Less commonly, right colon NETs may be small lesions that are discovered during pathological examination of a resected specimen for another indication.

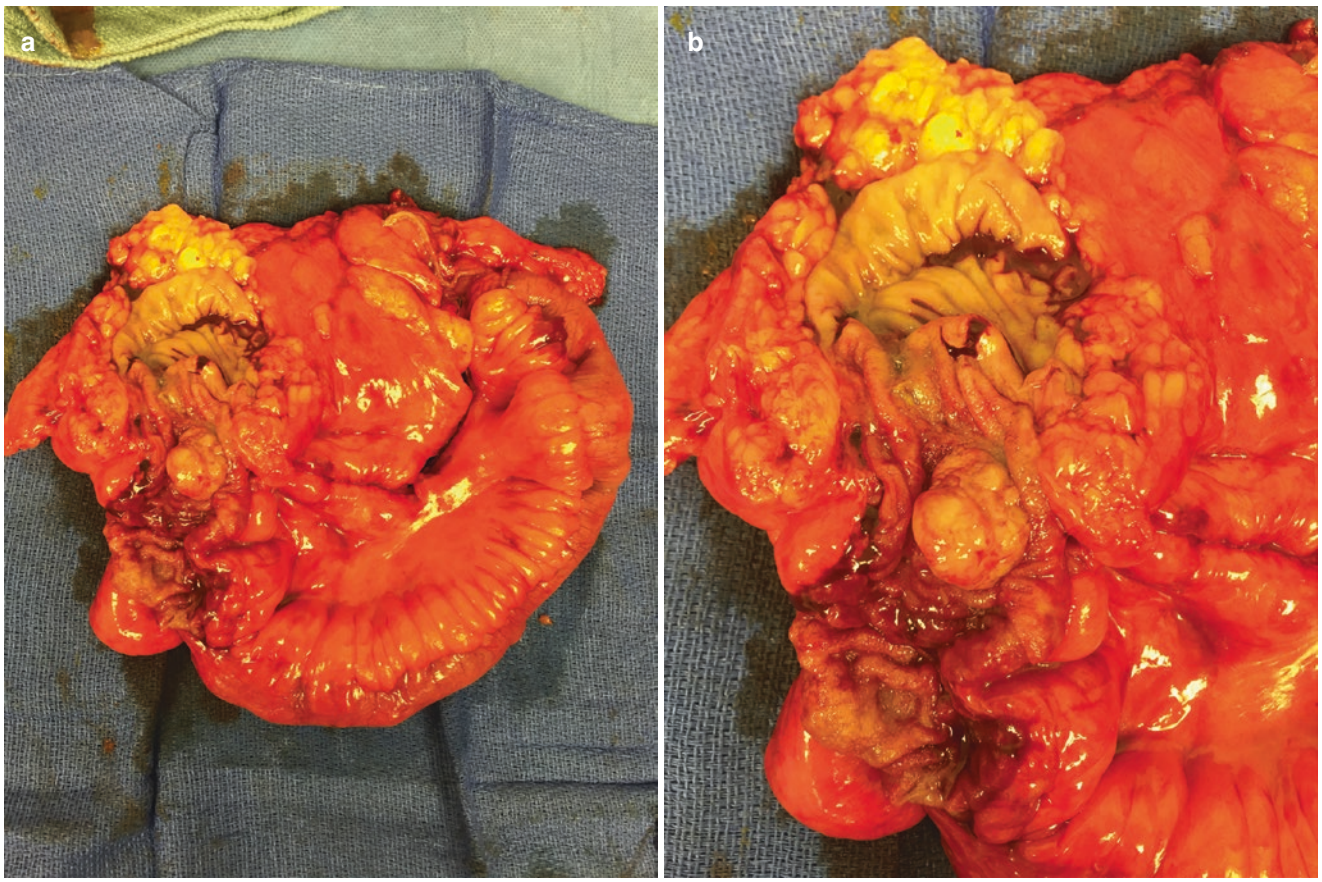

Fig. 34.3 (**a**) Surgical specimen demonstrating a NET of the terminal ileum. Note the desmoplastic response of the mesentery. (**b**) Close-up view of the lesion

Dissimilar to midgut NETs, most hindgut NETs are small submucosal neoplasms that follow an indolent disease course [47, 67]. Treatment is determined by size and depth of invasion (Fig. 34.4). Small (<1 cm) colorectal NETs that are confined to the submucosa (T1) can be managed with endoscopic resection during colonoscopy [46]. In several retrospective series, endoscopic resection was successful for these lesions, with positive resection margins being the sole predictor of recurrence (5–20%) [74–79]. Thus, when being removed endoscopically, the site should be tattooed to facilitate further management in the case of positive margins. To overcome the limitations of standard colonoscopy, two-channel endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD) techniques have also been used for hindgut NETs [59, 60]. In a recent meta-analysis comparing conventional colonoscopy, EMR and ESD, complete resections were significantly less likely with conventional colonoscopy compared to advanced techniques (OR 0.42 95% CI 0.25–0.71), with no difference between different advanced techniques [80]. The relevance of positive margins for small WDNETS that are G1 and have no high-risk features is not known. National Comprehensive Cancer Network (NCCN) recommends that patients with these lesions be re-examined endoscopically at 6–12 months, and if there is no recurrence, they can continue to be surveyed [49]. However, for endoscopically resected lesions that are G2 with positive margins, further management is recommended [49].

The treatment of rectal NETs 1–2 cm in size is controversial. In a multicenter retrospective review of over 200 rectal NETs, size >1 cm and lymphovascular invasion were independent predictors of lymph node metastases, whereas the presence of lymph node metastases and lymphovascular invasion was associated with subsequent development of distant metastases [81]. Of note, most small NETs in this cohort were managed by colonoscopic removal or local excision, with only six patients managed by transanal endoscopic surgery (TES). Current guidelines recommend that rectal NETs between 1 and 2 cm that are confined to the submucosa (T1) or muscularis propria (T2) without any lymph node metastases or adverse histologic features (lymphovascular or perineural invasion), be managed by transanal excision [41]. TES is an excellent technique for these tumors as it offers good visualization, exposure, and access for performing a full-thickness excision with negative margins, even in the

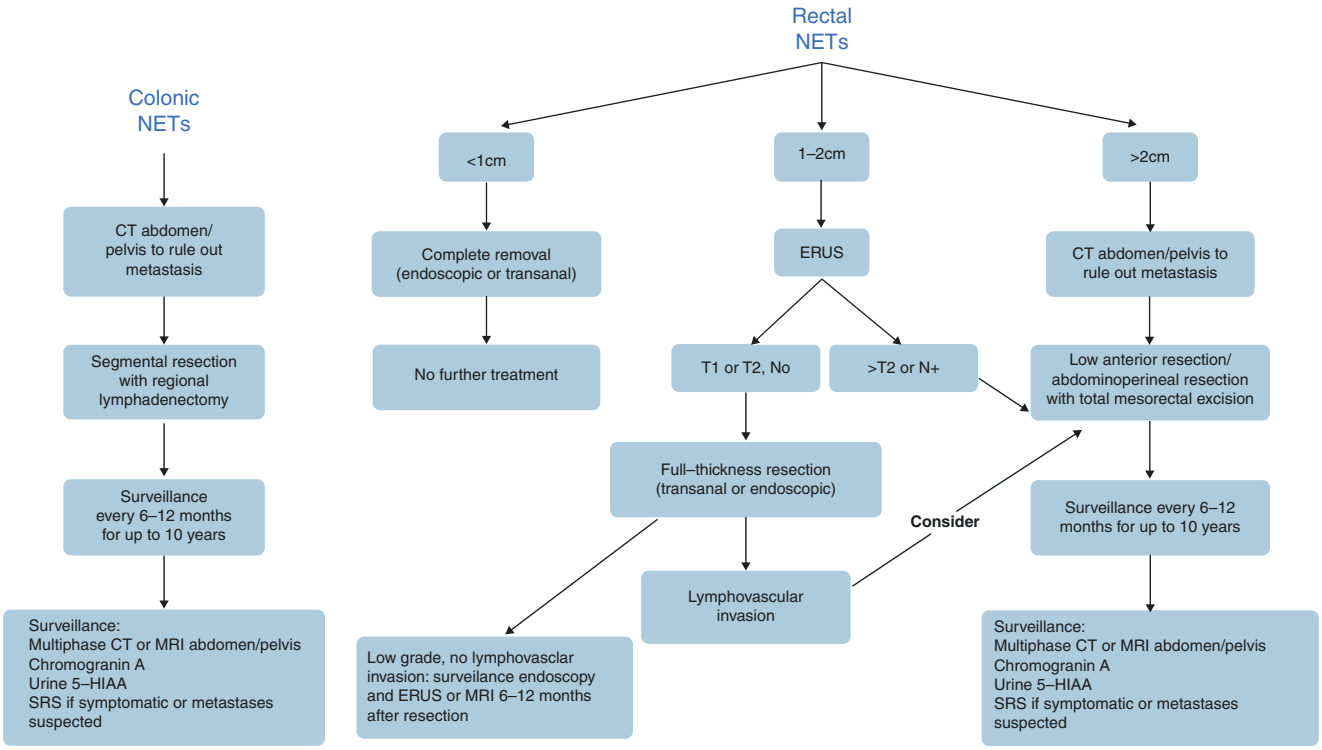

Fig. 34.4 Approach to the diagnosis, treatment, and surveillance of midgut and hindgut NETs. (Adapted from Ford [67])

proximal rectum (Fig. 34.5). In the case of endoscopically resected rectal NETs with a positive margin, TES can be used to re-excise the scar when indicated and obtain a negative margin [46, 49]. Small colonic NETs are less common than rectal NETs. When these tumors are small, they cannot be accurately evaluated for depth of invasion or presence of lymph node metastases. There are limited data showing a low rate (4%) of lymph node metastases with small colonic NETs, so it may be reasonable to remove them endoscopically, whenever possible [82]. Colonic and rectal NETs larger than 2 cm, invading the muscularis propria, with suspected lymph node involvement or adverse histologic features should generally be managed with radical resection and lymphadenectomy using the same oncologic principles of surgery for adenocarcinoma [67, 83]. Currently, there is no evidence for routine adjuvant medical therapy after surgery in any of these tumors [41, 49, 68, 84].

The management of metastatic NETs requires a multidisciplinary approach including surgery, hormonal therapy, chemotherapy, radiation, and interventional radiology [41, 68]. Somatostatin analogs (e.g., octreotide, lanreotide, and pasireotide) are the primary medical treatment for functioning and nonfunctioning metastatic NETs, as up to 80% of NETs have somatostatin receptors [85–88]. In cases of carcinoid syndrome, these drugs can control symptoms by inhibiting serotonin secretion. Interestingly, somatostatin analogs may also have antiproliferative properties and thus can be used for advanced disease control, regardless of symptoms [65]. Other medical treatment focuses on symptomatic treatment of the hormonal syndrome including the treatment of diarrhea with loperamide, diphenoxylate/atropine, and other antidiarrheal medications, and the use of antihistamines or H2 receptor antagonists for flushing.

Chemotherapy options for NETs remain limited. In the Eastern Cooperative Oncology Group randomized control trial, patients with metastatic NETs were randomized to 5-fluorouracil (5-FU) plus doxorubicin or 5-FU plus streptozocin. The median progression-free survival (PFS) was 4.5 and 5.3 months, respectively, and overall survival was 15 and 24 months, respectively. Thus, to date, there appears to be no dramatic survival benefit for chemotherapy, and its use can be reserved for patients who have exhausted all other options [89]. Interferon α has been used to induce disease stability in advanced cases. In a pooled analysis, only 37 (12%) of 309 patients treated with interferon α had a response [90]. Radiation therapy is mainly used in the palliation of NETs with bone metastases.

Debulking of liver metastases, if anatomically possible, has been shown to improve survival and aid in the palliation of hormone-related symptoms in patients with metastatic NETs [91]. As metastatic carcinoid tumors derive most of their blood supply from the hepatic artery, chemoembolization may play an important role in the treatment and pallia-

tion of systems. Patients with large tumors or those who are refractory to somatostatin frequently experience significant short-term improvement in their symptoms [91, 92]. Liver transplantation has also been reported in patients with metastatic NETs, with outcomes similar to transplantation for hepatocellular carcinoma [91, 93].

Surveillance

NETs can recur even many years after resection, but there is little consensus about the best surveillance strategy (Fig. 34.3)**.** For hindgut NETs <1 cm as per NCCN and NANETS, no follow-up is needed as these tumors have a very low risk of recurrence after complete removal [49, 68]. For 1–2 cm rectal NETs excised by endoscopic or transanal techniques, NANETS recommends no surveillance, while NCCN recommends ERUS or MRI at 6 and 12 months. For more advanced hindgut NETs, surveillance with an office visit and CT or MRI scans of the abdomen and pelvis are recommended on an annual basis. Since NETs may recur years after the initial diagnosis, surveillance for 7–10 years is recommended [68]. During surveillance after resection of advanced NETs, CgA and/or 5-HIAA may be considered.

Prognosis

Primary tumor site, tumor size, and stage are the strongest predictors of long-term survival [94]. Hindgut NETs have a much better survival rate than midgut NETs. The 5-year survival for rectal NETs <1 cm with no lymphovascular involvement is almost 100%, while node-positive rectal NETs and those with metastatic disease, have 5-year survival rates of 54–73% and 15–30%, respectively [47, 95]. Midgut NETs have the worst prognosis regardless whether they are localized or metastatic. For patients presenting with localized node-negative disease, 5-year survival can reach 80%, while those with node positive tumors have a < 40% 5-year survival [96]. Patients with metastatic midgut NETs are usually incurable with a reported median survival of 5 months [42, 47].

Lymphoma

Incidence and Distribution

Primary extranodal lymphoma is defined as lymphoma that is identified in a primary organ with no other clinical evidence of spread from distant lymph nodes or other organs, and accounts for 10–30% of all lymphoma. The gastrointestinal (GI) tract is the most common site to develop extranodal primary lymphoma; however, the colon and rectum are the least common GI location, accounting for only 10% of GI lymphomas and < 1% of all colorectal neoplasms [97, 98]. The most common colorectal site of involvement is the cecum, reported in 73% of patients, followed by the rectum [97]. Colorectal lymphoma occurs in about 3.5 in 2000 per million and is most commonly diagnosed between the ages of 50 and 70 years and among men (2:1) [99].

Risk factors for primary colorectal lymphoma remain largely unknown; however, established risk factors for primary extranodal non-Hodgkin's lymphoma (NHL) in general include a family history of lymphoma, personal history of radiation or chemotherapy, organ transplantation, immunosuppression, viral infections (e.g., HIV, hepatitis C), and exposures to toxins such as pesticides. Inflammatory bowel disease (IBD) has not been shown to be a risk factor for lymphoma; however, immunosuppressive medications for IBD including azathioprine, mercaptopurine, and infliximab have been associated with an increased risk of GI lymphoma [100–102].

Clinical Presentation

Unintentional weight loss, night sweats, fevers, and lethargy are the hallmark of colorectal lymphoma, in addition to a palpable abdominal mass (present in up to 80%) [103]. Other symptoms include those that mimic colorectal cancer, such as bleeding of the rectum, anemia, abdominal pain, diarrhea, or obstructive symptoms due to the large size of these lesions.

Histology

The vast majority of primary extranodal lymphomas are NHL. Similar to other primary extranodal lymphomas, colon and rectal lymphomas are usually NHL, with only case reports of primary colorectal Hodgkin lymphoma [104]. There are over 60 different subtypes of NHL as per the 2016 revision of the World Health Organization (WHO); however, the most common subtype of colorectal NHL is diffuse large B cell (DLBC) lymphoma (Table 34.5) [105]. Determining the specific histologic subtype of NHL is important, as it dictates the treatment options and expected outcomes.

Table 34.5 Most common subtypes of GI lymphoma based on the updated WHO classification

Subtype	Proportion (%)
Extranodal marginal zone B cell lymphoma	~45
Diffuse large B cell lymphoma	~45
Follicular lymphoma	<5
Mantle cell lymphoma	<5
Burkitt's lymphoma	<5
T cell lymphoma	<5

Adapted from Gay et al [105]

Diagnostic Tests

Diagnosis of primary extranodal NHL should be considered when lymphoma is identified in the colon or rectum with no other clinical evidence of spread from distant lymph nodes or other organs. Diagnostic criteria were first established by Dawson in 1961 as (1) a dominant colorectal lesion with only local lymphadenopathy, (2) no superficial palpable lymph nodes on clinical exam, (3) no radiologic evidence of chest lymphadenopathy, (3) a normal peripheral white blood cell smear and differential, (4) uninvolved liver, and (5) uninvolved spleen. More recently, these criteria have become more liberal to include any extranodal dominant site after clinical staging is complete, regardless of other lymph node involvement.

Diagnosis of lymphoma and the determination of the specific subtype are based on histologic, flow cytometric, and molecular evaluation of an adequate tissue specimen. In the case of a colorectal mass incidentally noted on radiographs, colonoscopy is typically performed as the next diagnostic maneuver. In cases of lymphoma, colonoscopy may show nonspecific abnormalities such as mucosal nodularity and induration, or an actual mass with or without ulceration (Fig. 34.6a, b) [106]. Colonoscopic biopsies are often too superficial and insufficient to confirm the diagnosis. At times, the diagnosis is only confirmed upon surgical resection. PET with computed tomography (PET/CT) scan of the chest, abdomen, and pelvis should be obtained to rule out extraintestinal disease. On imaging, primary lymphoma is more likely to demonstrate extension into the terminal ileum, have well-defined margins, preservation of fat planes, absence of invasion into adjacent structures, and perforation without a desmoplastic reaction, compared to colorectal adenocarcinoma. A bone marrow biopsy is also critical to assure accurate stage and confirm localized disease.

Several staging systems for primary GI lymphomas exist; however, the modified Ann Arbor staging system is most widely used (Table 34.6) [107–110]. Even though this staging system has been validated in colorectal lymphoma, it is not specific to primary GI lymphomas [111].

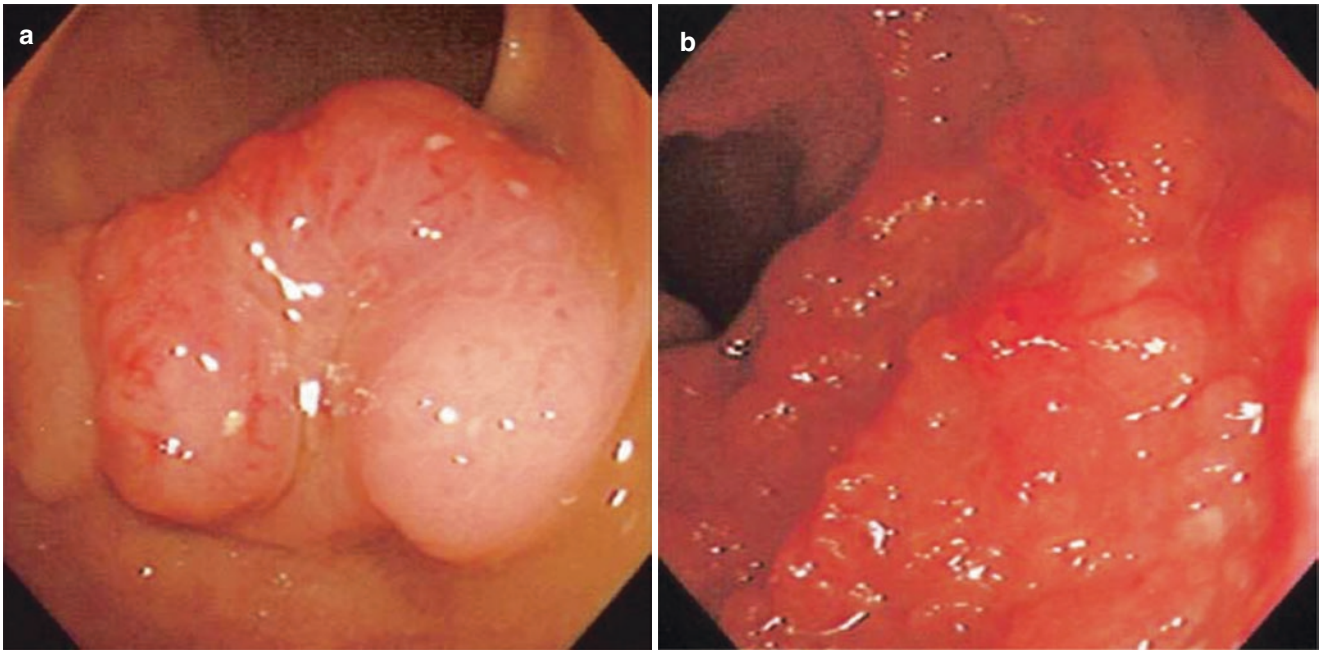

Fig. 34.6 (**a**) Lymphoma presenting as a fungating mass with a smooth, lobulated, non-ulcerated surface as seen on colonoscopy [106]. (**b**) Lymphoma presenting as a diffuse nodular lesion without a definite mass. (Reused with permission from Myung et al. [106]. Copyright © 2003 Elsevier)

Table 34.6 Ann Arbor staging

Stage	Description
I	Involvement of a single lymph node region or lymphoid structure
II	Involvement of two or more lymph node regions on the same side of the diagram
III	Involvement of lymph regions or structures on both sides of the diaphragm
IV	Involvement of extranodal site(s) beyond that designated E
A	No symptoms
B	Fever (38°), drenching sweats, weight loss (10% body weight over 6 mo)
E	Involvement of a single, extranodal site contiguous or proximal to known nodal site

Adapted from Rohatiner et al. [107]

Treatment

In contrast to nodal lymphoma, where chemotherapy and radiation are the mainstay of treatment, colorectal lymphoma presents a management challenge due to the high risk of complication when the bowel is irradiated. Given the limited availability of high-quality data to guide decision-making, the best approach to the management of colorectal lymphoma requires a multidisciplinary approach with early involvement of surgeons, radiation oncologists, and malignant hematologists. In general, treatment consists of surgery followed by chemotherapy alone, or chemotherapy with or without radiation therapy.

In the absence of disseminated disease, surgical resection is generally performed for colorectal lymphomas. The rationale for surgical treatment is twofold: cure and prevention of obstruction, perforation, or bleed. In a large retrospective cohort of 345 patients with colorectal DBCL from 16 hospitals in South Korea, patients with localized disease who underwent surgical resection followed by chemotherapy had lower relapse rates than with chemotherapy alone (15.3% vs. 36.7%, $p < 0.01$) [112]. Overall 3-year survival was significantly better with surgery followed by chemotherapy compared to chemotherapy alone (91% vs. 62%, $p < 0.001$). On multivariate cox regression, adjusting for age, performance status, lactate dehydrogenase level, number of extranodal involved sites, and stage, surgery followed by chemotherapy was a significant prognostic indicator of overall survival.

In the only available prospective cohort of 40 patients with DLBCL who received primary surgical resection with lymph node dissection and postoperative chemotherapy, the estimated 5-year overall and disease-free survival rates were 88.9% and 83.1% [111]. However, in earlier years, when operative series were less selective and included patients with more advanced disease, far worse outcomes were observed [113, 114]. Thus, in early-stage disease, definitive local control by surgical resection is a good strategy.

Based on the data available in the literature, the proportion of patients with no regional lymph node involvement (stage IE) ranges from 14% to 24%, while the majority of patients have regional lymph node involvement (stage IIE) in

addition to their primary tumor at the time of surgery (62–86%). Thus, an extended lymph node dissection (i.e., not limited to grossly abnormal nodes) similar to colon adenocarcinoma is advocated [115]. Following surgical resection, chemotherapy with three to six cycles of cyclophosphamide, doxorubicin, vincristine, and prednisolone (CHOP), with or without rituximab is recommended.

For unresectable DLBCL of the colon or rectum, or for patients with localized disease who are unfit for surgery, treatment with a full six cycles of CHOP chemotherapy is generally recommended. In nodal lymphoma, radiation is considered for incomplete positron emission tomography (PET) response after completion of systemic chemotherapy. However, the small and large bowel are particularly susceptible to complications of radiation, thus external beam radiation is not a preferred adjuvant option in the treatment of colorectal lymphoma. Radiation has been used as part of the treatment for rectal lymphomas, as this region can be irradiated with limited damage to the small bowel [116].

Two other scenarios warrant mention, both of which are managed operatively. Occasionally, colonic lymphoma will present with acute perforation, in which case resection is warranted. Rarely, chemotherapy will induce necrosis of the tumor that has replaced the bowel wall, resulting in subacute perforation with abscess and/or fistula. Resection may be necessary in this case, typically after percutaneous drainage of abscess, antibiotic therapy, and optimization of blood counts.

In general, treatment of the less common subtypes of primary colorectal lymphoma is also centered on surgical resection and chemotherapy for early disease, and chemotherapy for more advanced disease. An important feature of lymphomas is their variable susceptibility to chemotherapy regimens. Generally, rapidly proliferating tumors are more susceptible to cytotoxic chemotherapy than indolent tumors.

Mucosa-associated lymphoid tissue (MALT) lymphoma most commonly occurs in the stomach and small bowel, with colorectal primaries only accounting for a minority of cases [117, 118]. *Helicobacter pylori* infection contributes to 90% of gastric MALT lymphoma; however, its role in colorectal MALT is unclear. There is a paucity of data on the ideal treatment of colorectal MALT lymphoma with case reports describing successful treatment with radiation alone, surgical resection, or endoscopic mucosal resection [119, 120]. Size determines the surgical approach (local excision vs. radical resection). Given the indolent nature of this tumor, systemic chemotherapy is reserved for the adjuvant setting (in the case of residual disease) or for disseminated disease. Successful use of a variety of agents, including alkylators, purine analogs, and anthracyclines has been reported [121].

Primary colorectal follicular lymphoma is an uncommon and poorly defined disease. Follicular colorectal lymphoma can be managed with aggressive upfront local therapy, including surgery and/or radiation [122]. However, given the toxicity of potential bowel radiation, upfront surgery may be the best option for localized disease. Adjuvant chemotherapy in the treatment of primary colorectal follicular lymphoma is of unclear additional benefit. There are case series that report long-term disease-free survival with surgery with or without adjuvant chemo-immunotherapy [122].

Primary T-cell lymphoma accounted for 18% of primary GI lymphomas in a series of 95 patients [123]. These tumors are characterized by multifocal ulcerative lesions in relatively young patients, a high rate of hematochezia, fever, or perforation, and have a poor prognosis even in cases of localized disease [123]. Mantle cell lymphoma is often discovered in the GI tract, as a secondary site of involvement rather than a primary tumor [124]. It usually is found in patients who present with abdominal symptoms at the time of their lymphoma diagnosis, which then prompted a GI evaluation.

Cytoreductive Surgery and Hyperthermic Intraperitoneal Chemotherapy

35

Michael A. Valente and Brendan John Moran

Key Concepts

- Peritoneal dissemination is a frequent occurrence in the natural history of colorectal cancer, which may be synchronous or metachronous.
- The clinical benefit of systemic chemotherapy in patients with colorectal peritoneal metastases is less than in patients with other metastatic sites.
- A substantial survival benefit, with some patients cured, can be achieved in selected patients undergoing CRS and HIPEC.
- Outcome of CRS and HIPEC for colorectal peritoneal metastases is best in patients with low disease burden and complete cytoreduction.
- Currently, a shift in focus is taking place from treatment of established colorectal peritoneal metastases to prevention and early detection, by identification of patients at high risk for developing colorectal peritoneal metastases.
- Combining CRS and HIPEC with limited resection of liver metastases is feasible and achieves good oncological outcomes in a highly selected group of patients.

Introduction

Peritoneal malignancy is a neoplastic condition affecting the peritoneum and may be primary or secondary. Primary peritoneal malignancy, such as peritoneal mesothelioma, is rare and much less frequent compared with secondary peritoneal malignancy, with the commonest primaries being advanced gastrointestinal tract cancers including colorectal, appendiceal, gastric, and nongastrointestinal causes, namely ovarian. In many patients, the disease diffusely involves the peritoneal cavity, including both the parietal and visceral peritoneum. This is termed carcinomatosis. Carcinomatosis is common in end stage gastrointestinal tract cancers and is a terminal event in many patients, often leading to inoperable gastrointestinal tract obstruction.

The visceral peritoneum covers all intraperitoneal organs, including the small and large bowel. Diffuse disease of the peritoneum, of the small bowel in particular, traditionally has precluded attempts at surgical cure. Palliative treatment by best supportive care, systemic drug treatments, and optimal pain relief provides best outcomes. Select patients with malignant intestinal obstruction may benefit from venting gastrostomy, palliative endoluminal stenting, or rarely surgical bypass.

In the past three decades a novel strategy has been proposed, and popularized, for select patients with peritoneal malignancy – cytoreductive surgery (CRS) and hyperthermic intraperitoneal chemotherapy (HIPEC). The technique arose from seminal work by Paul Sugarbaker and colleagues at the National Institute of Health in the 1980s. The anti-cancer drug 5-fluorouracil (5-FU), developed in 1957 and still in use today as a key component of practically all colorectal cancer chemotherapeutic regimens, was evaluated in a randomized controlled trial, administered by either intravenous or intraperitoneal administration in patients with advanced colon or rectal cancer [1]. A unique feature of this study was a per protocol second look laparotomy at 6 months postoperatively. The number of patients recruited was low and the route of administration did not improve survival, or time to recurrence. However, intraperitoneal 5-FU significantly reduced peritoneal implants at second look laparotomy with 2 out of 10 having peritoneal carcinomatosis in the intraperitoneal 5-FU group compared with 10 out of 11 in the systemic 5-FU group. The concept of peritoneal disease control by intraperitoneal chemotherapy was a stimulus to pursue

this strategy for patients with pseudomyxoma peritonei (PMP) where, despite low-grade histological features, disease progresses within the peritoneal cavity, usually without other metastatic disease, and surgery alone generally fails to control the disease. Sugarbaker proposed, and popularized, this treatment for PMP. The indications gradually expanded to include other visceral malignancies. CRS and HIPEC have evolved into an effective oncological treatment strategy in select patients, and one of the fastest growing novel surgical cancer strategies of the past two decades.

Pseudomyxoma Peritonei (PMP): The Pathophysiology of Peritoneal Disease and the Re-distribution Phenomenon

Pseudomyxoma peritonei (PMP) is an uncommon condition and until recently was reported to have an incidence of one per million per year. This figure of one per million arose not from hard data, but rather was a relatively crude estimate made by one of the authors of this chapter (BJM) in an application to the English National Institute of Health Commissioning Service to establish a treatment center in 2000. Interestingly this figure, which was based merely on guesswork, was adopted globally as the widely accepted incidence of the condition, partly due to a publication by the English National Institute for Clinical Effectiveness (NICE) in 2004 entitled "Complete cytoreduction for Pseudomyxoma (Sugarbaker technique)" [2].

However, the true incidence of PMP is now considered two to four operable cases, per million, per year. PMP is characterized by diffuse mucinous ascites secondary to peritoneal implants and colloquially PMP is also known as "jelly belly" [3]. PMP was traditionally considered a benign condition, but its behavior over time suggests that it should always be considered, at best, a "borderline malignant" condition with inevitable disease persistence and progression [3]. While traditionally diagnosed at laparotomy, increasingly the diagnosis is considered prior to laparotomy, due to increased awareness of the condition and advances in cross-sectional imaging and percutaneous biopsy techniques.

The term "pseudomyxoma peritonei" was coined by Werth in 1884 in a woman with a mucinous carcinoma of the ovary, and Frankel went on to describe a case of PMP in association with a cyst of the appendix in 1901 [3]. While there has been ongoing discussion as to the origin of PMP, particularly in females, most authorities, and recent reviews, now accept that, in the majority of patients with PMP, the primary is a perforated mucinous epithelial tumor of the appendix [4].

Recently, a consensus agreement was published on the pathological classification of primary tumors of the appendix and peritoneal implants, by Carr and colleagues on behalf of the Peritoneal Surface Oncology Group International (PSOGI) group [5]. Appendiceal tumors are characterized as low-grade appendiceal mucinous neoplasms (LAMNs), high-grade appendiceal mucinous neoplasms (HAMNs), and appendiceal adenocarcinomas with, or without, signet ring cell morphology. Peritoneal implants are classified as either mucinous carcinoma peritonei-low grade or mucinous carcinoma peritonei-high grade (see Chap. 41, *Appendiceal Neoplasms)* [6]. All types of mucinous appendiceal tumors (from low grade to signet ring cell) can result in mucinous ascites, manifesting as the clinical syndrome of PMP. Compared with colorectal cancers, appendiceal mucinous neoplasms usually stay confined to the peritoneal cavity and rarely metastasize to lymph nodes or other distant sites, and thus, systemic chemotherapy is generally not effective in these patients. These facts make these patients candidates for aggressive locoregional therapy, namely CRS and HIPEC.

Despite the rarity of PMP, there are now a number of publications reporting long-term outcomes, in large series from both single and multiple centers [7, 8]. Current intraperitoneal treatment strategies of other peritoneal malignancies have evolved mainly from experience with PMP.

The Peritoneal Cavity

The anatomy and pathophysiology of the peritoneal cavity are poorly understood. The peritoneum is a serous membrane that lines the abdominal cavity and envelops most of the abdominal organs. The peritoneum originates from the mesoderm and is composed of a layer of mesothelium, supported by a thin layer of connective tissue. The peritoneal lining of the abdominal cavity supports many of the abdominal organs and serves as a conduit for blood vessels, lymphatics, and nerves to the abdominal organs. The peritoneum is one continuous sheet, forming into two layers with a potential space, the peritoneal cavity, in between. The outer layer (parietal peritoneum) is attached to the inside of the abdominal wall and the walls of the pelvis. The inner layer (visceral peritoneum) is thinner than the parietal peritoneum and envelops the intraperitoneal organs. The mesentery is a double layer of visceral peritoneum, attached to the gastrointestinal tract, enveloping the blood supply, lymphatics, and nerves to the gastrointestinal tract organs.

The peritoneal cavity contains approximately 50 milliliters of serous fluid which acts as a lubricant allowing gastrointestinal peristalsis and motility. The peritoneal cavity is subdivided into the greater sac (the main peritoneal cavity) and the lesser sac, enveloped by the lesser and greater omentum (Fig. 35.1). The lesser (gastro-hepatic) omentum is attached to the lesser curve of the stomach and the liver. The greater omentum (gastrocolic) is attached to the greater curve of the stomach, forms the anterior border of the lesser

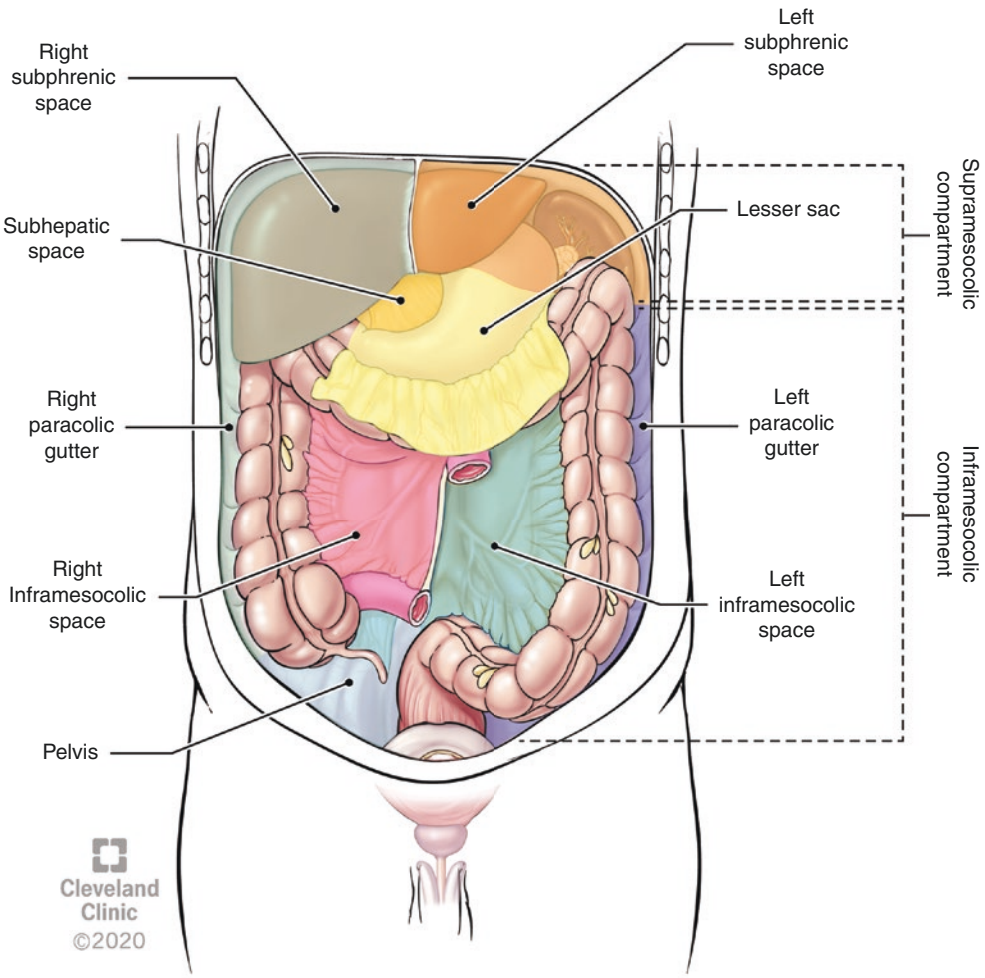

Fig. 35.1 The peritoneal cavity and spaces. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2020. All Rights Reserved)

sac, then extends inferiorly for a variable distance anterior to the intestines, and then curves superiorly to attach to the transverse colon and acts as an insulating and protective layer. The omentum has often been called "the policeman" of the abdomen as it moves toward, and tries to contain, intraperitoneal inflammatory pathology.

The fluid in the peritoneal cavity originates from serous glands and is constantly being produced, renewed, and absorbed to maintain homeostasis. The main purpose of this fluid is as a lubricant, similar to oil in an internal combustion engine in a motorcar. As in a combustion engine, where an oil filter is required to remove particles from the combustion process, the peritoneal cavity has absorption and filtration systems that both remove fluid and filter out abnormal contents, such as bacteria or free-floating cells. The main sites of fluid absorption are the under-surfaces of the diaphragm (particularly the right side) and the greater and lesser omentum.

The distribution and spread of PMP within the peritoneal cavity have been described as the "*re-distribution phenomenon*" (Fig. 35.2) [9]. Redistribution involves three main mechanisms, namely normal peritoneal fluid circulation and absorption, an effect of gravity in the standing and lying position, and relative (indeed often total) sparing of motile organs, particularly the small bowel. Figure 35.2 outlines an appendix tumor with peritoneal spread, but the concept is similar for any motile cells within the peritoneal cavity. Fluid, containing tumor cells, is absorbed and filtered in two main areas, namely the omentum (particularly the greater omentum) and via lacunae on the under-surface of the diaphragm (particularly on the right side). This accounts for the concentration of disease in the greater omentum (the so-called omental cake) as the omentum functions to absorb fluid and concentrate malignant cells.

Gravitational effects result in disease concentration in the pelvis and paracolic gutters. Constant peristaltic movement of the intestinal organs, particularly the small bowel, offers relative protection from tumor involvement, although more invasive tumor cells (colorectal adenocarcinoma, for example), surgical adhesions, and advanced disease often overcome this protective effect, ultimately resulting in small bowel involvement.

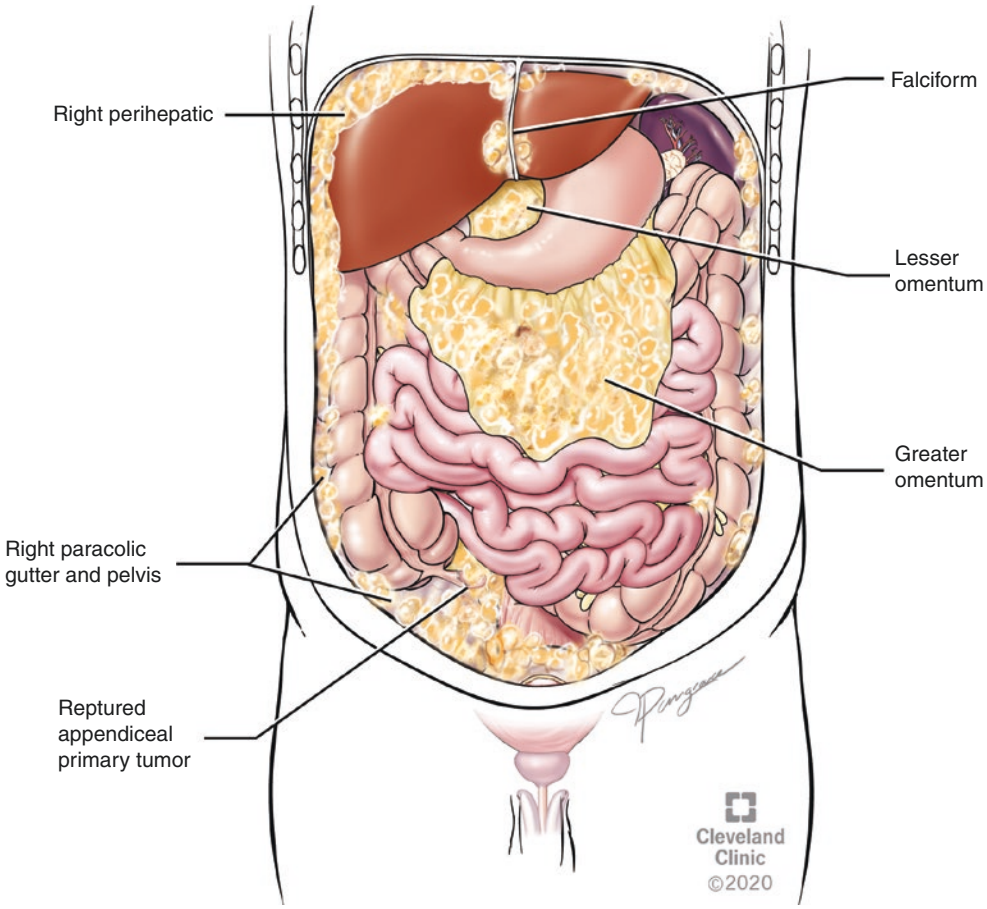

Fig. 35.2 Ruptured appendiceal neoplasm highlighting the "redistribution phenomenon." (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2020. All Rights Reserved)

The concepts of the redistribution phenomenon are applicable to all peritoneal malignancies where distribution and concentration of disease follow these mechanisms.

Colorectal Cancer and the Concept of Resectable Peritoneal Metastases

As outlined previously, "carcinomatosis" implies diffuse peritoneal disease and is a feature of advanced colorectal cancer. Colorectal cancer cells are generally more aggressive, and invasive, compared with low-grade appendiceal neoplasms and commonly invade the small bowel peritoneum, and indeed the wall of the bowel. In these scenarios CRS may not be possible, as removal of large parts of the small bowel will result in degrees of intestinal failure and poor quality of life. Thus, in the context of CRS and HIPEC for advanced colorectal cancer we favor the term "colorectal peritoneal metastases" (CPM) rather than "carcinomatosis." This terminology is analogous to similar terminology for liver, lung, and other metastatic disease, aiming to clarify that colorectal "carcinomatosis" (diffuse peritoneal disease) is not amenable to cure by CRS and HIPEC and that *resectable* CPM is the basis for case selection. Colorectal adenocarcinoma metastasizes by lymphatic, hematogenous, and transperitoneal dissemination. Synchronous CPM occurs in approximately 7% of patients, while a further 10–20% of patients develop metachronous CPM [10, 11]. Risk factors for peritoneal dissemination include T4 stage, possibly intraluminal stenting of an obstructing tumor, tumor perforation, poor differentiation grade, mucinous histology, and signet ring cell histology [12–14].

Various hypotheses exist regarding the pathogenesis of peritoneal metastases, some suggesting direct transperitoneal spread while others suggesting subperitoneal lymphatic dissemination pathways in addition to transperitoneal spread. Regardless of the specific pathway, peritoneal dissemination of free-floating peritoneal tumor cells may occur via the redistribution phenomenon and may follow predictable patterns of disease spread, as occurs in pseudomyxoma peritonei (PMP). These sites include the greater omentum, the pelvis, and ovaries in females and on the right hemidiaphragm with relative sparing of the small bowel [15]. Consequently, it is crucial to focus on these sites (the under surface of the right diaphragm, the omentum, and the pelvis) at cross-sectional imaging, laparoscopy, or laparotomy, when assessing patients with colorectal cancer for peritoneal spread.

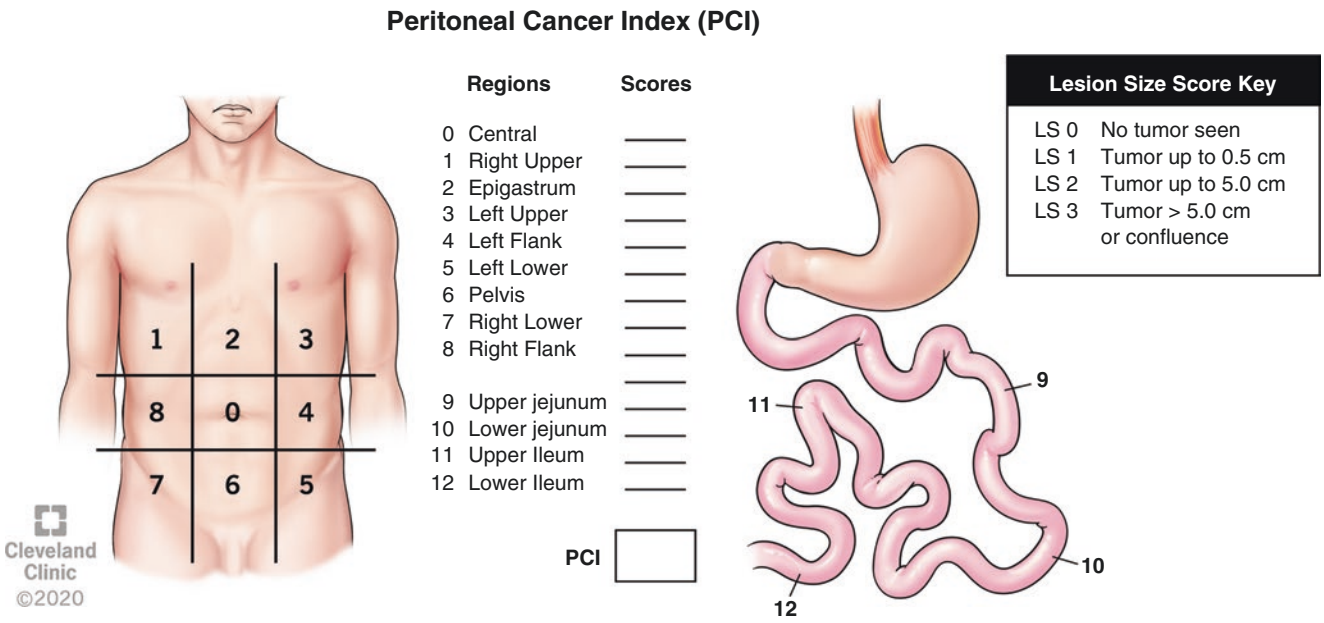

Fig. 35.3 The Peritoneal Cancer Index (PCI). (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2020. All Rights Reserved)

There are some crucial differences with CPM when compared to PMP. Firstly, due to the invasive nature of tumor deposits, small bowel serosal or mesenteric involvement is more common, which has clear implications for treatment and prognosis. Additionally, as a significant proportion of CPM are metachronous and occur in patients who have already undergone surgical resection, tumor deposits often develop along previously dissected tissue planes, such as Toldt's fascia and, in patients with previous rectosigmoid tumors, in the presacral/mesorectal excision plane.

An ongoing issue is that low-volume, diffuse disease is virtually impossible to detect by any current noninvasive imaging modality and neither CT, PET-CT nor MRI accurately detects lesions below 3–5 mm in size. For this reason, diagnostic laparoscopy may provide a more accurate assessment, at least of the accessible peritoneal cavity, if CRS and HIPEC are planned for patients with colorectal peritoneal metastases.

The Peritoneal Cancer Index (PCI)

The extent and distribution of peritoneal malignancy determine the likelihood that the disease can be surgically resected, the extent of the surgical procedure required, and the long-term prognosis in terms of disease control. The two major prognostic factors in patients undergoing surgical treatment of peritoneal malignancy are completeness of tumor resection and extent of peritoneal disease. Unsurprisingly, these prognostic factors are collinear, in that complete cytoreduction is more likely in cases of limited disease.

The most widely used and comprehensive staging system for peritoneal disease is the peritoneal cancer index (PCI), described by Sugarbaker as a record of disease extent assessed at laparotomy (Fig. 35.3) [16]. The abdomen is divided into nine regions with four further regions of the small bowel, giving thirteen regions in total. Lesion size in each region is counted as 0–3, where 0 equals no disease and 3 is tumor masses >5 cm. Thus, PCI score may range from 0 to a maximum of 39.

In patients with CPM, complete cytoreduction and HIPEC result in overall 5-year survival rates of 40–60% in highly selected patients [17–19]. However, pre-resection PCI appears to be an independent predictor of survival after CRS and HIPEC for CPM, even if patients have had complete cytoreduction [20–22]. One of the largest reports on patients treated with CRS and HIPEC for CPM, a retrospective study of 525 patients, treated by a French multicenter group, demonstrated that 5-year overall survival rates were significantly different dependent on the PCI at laparotomy. The 5-year survival was 44% for PCI < 6, 22% for PCI 7–12, and 7% for PCI >19 [22]. In addition, unsurprisingly, the rates of postoperative morbidity and mortality correlated with increasing PCI in this series.

The limitations of PCI are that its accuracy can only be assessed at laparotomy. However, there are increasing attempts to estimate PCI using other methods. Cross-sectional imaging, in the form of CT, PET-CT, and MRI, is being used to give an estimate of PCI. Due to the limitations

of imaging for low-volume disease, this should be classified as "Radiological PCI." It is also possible to estimate "Laparoscopic PCI" during laparoscopic assessment of the peritoneal cavity, which is more feasible and accurate if a primary tumor is in place and there has been no, or little, prior abdominal surgery. In the field of colorectal peritoneal metastases, most patients considered for CRS have had the primary tumor excised, and indeed many may have initially presented as an emergency with bowel obstruction, such that laparoscopic assessment may be difficult, dangerous, and limited by adhesions. In summary, "Radiological and Laparoscopic PCI" are helpful, in that the morbidity of laparotomy is often avoided, although it should be remembered that these assessment modalities commonly underestimate the actual PCI as determined at laparotomy.

PCI has also been applied to measure peritoneal tumor burden in other diseases, such as PMP. However, it is important to realize that the "C" in PCI is for cancer and PCI was not designed to evaluate PMP, which varies from low grade to high grade, both with regard to histologic appearance and disease behavior. Although "PCI" is useful in PMP as a measure of extent of disease, PCI should *not* be used to select patients with PMP for CRS and HIPEC, because PMP patients with high PCI scores are often amenable to complete CRS, and potentially cure, especially when treated in a high-volume specialized unit.

Cytoreductive Surgery: "Complete Cytoreductive (CC)" Scoring System

The concept of cytoreductive surgery (CRS) involves complete macroscopic tumor removal based on fundamental surgical principles and an understanding of the "re-distribution" of tumor within the peritoneal cavity. In this context CRS will usually encompass a radical greater and lesser omentectomy, pelvic and possibly diaphragmatic peritonectomy, and bilateral oophorectomy in females. Depending on the extent of associated bowel resections, a temporary or permanent stoma may be necessary. Temporary stomas are usually fashioned for more extensive left-sided anastomoses but should be considered for all anastomoses, if anatomically possible. There are no definitive data to guide the decision to construct an anastomosis before or after the administration of chemotherapy. Similarly, the choice of stapled or hand-sewn anastomotic technique has not proven to be associated with outcome [23–28].

One of the most important prognostic factors in CRS is the completeness of cytoreduction score (CCS). The CCS is performed by the surgeon at the end of the procedure and classified as follows: CC-0 indicates that no visible macroscopic residual cancer remains on any peritoneal surface; a CC-1 indicates persistent tumor nodules of <2.5 mm in size. It should be noted that any tumor nodule that is smaller than 2.5 mm may be amenable to eradication by intraperitoneal chemotherapy, and thus CC-1 is classified along with CC-0 as a complete cytoreduction (including for PMP from LAMN). CC-2 refers to residual tumors after cytoreduction that are between 2.5 and 25.0 mm; CC-3 refers to residual tumors after cytoreduction that are greater than 25.0 mm (or a confluence of unresectable tumor nodules at any site in the peritoneal cavity).

Table 35.1 Peritonectomy procedures and organ resections in cytoreductive surgery

Peritonectomy	Organ resections
Right parietal	Greater omentum
Left parietal	Lesser omentum
Pelvic	Spleen
Right diaphragmatic	Ovaries/fallopian tubes
Left diaphragmatic	Uterus
Right liver capsulectomy	Gall gladder
Left liver capsulectomy	Partial/total gastrectomy

The principles of cytoreductive surgery have mostly emanated from surgical management of PMP where, paradoxically, the most extensive surgery may be required for what is pathologically the least aggressive disease. The peritonectomy procedures and the main organs resected in patients with PMP are outlined in Table 35.1. In clinical practice, patients with advanced PMP may require a combination of the majority of these procedures. Partial or complete gastric resection is clearly a major procedure and not commonly required, though in a large series reported by DiFabio et al., 12% of all patients with PMP treated by CRS and HIPEC had a partial or total gastrectomy [29]. Clearly such combinations of extensive resections are unlikely to be of benefit to patients with biologically more aggressive disease, such as CPM.

In contrast to PMP, where both CC0 and CC1 are considered a complete cytoreduction, previous studies in CPM have shown that significant survival benefit of CRS and HIPEC for CPM is achieved primarily in patients undergoing a CC0 cytoreduction, and that CC1 has poorer outcomes [17, 18, 30]. Unfortunately, a complete cytoreduction is not achievable in a significant proportion (estimated at approximately 20%) of patients at operation for established CPM, due to either disease volume or distribution [8]. The main drawback to the CC score is that it can only be calculated after the surgical procedure has been completed.

Extensive small bowel involvement is the most frequent reason for (expected) incomplete cytoreduction, in which case the procedure may have to be abandoned (Fig. 35.4). In contrast to PMP, there is little evidence to support a role for surgical debulking procedures in the treatment of extensive CPM; a possible exception may be palliative bilateral salpingoophorectomy in patients with progressive, chemotherapy-resistant, and symptomatic ovarian metastases.

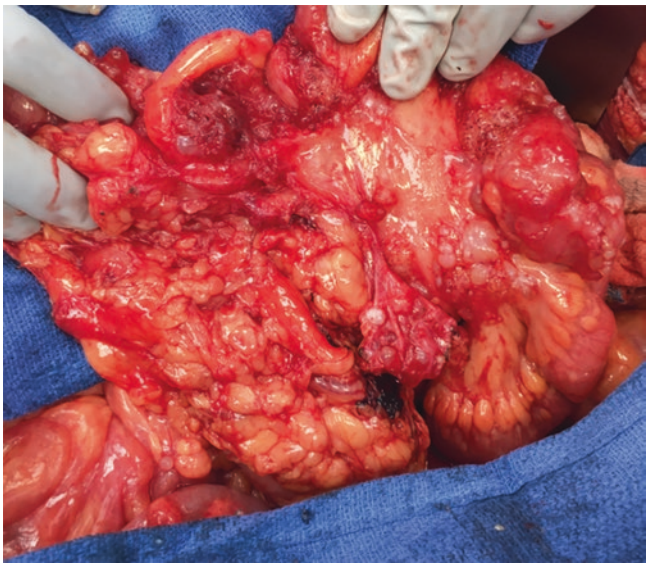

Fig. 35.4 Extensive small bowel involvement precluding a complete cytoreduction in a patient with colorectal peritoneal metastases

The outcome of CRS and HIPEC for colorectal peritoneal metastases depends on various factors, the most important of which are initial disease extent (traditionally, PCI > 19 has been considered a contraindication to surgery) and completeness of cytoreduction [21, 22, 31]. A complete cytoreduction and HIPEC is associated with 5-year survival rates of 40–60% in a highly selected patient population [17, 18, 21, 30–32].

In addition to disease extent and completeness of cytoreduction, prognosis is also adversely affected by signet ring cell histology, presence of systemic metastases, and increased expression of vascular endothelial growth factor (VEGF) by tumor cells [33]. A recent report has also suggested that the outcomes of CRS and HIPEC in patients with inflammatory bowel disease-related colorectal cancer are significantly worse compared to patients without inflammatory bowel disease [34]. In addition, the detection of free cancer cells in peritoneal fluid cytology is associated with reduced survival, although the clinical significance of this finding as an independent prognostic variable is debated [35, 36].

In contrast to traditional belief, the presence of ovarian metastases of colorectal cancer origin is no longer considered to be associated with decreased survival outcomes, provided that a complete cytoreduction is achieved and combined with HIPEC [37, 38].

Hyperthermic Intraperitoneal Chemotherapy (HIPEC)

Hyperthermia has for many years been proposed in the treatment of malignancy and has anti-tumor effects and enhances the effect of several anti-cancer drugs. In the last two decades of the twentieth century, experimental evidence supported the safety and efficacy of perfusion of warm chemotherapy, at temperatures of 42–43 °C, in both animals and humans.

Personal experience by one of the authors (BJM) also noted that perfusion of heated chemotherapy helps to restore patient physiology as patients undergoing CRS are often hypothermic at the end of a long laparotomy, despite efforts to maintain body temperature by "Bear Huggers" and the use of heated intravenous fluids. The normalization of body temperature, and the time taken for chemotherapy perfusion, was noted to markedly reduce the need for reoperation for bleeding in the postoperative period.

In the last decade of the twentieth century, there were a number of names for the concept of heated chemotherapy, which included CHIP (chemo-hyperthermie intraperitonei) by the French, HIPC (heated intraperitoneal chemotherapy) and IPHC (Intra Peritoneal Hyperthermic Chemotherapy) by North American groups, and HIPEC (hyperthermic intraperitoneal chemotherapy) by the Dutch. Moran proposed in 2002 that the most appropriate term to describe the entity was HIPEC and the term HIPEC gained support from the Peritoneal Surface Group International to encompass heated intraperitoneal chemotherapy [39]. The terminology of CRS and HIPEC is now well established and HIPEC has become a globally accepted term, facilitating a common language.

HIPEC is performed after a complete macroscopic cytoreduction. The abdominal cavity is perfused by the open, semi-open, or closed techniques (Fig. 35.5), using either oxaliplatin or mitomycin C. Common regimen utilized for CPM include mitomycin C over 60–90 minutes at 41–43 °C with an open or closed technique, and oxaliplatin over 30 minutes at 43 °C with an open technique. Additionally, simultaneous intravenous infusion of 5-FU has also been included in some protocols. There currently exists no standard regimen of duration, or chemotherapy drug, for either appendiceal mucinous tumors or colorectal peritoneal metastasis. Additionally, various protocols are in place at different institutions and current evidence does not show superiority of one over another.

Pressurized Intraperitoneal Aerosol Chemotherapy (PIPAC)

An extension of the concept of intraperitoneal chemotherapy was proposed by Marc Reymond and colleagues in 2011 [40]. The concept of pressurized intraperitoneal aerosol chemotherapy (PIPAC) was developed as a treatment strategy for patients with diffuse low-volume disease, in effect carcinomatosis, whereby aerosol chemotherapy is injected at laparoscopy to control disease not amenable to surgical resection. Disease control and palliation of ascites have been reported in ovarian, gastric, and colorectal carcinomatosis, and in peritoneal mesothelioma, with infrequent complica-

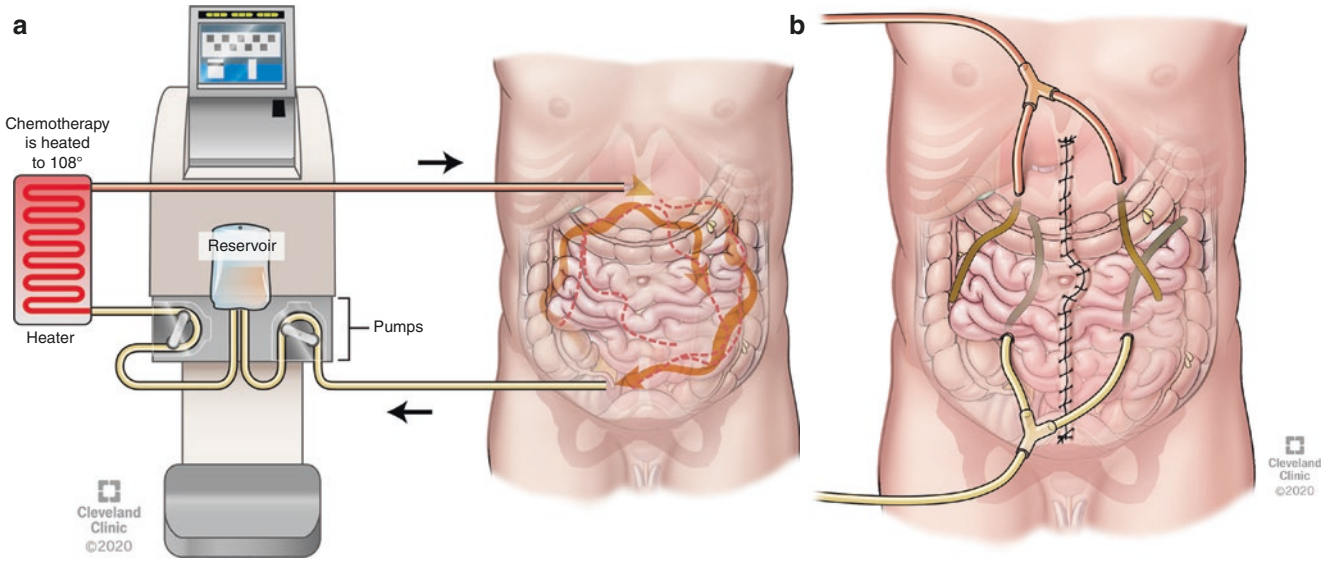

Fig. 35.5 (**a**) Catheters used for chemoperfusion during HIPEC. (**b**) Closed chemotherapy perfusion technique. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2020. All Rights Reserved)

tions. Research is ongoing and there are suggestions that PIPAC might also be useful as a neoadjuvant therapy in highly selected patients with the intent to convert unresectable peritoneal metastases to resectable.

Evidence Base for CRS and HIPEC for Colorectal Peritoneal Metastases (CPM)

Traditionally, patients with CPM were considered incurable and underwent palliative chemotherapy, often with disappointing results. Although systemic therapy for metastatic colorectal cancer has evolved over recent years, particularly with the development of biologic therapies, the survival benefit achieved with modern systemic therapy remains limited. A subgroup analysis of the Dutch CAIRO2 study showed that patients with CPM treated with modern systemic chemotherapy (capecitabine with oxaliplatin) combined with biological agents (bevacizumab and, in selected patients, cetuximab) had a limited median overall survival of 15 months and a median progression-free survival of just 6 months. Moreover, these survival outcomes were significantly worse than those achieved in patients with nonperitoneal metastatic disease [41]. A pooled analysis of two US trials comparing various chemotherapy regimens for metastatic colorectal cancer showed that, in all chemotherapy arms, patients with peritoneal metastatic disease had significantly worse survival than those with nonperitoneal sites of disease, with a median overall survival of just 12.7 months [42].

There is evidence to support CRS and HIPEC for CPM, mainly derived from cases series, but also a few randomized trials. Verwaal and colleagues conducted a phase III randomized controlled trial, first reported in 2003 with longer term follow-up in 2008 [18, 30]. One hundred and five patients were randomized to either receive 5-FU and leucovorin (standard treatment at the time) and palliative surgery or CRS and HIPEC with mitomycin C. The median 2-year survival was significantly higher in patients who had CRS and HIPEC (22.2 vs. 12.6 months) compared with those who had systemic chemotherapy and palliative surgery. Furthermore, patients that underwent HIPEC who had a CC-0 resection had a 5-year survival of 45% [30].

In 2009 Elias et al. reported on a French retrospective series of patients with CPM who had complete cytoreduction and HIPEC following systemic chemotherapy versus those who just received oxaliplatin and/or irinotecan-based chemotherapy alone [17]. Both groups of 48 patients each received a mean of 2.3 lines of chemotherapy. The authors reported a 5-year overall survival of 51% and median survival of 62.7 months in the CRS/HIPEC group versus 13% and 23.9 months in the chemotherapy-only group [43].

There has been much recent discussion on the relative contributions of CRS and HIPEC to survival in patients with CPM. Results from the PRODIGE 7 trial were presented in 2018, though the full results have not yet been published [44]. This was a French multicenter randomized trial in patients with resectable CPM in whom a complete cytoreduction was achieved. Patients were randomized to CRS alone or CRS with oxaliplatin-based HIPEC. The trial finished accrual in 2013. A few striking features have been presented, including the fact that the median survival was the same in both groups (42 months). Patients treated by HIPEC had increased complication rates at 90 days, though no difference in treatment-related mortality was observed, 1.5% in

both groups. These results have been interpreted as indicating that HIPEC is of no additional benefit to patients with CPM who undergo CRS. The peer-reviewed full publication is awaited with interest. While there are no survival benefits, there may be other benefits that have not come to light. One of us (BJM) has proposed that, based on clinical experience, and some experimental evidence, that HIPEC might prolong "obstruction free survival" [45].

There are also suggestions that oxaliplatin lacks effectiveness as an intraperitoneal agent for CPM and mitomycin C may re-emerge as optimal intraperitoneal chemotherapy pending further studies on novel intraperitoneal strategies. What is clear is that optimal CRS can produce good outcomes in highly select patients and that HIPEC may be a beneficial adjunct. A randomized controlled trial in ovarian cancer published in 2018 reported better survival in the HIPEC and CRS arm compared with the CRS alone arm [46].

The Role of Systemic Chemotherapy: Before or After CRS and HIPEC?

There is controversy as to the indication, timing, and efficacy of perioperative systemic chemotherapy in both the neoadjuvant and adjuvant setting. The rationale to administer chemotherapy stems from the fact that approximately 50% of patients that undergo CRS and HIPEC may develop extraperitoneal recurrence [47]. Many patients with CPM have had adjuvant therapy after primary tumor resection and additional further chemotherapy for recurrence. However, there is little evidence to support additional chemotherapy after CRS and HIPEC in the adjuvant setting. A recent retrospective report on 280 patients undergoing CRS and HIPEC for CPM showed no difference in survival associated with timing of systemic chemotherapy, either before or after CRS/HIPEC [48]. A systematic review in 2017 concluded that adjuvant systemic chemotherapy may confer a survival benefit but the role of neoadjuvant therapy is unclear and in some cases may be associated with reduced overall survival [49]. Alternatively, some evidence suggests that subsets of patients may benefit from systemic chemotherapy after recovery from CRS and HIPEC [50].

Neoadjuvant chemotherapy prior to CRS and HIPEC has been used by some investigators as a strategy to downstage peritoneal tumor burden, and to predict favorable tumor biology, similar to its use prior to resection of liver metastases. Waite and colleagues conducted a systematic review on the use of neoadjuvant and adjuvant chemotherapy with CRS and HIPEC and found that seven studies showed little evidence in favor of neoadjuvant therapy [49]. Alternatively, Passot et al. analyzed 115 patients with CPM who received neoadjuvant chemotherapy: patients who had a major or complete response had a significant improvement in survival compared to those who had minor or no response [51]. The authors concluded that histopathologic response to neoadjuvant chemotherapy should be considered as a new prognostic tool in the management of CPM. Clinical experience suggests that neoadjuvant systemic chemotherapy may select good responders (akin to liver metastases) and also allows a trial of time with subsequent re-imaging in initial borderline resectable cases.

Current Guidelines for Initial and Definitive Management of CPM

In general, it is recommended that patients with a definitive, or likely, diagnosis of CPM are referred to, or their case reviewed remotely by physicians at, a peritoneal malignancy treatment center before commencement of treatment (either surgical or chemotherapeutic). If CPM is diagnosed during a surgical procedure, it is recommended that surgical intervention and disruption of anatomical planes are kept to a minimum. In this context, in a case of impending intestinal obstruction, defunctioning stoma formation is preferred over resection [3]. Guidelines for initial management and a proposed treatment algorithm are provided (Figs. 35.6 and 35.7).

Prophylactic CRS and HIPEC in Advanced Cancer

As previously described, low-volume CPM is difficult to detect on imaging and CRS and HIPEC are maximally effective provided complete cytoreduction is achieved. The outcomes of CRS and HIPEC for patients with CPM are dependent on two key factors, complete cytoreduction and extent of peritoneal disease (PCI). For these reasons there has been some focus on preventing CPM and/or early detection of limited disease in patients at high risk of CPM. High-risk factors include the following:

- Limited, synchronous peritoneal metastases completely resected at primary tumor surgery
- Isolated synchronous ovarian metastases
- Primary tumor perforation
- pT4 primary tumor
- Mucinous primary tumor

A number of investigators have targeted these high-risk groups, often at second look laparotomy [52, 53] or by treating high-risk groups with prophylactic HIPEC [54]. Some encouraging results were reported in these reports, but the strength of the evidence is weak due to selection bias.

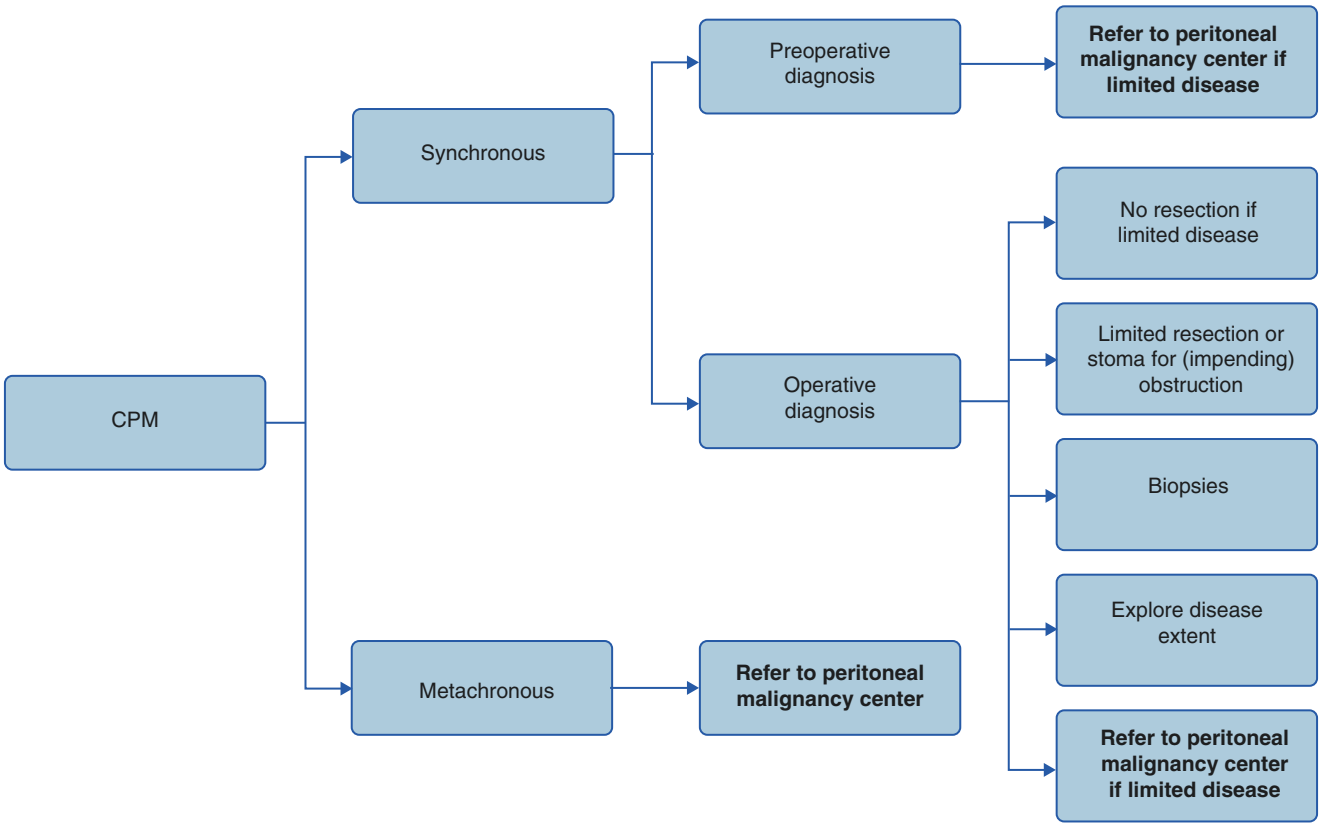

Fig. 35.6 Initial management of colorectal peritoneal metastases. *CPM* colorectal peritoneal metastasis

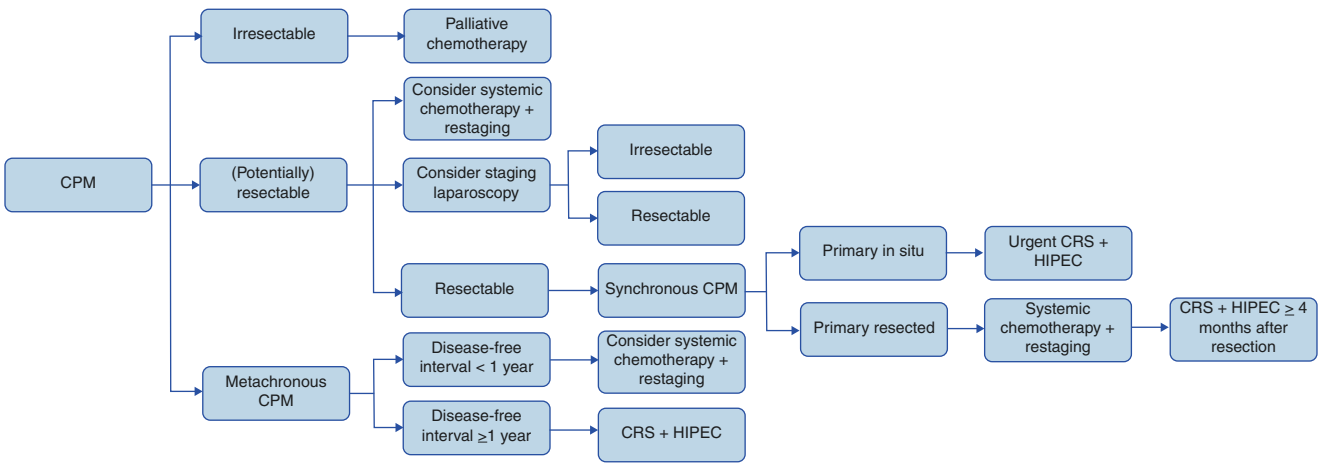

Fig. 35.7 Definitive management of colorectal peritoneal metastases in peritoneal malignancy centersz

Currently there are three distinct strategies under evaluation: a proactive approach, where patients considered to be at high risk of peritoneal dissemination undergo CRS (including resection of the primary tumor combined with resection of organs at high risk of involvement, for example, omentectomy and bilateral salpingo-oophorectomy in females, combined with HIPEC); an adjuvant approach, where selected patients undergo HIPEC in the immediate or delayed postoperative period after primary resection; and a second look approach, where selected patients undergo a systematic second-look operation sometime between 6 months and 1 year after primary resection, with cytoreduction of any observed peritoneal disease and HIPEC. Proactive CRS and HIPEC are currently being investigated in the Italian Promenade trial. Patients with high-risk T3/T4N0 colonic cancer (defined as ≥5 mm invasion beyond the muscularis propria on preoperative imaging) are randomized to either standard surgical resection or proactive cytoreduction (resection of the primary tumor combined with omentectomy, appendectomy, and BSO)

with oxaliplatin-based HIPEC. Both arms are then treated with adjuvant systemic chemotherapy where patients have poor prognostic factors.

A similar trial, the Spanish HIPECT4 study, randomizes patients with T4a/b colorectal cancer to either standard surgical resection or proactive CRS and mitomycin C-based HIPEC [55].

Adjuvant HIPEC is currently being investigated in the Dutch COLOPEC trial. Patients undergoing curative surgery for T4, or perforated colon cancer, without systemic metastases are randomized to either adjuvant systemic chemotherapy or adjuvant HIPEC (by either laparoscopic or open surgery) at the time of or within 10 days of surgery if feasible [56]. If not feasible within 10 days of primary resection, HIPEC is performed 5–8 weeks after primary resection, followed by adjuvant systemic chemotherapy. The primary endpoint is peritoneal recurrence-free survival at 18 months after resection, determined by CT and, if negative, by diagnostic laparoscopy. Initial results have shown that adjuvant oxaliplatin HIPEC in patients with T4 or perforated colon cancer did not result in an improved 18 months "peritoneal metastases free" survival. Long-term results are awaited.

A second-look strategy was published in 2011 by Elias et al. [52]. In total, 41 patients, with no detectable recurrence on imaging and normal tumor markers, had second-look surgery 1 year after primary tumor resection. Patients were recruited based on three tumor-associated factors: resected minimal synchronous macroscopic CPM, synchronous ovarian metastases, and primary tumor perforation. Overall, 21/41 (56%) had peritoneal metastases at second-look operation and underwent a complete cytoreduction; all 41 patients received oxaliplatin-based HIPEC. Five-year overall and disease-free survival rates following second-look surgery were 90% and 44%, respectively. Based on this study, the French ProphyloChip trial was designed and initiated. In this study, all patients with colorectal cancer and at high risk of developing CPM (minimal CPM resected simultaneously with the primary tumor, ovarian metastases, perforation of the primary tumor, iatrogenic rupture of the primary tumor during surgery) initially receive standard adjuvant chemotherapy. Patients with no detectable recurrence were randomized to either ongoing surveillance or a second-look laparotomy and HIPEC. Initial results report no difference in the primary endpoint of 3-year disease-free survival. The full published details are awaited.

Synchronous Colorectal Peritoneal and Other Site Oligo-Metastases

Patients with metastatic disease to both the peritoneum and other sites (liver, lung, etc.) are considered to have acquired their metastases by different mechanisms, such as blood borne and transperitoneal. Thus, they have not typically been considered candidates for CRS and HIPEC. In such cases systemic disease progression may negate attempts at local control of peritoneal disease, and morbidity and mortality of CRS and HIPEC may be detrimental to quality of life and survival. More recently the presence of isolated, treatable metastases, such as liver and lung, has not been considered absolute contra-indications to CRS and HIPEC in patients with limited resectable CPM.

Most of the evidence in this field has emanated from reports on patients with synchronous liver and peritoneal colorectal metastases, two of the most common metastatic sites. Elias and colleagues published outcomes on a small series in 2006 with good outcomes in highly selected cases [57]. Two systematic reviews support this strategy in highly selected cases [58, 59].

The general recommendations are that patients with up to three resectable liver metastases and low PCI (PCI < 10) may benefit, with some cured, when liver resection is combined with CRS and HIPEC. There has been little published on treatment strategies for patients with oligometastatic lung metastases and CPM but from personal experience, similar principles apply whereby treatable (either by surgical excision or ablation) lung metastases are not an absolute contra-indication to CRS and HIPEC in patients with low PCI colorectal peritoneal metastases.

Palliative CRS for CPM

There is increasing evidence that complete tumor removal is a prerequisite for effective CRS and HIPEC in patients with CPM. The morbidity, mortality, and impairment of quality of life of what is termed "tumor debulking" will generally outweigh any benefit. Systemic chemotherapy and best supportive care will provide optimal outcomes in most cases where complete cytoreduction cannot be accomplished. An exception to this approach is in female patients with large ovarian colorectal metastases where progression is common despite systemic chemotherapy, as ovarian metastases can be a sanctuary site from systemic chemotherapy. Palliative surgery may be appropriate in such cases. It is debatable if HIPEC is helpful, but in our experience has limited complications and may prolong obstruction-free survival [45].

Conclusion

The strategies for management and prevention of colorectal peritoneal metastases are evolving globally and much progress has been made in defining a subgroup of patients most likely to benefit from cytoreductive surgery and hyperthermic intraperitoneal chemotherapy. The combination of CRS

and HIPEC has potential to improve outcomes in many patients with CPM, with cure in a proportion. Further work is needed in defining optimal candidates for CRS and HIPEC, and defining the optimal agents used and the relative timing of intraperitoneal and adjuvant systemic chemotherapy. What has clearly emerged is that complete cytoreduction is crucial in achieving the best outcomes for patients.

Colorectal Cancer: Minimally Invasive Surgery

36

Antonino Spinelli

Key Concepts

- Minimally invasive colorectal surgery has evolved considerably, especially in the last 30 years.
- Potential advantages of a minimally invasive approach go beyond smaller incision size: reduced interference with body homeostasis has positive impacts both in the clinical and social spheres.
- MIS for colon cancer has been well accepted for many years, but the application of MIS techniques to rectal cancer is more controversial.
- Techniques utilized to perform proctectomy are not as mature as those to perform colectomy, and potential advantages/risks of minimally invasive proctectomy versus open proctectomy are still debated.

Introduction

Minimally invasive colorectal surgery has evolved considerably, especially in the last 30 years. The first descriptions of laparoscopic-assisted colectomies for cancer were in 1991 by Schlender [1] (one case of right colectomy), Fowler and White [2] (one case of sigmoid resection), and Jacobs et al. [3] (20 cases of right colectomies or sigmoid resection for benign or malignant diseases). In 1992, Phillips et al. [4] described for the first time a laparoscopic, intracorporeal, hand-sewn purse-string suture and transanal natural orifice specimen extraction (NOSE) applied in 51 patients. In 1994, Darzi et al. [5] described a left colon resection with transanal NOSE followed by a triple-stapled intracorporeal colorectal anastomosis. In 1995, Mentges et al. [6] described a technique that consisted in performing a proctotomy in the anterior rectal wall to insert the anvil of a circular stapler into the peritoneal cavity and to perform NOSE by means of transanal endoscopic microsurgery (TEM) platform. Contrary to the prior reports, which emphasized limiting incision size as the primary goal, in 2005, Chang et al. [7] published a series of hand-assisted laparoscopic (HALS) sigmoid colectomy with Pfannenstiel incision, attributing the following advantages to the technique: direct visualization of the colorectal anastomosis obviating the requirement for reestablishing pneumoperitoneum prior to performing anastomosis.

At first glance, one might think that the earlier literature was focused only on technical aspects. This was true early on, as, for example, a 1992 report from Wexner et al. [8] emphasized the benefits of laparoscopy, focusing mainly on perioperative outcomes. However, shortly thereafter, concerns were voiced regarding oncologic outcomes following laparoscopic colectomy, specifically the phenomenon of port site tumor recurrence. In 1994, a report raised concerns about high rates (21%) of port site recurrence, prompting several surgical societies to advise against performing laparoscopy for curable cancer [9]. This was a troubling time for surgeons attempting to perfect laparoscopic colectomy techniques, because if neoplasia was off limits, the majority of laparoscopic colectomies would be performed for inflammatory conditions (diverticulitis and inflammatory bowel disease), which are much more challenging entities from a technical perspective.

Multiple basic science and clinical studies were launched, attempting to determine whether port site recurrences were a common phenomenon and, if so, were they due to suboptimal technique or did they arise from some as yet unknown adverse effect of pneumoperitoneum on cancer cells during mobilization of a visceral malignancy [10–12]. Review of select videos from index colectomies following which port site recurrences occurred suggested that technical issues may

be the primary concern. Clinical series were published in which port site recurrence rates were approximately 1% (similar to wound implant rates following open surgery), which was reassuring. During this period, data from the American Society of Colon and Rectal Surgeons (ASCRS) registry were published, reporting an incisional recurrence rate of 0.4% after laparoscopic surgery for colon cancer [13].

In the late 1990s and early 2000s, a number of prospective randomized controlled trials (RCTs) were undertaken to investigate the impact of laparoscopic surgery on oncologic and postoperative outcomes following segmental colectomy for curable intraperitoneal colon cancer. All studies came to similar conclusions, namely, that laparoscopic colectomy, when performed by experienced surgeons, was oncologically not inferior to open colectomy [14–19]. Laparoscopy was associated with faster postoperative recovery, about 1 day shorter hospital stay, improved short-term functional outcomes, and better cosmesis. However, by 2–3 months following surgery, there were no major differences in function or quality of life, and laparoscopy was associated with longer operative times and increased cost. Despite the rather modest benefit of laparoscopy demonstrated by RCTs, some surgeons interpreted the data as demonstrating that laparoscopy was clearly superior to open surgery and considered this a free pass to perform any type of colorectal resection laparoscopically. Others took a more measured approach, acknowledging that there is a steep learning curve, with at least 20–152 laparoscopic cases considered as the minimum to achieve basic proficiency in this technique [20–27]. After the publication of RCTs demonstrating non-inferiority of laparoscopic segmental colectomy for cancer, the ASCRS, the American College of Surgeons (ACS), and the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) published statements supporting the use of laparoscopy colectomy for cancer by appropriately trained surgeons.

The twenty-first century saw the development of organized approaches to performing laparoscopic colorectal surgery, with early laparoscopic adopters proposing standardized sequential operative steps and port placements for their preferred technique [28–31]. Over the last 20 years, a number of minimally invasive techniques were proposed to overcome some of the limits of straight laparoscopy (see below) [32–39]. Hand-assisted laparoscopic surgery (HALS) was proposed to provide reasonable solutions to some legitimate concerns. For example, HALS allows manual palpation of a rectal tumor for providing adequate distal transection of the rectum as well as decreased operating time for left-sided colectomy and total abdominal colectomy [32, 40]. The advent of robotic technology gave back to surgeons degrees of freedom lost by the use of laparoscopic, non-wristed instruments as well as three-dimensional view, stable camera platform, and tremor filtering. However, the bulkiness of the machine, the fact that the surgeon's assistant at the table only sees a two-dimensional image, lack of haptic feedback, increased operative time, and increased cost are the disadvantages and warrant more objective evaluation prior to pronouncing robotic laparoscopic surgery superior to other approaches [39]. Furthermore, technological advances of "conventional" laparoscopic optics and imaging technology have resulted in 3D laparoscopes that mitigate some of the robot's advantages. In 2010, the technique of transanal total mesorectal excision (TaTME) was proposed, aiming to overcome some of the technical challenges of abdominal rectal resections [33]. TaTME is built on a variety of techniques: transabdominal-transanal proctosigmoidectomy (TATA) [35], transanal endoscopic microsurgery (TEM) [34], transanal minimally invasive surgery (TAMIS) [36], natural orifice specimen extraction (NOSE) [37], and natural orifice transluminal endoscopic surgery (NOTES) [38].

It is important to point out that the potential advantages of a minimally invasive approach go beyond smaller incision size. Reduced interference with body homeostasis has positive impacts both in the clinical (less systemic inflammatory response to surgery, lessened magnitude of wound complications, shorter hospital stay) and social spheres (less work and social inactivity, less disability, less fear and anxiety). In some ways, geriatric, obese, and otherwise vulnerable patients may experience a greater reduction in morbidity than their younger, healthier counterparts [41] .

We have chosen to focus the remainder of this chapter on minimally invasive techniques to treat patients suffering from rectal cancer. We felt this was appropriate given the fact that laparoscopic colectomy for intraperitoneal colon cancer has been well accepted for many years, but the application of MIS techniques to rectal cancer is more controversial. In addition, the techniques utilized to perform proctectomy are not as mature as those to perform colectomy. We will review some of the pertinent literature on the topic, but we will not attempt to perform a systematic review of the evidence available in the literature. Rather, our primary objective is to provide a step-by-step how-to guide for surgeons, as well as to describe potential advantages and technical challenges. The techniques outlined are those preferred by the authors currently. Certainly other techniques have been utilized successfully by other surgeons, although the basic principles for a successful operation are common to all.

Minimally Invasive Rectal Cancer Surgery

Laparoscopic Rectal Cancer Surgery

Laparoscopic proctectomy for rectal cancer is a complex operation and should be performed carefully by a laparoscopic expert who has mastered the learning curve. The mag-

nified view of the pelvis should potentially lead to potential clinical advantages such as the achievement of negative radial margins, spared autonomic nerves, and avoidance of ureteral injury. However, laparoscopy has some technical limitations such as poor ergonomics, two-dimensional view, inflexible instruments, coning, and fulcrum effect that may negatively impact attempts to operate in narrow anatomical fields such as the pelvis. A meaningful example of these limitation is the 12% rate of involved circumferential radial margins (CRM) after laparoscopic restorative proctectomy (versus 6% in the open arm), as well as the 34% rate of conversion from laparoscopic to open operation, as reported in the CLASICC trial [42]. Accordingly, the trial concluded that suboptimal short-term outcomes after laparoscopic-assisted anterior rectal resection for cancer do not yet justify its routine use. However, long-term results after a median follow-up of 5 years showed no differences between laparoscopic and open techniques in overall survival (OS) and disease-free survival (DFS) in rectal cancer surgery [14]. Results of the COREAN trial [43, 44] showed short-term benefits for the laparoscopic approach (decreased blood loss, postoperative pain, and length of hospital stay) and comparable 3-year DFS in patients with non-metastatic mid-low rectal cancer undergoing proctectomy after neoadjuvant chemoradiotherapy. Recently, there has been controversy regarding the safety of laparoscopic proctectomy for rectal cancer. Two large RCTs, ACOSOG Z6051 [18] in the United States, and the ALaCaRT trial [19] in Australia and New Zealand failed to demonstrate noninferiority of the laparoscopic approach, using a composite assessment measure of successful resection (radial margin negative, distal margin negative, and mesorectal grade complete or nearly complete), all of which have been demonstrated to have prognostic significance in other trials. There were no differences in duration of hospital stay; incision length was shorter in the laparoscopic group. The authors of both trials concluded that, based on their data, laparoscopic proctectomy should not be performed for rectal cancer. It is unclear how many surgeons migrated away from laparoscopic proctectomy after publication of those trials. It is somewhat reassuring that, despite the concerns regarding the quality of the mesorectal dissection in the laparoscopic group, the 3-year DFS in the ACOSOG trial was equivalent for the laparoscopic and open groups [18]. A greater understanding of the relative risks and benefits of laparoscopic proctectomy will be gained when long-term oncologic results are mature. Controversy regarding the appropriateness of laparoscopy for rectal cancer should not be surprising, as laparoscopic exposure and retraction in the deep pelvis can be challenging, as a result of bulky uterus and adnexa, redundant pelvic peritoneum, bulky tumors, and narrow pelvis. These factors continue to limit the widespread application of minimally invasive proctectomy for both the laparoscopic and robotic approaches.

Laparoscopic Proctectomy

Indications

Patients presenting with resectable, histologically proven adenocarcinoma of the rectum without documented involvement of the external sphincter are candidates for laparoscopic resection of the rectum with anastomosis. Those with cancer of the upper third of the rectum should be considered for low anterior resection (LAR) with partial mesorectal excision as long as an adequate distal resection margin is achieved. Patients with cancer of the mid and distal thirds of the rectum should be considered for LAR with total mesorectal excision (TME), guaranteeing at least a 1-cm distal resection margin. Patients with cancer of the very low rectum involving the internal anal sphincter can be considered for intersphincteric resection (ISR) with hand-sewn coloanal anastomosis, although there are concerns regarding high +CRM rates and suboptimal functional results [45].

Preoperative Considerations

Patient selection for laparoscopic LAR is the key to a successful operation and a good patient outcome. The only absolute contraindication is the inability to tolerate pneumoperitoneum and steep Trendelenburg positioning. Relative contraindications include morbid obesity, prior pelvic surgery, severe cardiopulmonary disease, and suspected or known massive intra-abdominal adhesions. Ureteral stent placement should be considered for patients with bulky pelvic tumors or prior pelvic surgery. Lighted stents in laparoscopic pelvic surgery have been described and may be of particular use in robotic cases given the lack of haptic feedback, but are not considered essential (Fig. 36.1). The patient should undergo stoma site marking and education, preferably by an enterostomal therapist, as many patients will undergo temporary diverting ileostomy or colostomy.

Surgical Technique

The following techniques are applicable to patients with rectal cancer that does not invade beyond the mesorectal fascia or into adjacent organs on preoperative cross-sectional imaging or physical examination.

Access to the Abdomen and Vessel Ligation

The patient is placed in the lithotomy or supine split-leg position with head, chest, and arms tucked because tilting the table will be necessary (Fig. 36.2). The surgeon stands on the patient's right side. Pneumoperitoneum is established through an open technique at the umbilicus where a 10-mm trocar is inserted for the 30-degree laparoscope camera. A 10-mm (or 12-mm) trocar placed in the right lower quadrant lateral to the rectus muscle sheaths allows the use of a stapling device. Three 5-mm ports are inserted under direct vision in the right upper quadrant, left lumbar, and left lower

Fig. 36.2 Laparoscopic proctectomy: patient positioning

quadrant (Fig. 36.3). The left ports are used by the assistant. Following initial inspection of the peritoneal cavity, the table is tilted in Trendelenburg and to the right; this allows placement of the small intestine in the right upper quadrant. Using 5-mm bowel graspers through the left-sided cannulas, the assistant holds the sigmoid ventrally under traction and to the left. In a medial-to-lateral fashion, the inferior mesenteric artery (IMA) is identified, and the retroperitoneum is incised

starting at the sacral promontory and proceeding to the root of IMA, taking care not to injure the superior hypogastric plexus, the left ureter, or the gonadal vessels (Fig. 36.4). Once the origin of the IMA is identified, the peritoneum is incised anteriorly over the pedicle and away from the left colic artery (Fig. 36.4). A gauze can be placed around the IMA and grasped on both sides, helping to lift the vessel during its isolation (Fig. 36.5). The dissection proceeds deep to the inferior mesenteric vein (IMV), sweeping the mesentery of the descending colon away from the retroperitoneum and taking care not to injure the pancreatic tail (Fig. 36.6). The IMV is isolated adjacent to the ligament of Treitz, taking great care to avoid injury to the communicating arterial branches of the left colic artery and left branch of the middle colic artery. The IMA and IMV are then divided after visualizing again the left ureter (Fig. 36.7).

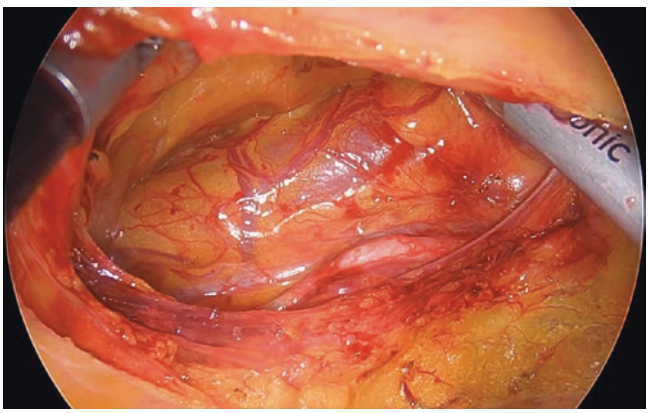

Fig. 36.4 Dissection of the inferior mesenteric artery (IMA). The retroperitoneum is incised starting at the sacral promontory and proceeding to the root of IMA taking care not to injure the superior hypogastric plexus, the left ureter, and the gonadal vessels (clearly visible in this picture)

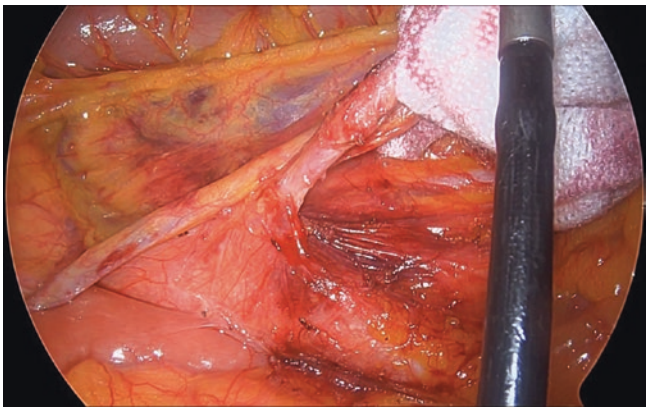

Fig. 36.5 A gauze can be placed around the inferior mesenteric artery (IMA) and grasped on both sides helping to lift the vessel during its isolation

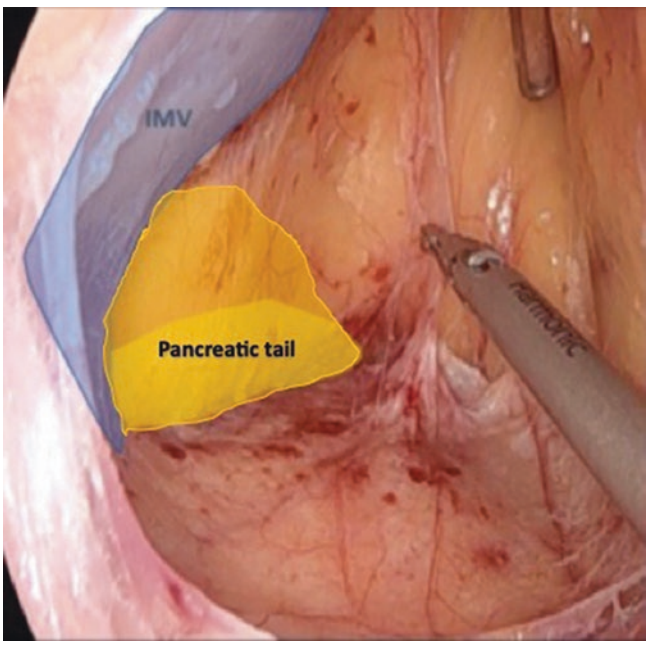

Fig. 36.6 Dissection of the inferior mesenteric vein (IMV). Care must be taken not to injure the pancreatic tail

Splenic Flexure and Left Colon Mobilization

Through the peritoneal window, the left mesocolon is dissected from the underlying retroperitoneal structures, including the gonadal vessels, ureter, Gerota's fascia, and pancreas. The rationale for performing splenic flexure mobilization is to ensure adequate length of the proximal colonic conduit, allowing for a tension-free luminal anastomosis as well as a tension-free mesentery so that blood supply is not compromised. Technical steps to perform splenic flexure mobilization include division of the omental attachments to the transverse colon, mobilization of the left colonic mesentery, and division of the bare area at the root of the mesentery of the distal transverse colon. The following situations warrant special caution: a history of aortic surgery (this can interrupt or reverse the normal circulation in the marginal artery), prior left nephrectomy, and previous colonic surgery with concern regarding arterial flow in the marginal artery (Fig. 36.8). The left colon is then mobilized by dividing the lateral peritoneal attachments along the white line of Toldt. After the mobilization of the left colon, the sigmoid mesocolon is divided.

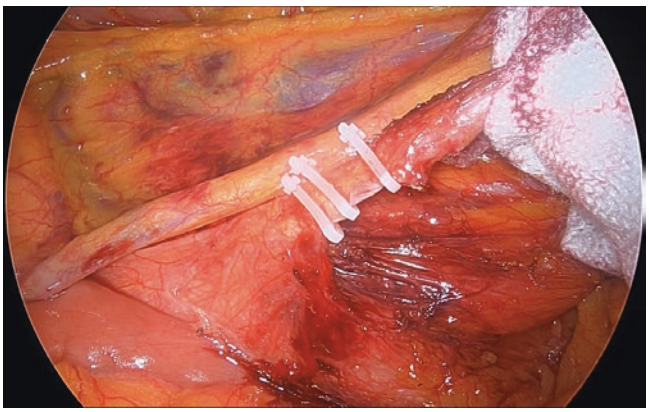

Fig. 36.7 Division of the inferior mesenteric artery (IMA)

Mesorectal Mobilization Using TME Principles

The peritoneum is incised at the lateral border of the mesorectum, medial to the ureters, connecting the plane of dissection anteriorly in the cul-de-sac at the anterior peritoneal reflection. The mesorectal dissection is then typically initi-

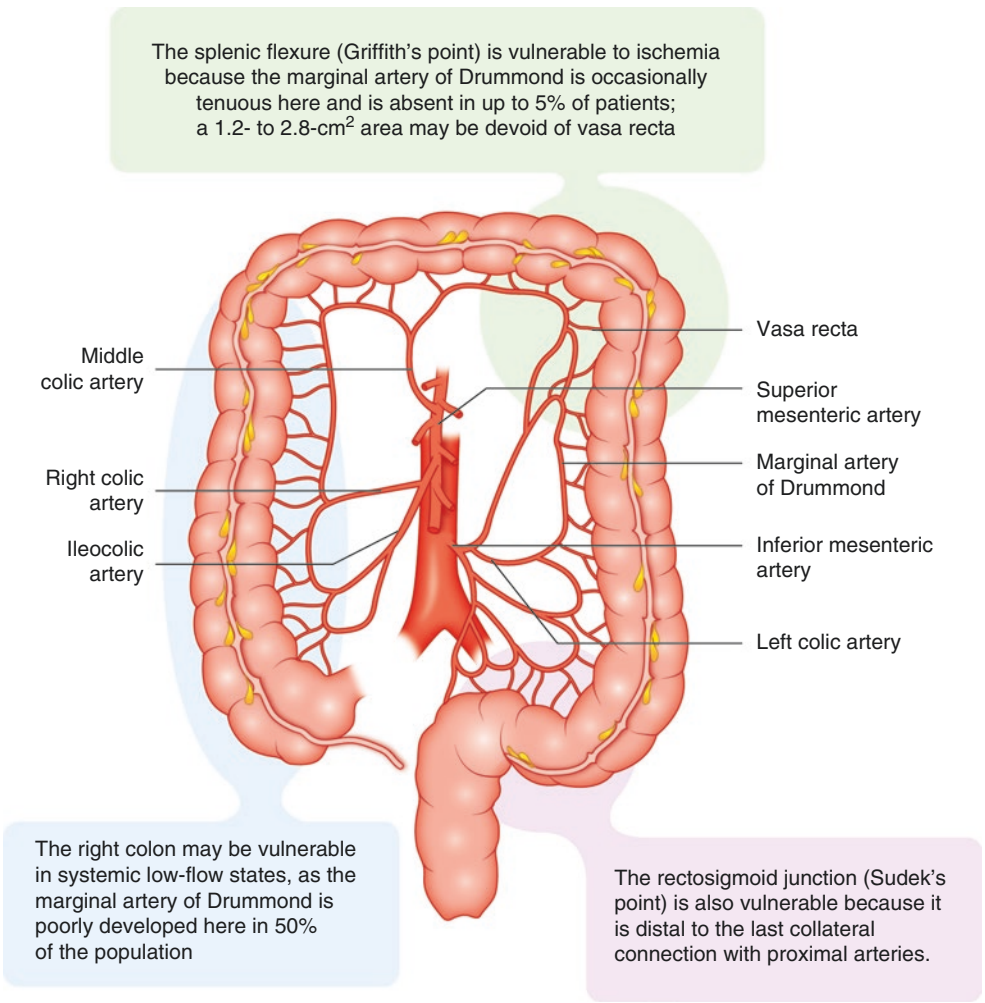

Fig. 36.8 The three critical points for colorectal vascular supply

ated posterior to the mesorectum, at the level of the sacral promontory. At this point, it is important that the assistant takes the redundant colon out of the pelvis; this will help to identify the plane between the parietal and the visceral layers of the endopelvic fascia which is dissected sharply with cautery. Care is taken to identify the hypogastric nerves as they travel anterolaterally across the aortic bifurcation, approximately 2 cm medial to the ureters bilaterally. Dissection along the fascia propria of the rectum (visceral peritoneum) will maintain a correct plane of dissection, avoiding to injure the hypogastric nerves posteriorly, the pelvic plexus laterally, and the anterior cavernous plexus anteriorly. The area of dissection may contain small blood vessels emanating from the pelvic sidewall whose bleeding may be controlled with cautery. The surgeon must be wary of straying into the pelvic sidewall, as this can result to bleeding from branches of the internal iliac vein and artery, as well as nerve injury. Dissection should be in an avascular plane; moderate-significant bleeding indicates you are likely in the wrong plane. Inferior to the level of S3, the rectosacral ligament (Waldeyer's fascia) is divided. Blunt dissection should be avoided to prevent tearing into the mesorectum or presacral fascia and injury to the presacral venous plexus. The angle of dissection follows the curve of the sacrum, proceeding anteriorly to the pelvic floor. Anterior dissection can be challenging in men. The plane of dissection anterior or just posterior to Denonvilliers' fascia should be chosen based on the position of the tumor. If the tumor is anterior in the rectum, dissection is anterior to the Denonvilliers' fascia, exposing the seminal vesicles bilaterally (Fig. 36.9). In females, anterior dissection occurs in the rectovaginal septum. Appropriate traction by the assistant is critical to provide appropriate tissue tension and exposure for dissection. Sometimes, applying perineal pressure can aid in the dissection as this maneuver elevates the pelvic floor. At this point, distal transection guaranteeing a margin ≥1 cm should be performed.

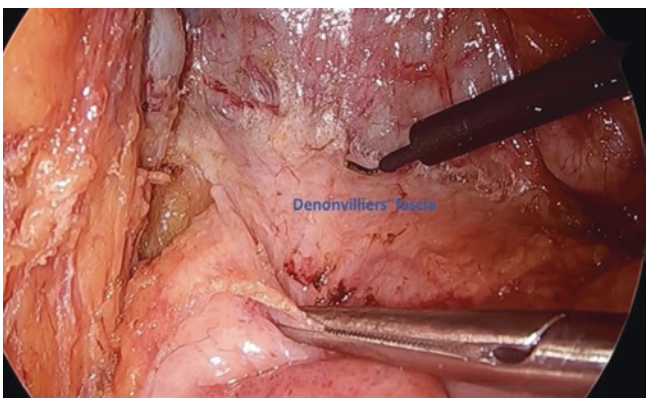

Fig. 36.9 In case of tumors located on the anterior rectal wall, the dissection is performed anteriorly to the Denonvilliers' fascia, exposing the seminal vesicles bilaterally

Precise localization of the tumor is paramount prior to any division of rectum or mesorectum during proctectomy. Video flexible endoscopy, or at least rigid proctoscopy, should be performed intraoperatively to ensure that the chosen transection site encompasses the entire tumor and mesorectum at risk with adequate margins.

When considering the next step in the operation, distal rectal transection, it should be noted that there are technical limitations to performing this maneuver laparoscopically [46]. One is the fulcrum effect of operating a stapler through a port placed in the iliac fossa. Another limitation is the degree of angulation of the currently available staplers. A virtual simulation study has shown that staplers will actually have to go through the iliac bone to achieve a 90-degree angle of rectal transection at the level of the levator ani muscle [47]. A third limitation is the number of cartridges required. Ideally, distal rectal transection should be accomplished perpendicularly with a single staple firing. However, in practice, multiple stapler firings are often needed for rectal transection, possibly increasing the risk of anastomotic leakage [48]. Furthermore, intersecting lateral staple lines (dog ears) obtained after double-stapled anastomosis techniques are also considered weak structural spots, areas possibly prone to leak [49]. Tilting the rectum to the left has been suggested to achieve a 90-degree angle of transection with laparoscopic 45-degree staplers, but this is not always feasible [50]. Additionally, double-stapling following oblique transection of the rectum may result in an anastomotic stricture because of the potential for suboptimal blood supply at the acute angle of transection. In order to avoid multiple firings, the stapler may be inserted through a suprapubic incision. The fulcrum effect, however, will remain unresolved, and the pneumoperitoneum may become unstable. An alternative method is to insert a conventional stapler through a gelatinous hand-assisted device. This has three advantages: the fulcrum effect is ameliorated by the consistency of the gel, pneumoperitoneum is stabilized by the seal of the hand port, and the tumor can be palpated and transection can be performed with a safe distal margin. However, this solution increases costs. If a hand-assisted device is anticipated to be utilized at this point in the case, it is more sensible to place it at the beginning of the case and use it throughout.

The specimen is typically extracted through a Pfannenstiel incision or by the left iliac fossa port, after positioning a wound protector. The descending colon is transected and the anvil is placed. Real-time indocyanine green fluorescence angiography (ICG-FA) may be helpful in assessing the vascular blood supply before transecting the colon [51–53] (Fig. 36.10), although there are no definitive data at this time to prove that ICG-FA is better than other methods of assessing perfusion to the proximal colon conduit. The results of the ongoing IntAct RCT will hopefully clarify this issue [54]. The double-stapled colorectal anastomosis is carried

Fig. 36.10 Application of real-time indocyanine green intraoperative fluorescence angiography (ICG-IFA) to assess the vascular blood supply before transecting the colon

out in accordance with the same principles described in conventional surgery. As noted above, intersecting lateral staple lines (dog ears) created after double-stapled anastomosis techniques are considered weak structural spots, possibly prone to leak (Fig. 36.11) [49]. Some techniques have been proposed to avoid at least one dog ear (Fig. 36.11, "tennis racket") or both (Fig. 36.12 "reverse smile" (Fig. 36.13) codi14419-sup-0001-VideoS1.mp4). In the first technique, the spike of the anvil is brought through the rectal stump laterally (as opposed to the middle), eliminating one intersecting staple line and thus one weak structural spot (Fig. 36.11). In the reverse smile maneuver, the spike is brought through the rectal stump in its central part, just posterior to the linear staple line. After the spike is brought through the stump, the shaft of the stapler is retracted slightly and the end of the stapler angled anteriorly. This pulls the two edges of the linear staple line toward the midline posterior to the spike, forming a "reverse smile" (Figs. 36.12 and 36.13). The intent is that the entire linear staple line of the rectal stump will then be excised when the anastomosis is created, essentially transforming a double-stapled into a single-stapled anastomosis (Figs. 36.14, 36.15, and 36.16) [55]. One must take great care to avoid entrapping other pelvic structures in the staple line, such as the vagina, during this maneuver. An alternative anastomotic technique to avoid intersecting staple lines and dog ears after a conventional cross-stapling of the distal rectum has been described [56]. Recently a proof of concept study for transanal distal transection of the rectum and single-stapled anastomosis was proposed to overcome the previously described limits of transection and anastomosis in rectal surgery (Fig. 36.17) (codi14631-sup-0001-VideoS1.mov) [57]. However, these alternative techniques still need a large-scale trial to critically assess their potential benefits. After the anastomosis is completed, leak test using gas (CO2 is preferred), either standard (via proctoscopy) or reverse (via insufflation of the peritoneum) (Fig. 36.18) (codi14399-sup-0001-VideoS1.mp4) [58], is performed. ICG-FA may be performed for a final check of perfusion to the anastomosis (Fig. 36.19). Diverting stoma (loop ileostomy or colostomy) should be considered, particularly in patients with distal anastomosis, prior radiation, or severe comorbidities.

Intersphincteric Resection

When intersphincteric resection (ISR) is contemplated, patients should undergo preoperative evaluation of anal sphincter function. ISR should be reserved for select cases of tumors not amenable to standard LAR, and patients should be carefully informed of the possible functional derangements. ISR entails transanal circumferential incision of the anal mucosa in the intersphincteric groove, which is located distal to the dentate line. ISR leads to en bloc resection of the rectum and internal sphincter; the specimen is extracted transanally. The descending colon is then

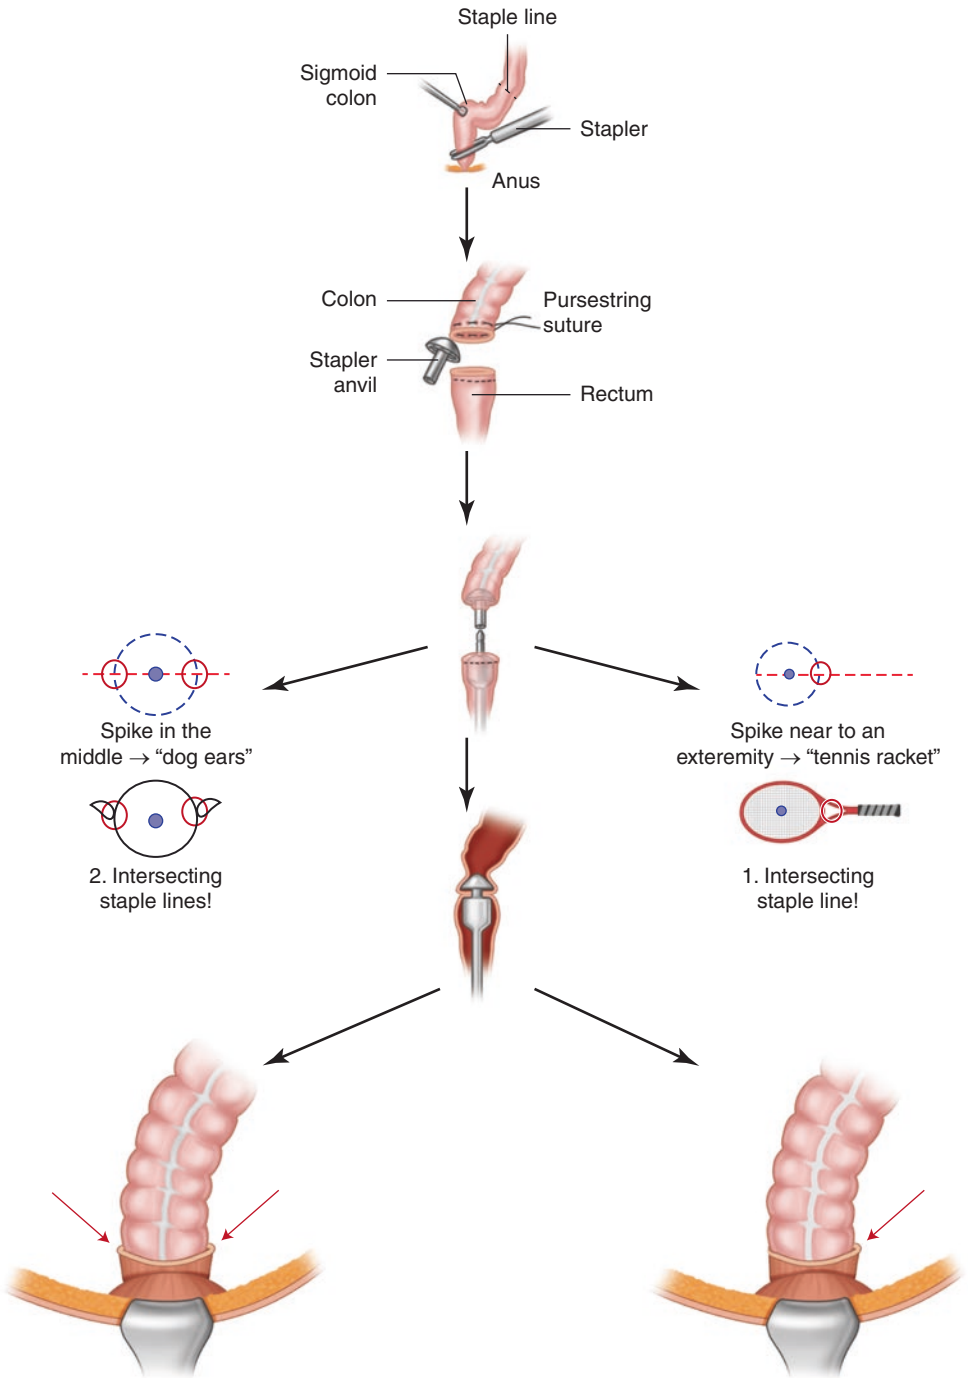

Fig. 36.11 Intersecting lateral staple lines (dog ears) created after double-stapled anastomosis techniques are considered weak structural spots, possibly prone to leak (left). One trick to eliminate one intersecting staple line, and thus one weak structural spot (dog ear), is to bring the spike of the anvil through the rectal stump laterally (as opposed to the middle). This was described as the "tennis racket" technique

divided, and a hand-sewn coloanal anastomosis with absorbable sutures is performed. A proximal diverting stoma is usually performed.

Laparoscopic Abdominoperineal Resection (APR)

Despite surgical options to spare the anal sphincter, APR is still required in approximately 18% of patients with rectal cancer [59]. Although published RCTs compared short- and long-term outcomes after laparoscopic and open rectal resections for cancer, which included APR [14–19, 42–44], a subset analysis for APR cases was not performed. As such, we have limited data to support or refute the use of laparoscopic techniques to perform APR. A prospective randomized trial by Ng et al. [60] specifically evaluated perioperative outcomes in patients with low rectal cancer undergoing open (n = 48) versus laparoscopic (n = 51) APR. The authors reported an earlier return of bowel function (3.1 days vs

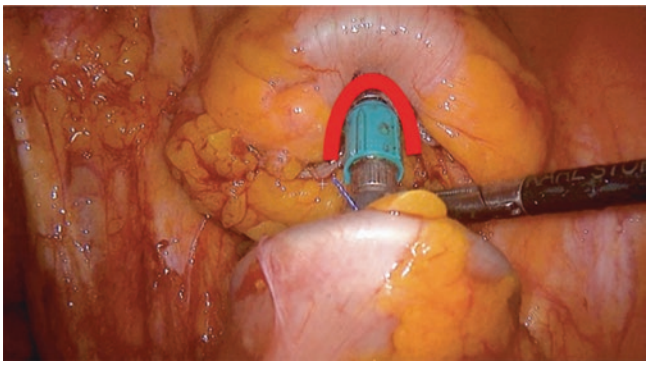

Fig. 36.12 The "reverse smile" technique: the spike is brought through the rectal stump in its central part, just posterior to the linear staple line. Then, the shaft of the stapler is retracted slightly and the end of the stapler angled anteriorly. Fig. 36.14 The intent of the reverse smile technique is that the entire linear staple line of the rectal stump will then be excised when the anastomosis is created, essentially transforming a double-stapled into a single-stapled anastomosis

Fig. 36.15 Complete staple line is clearly visible on the donut

4.1 days; $p < 0.001$) and improved time until independent ambulation (4.4 days vs 5.9 days; $p = 0.005$) in the laparoscopic group but higher cost ($9588 vs $7517; $p < 0.001$) and longer operative time (213 min vs 163 min; $p < 0.001$). Consistent with the findings of the CLASICC trial [42], a 5-year survival was equivalent between the two approaches (75% vs 76%; $p = 0.20$). Unfortunately, studies on laparoscopic APR infrequently report CRM involvement rates. Among 19 studies published since 1994 that reported oncologic outcomes of laparoscopic APR, only 6 [61–66] included data on CRM involvement, which ranged from 2% [66] to 21% [62]. Two studies [63, 64], including the Dutch TME trial [64], reported an association between higher tumor stage and CRM involvement. In a subset analysis of the Dutch trial, the rate of positive CRM was 30% in the 455 patients who underwent APR [64]. The relatively high rate of CRM seen in the Dutch randomized trial raises the issue of selection bias in other non-randomized comparisons, in which it is likely that patients with more advanced tumors undergo open operations. In conclusion, existing data on

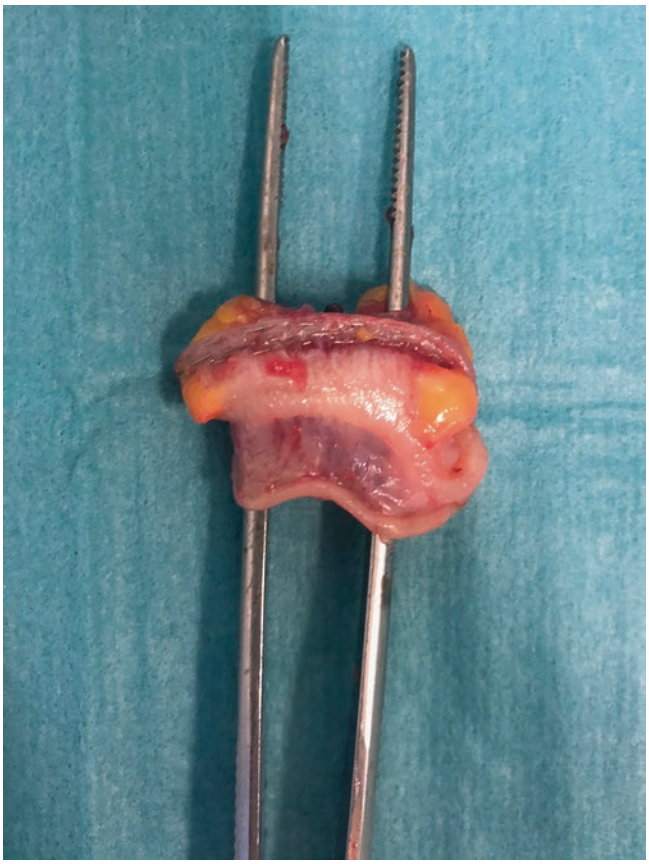

Fig. 36.16 Completed staple line is clearly visible on the donut

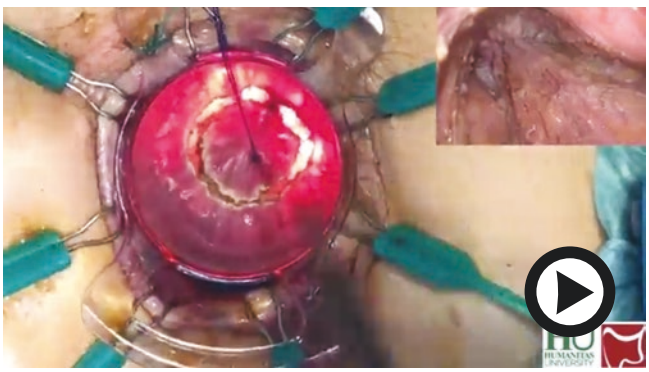

Fig. 36.17 Transanal distal transection of the rectum and single-stapled anastomosis. https://doi.org/10.1007/000-33j

laparoscopic versus open APR suggest that, when performed by skilled surgeons, the laparoscopic approach is associated with reasonable oncologic outcomes with possible faster recovery [66, 67].

Preoperative Considerations

Abdominoperineal resection (APR) is indicated for low rectal cancers, recurrent rectal cancers, as well as salvage therapy for anal cancer or melanoma. Additionally, APR may provide a better quality of life compared to LAR/coloanal anastomosis for patients who have marginal baseline continence or are at risk for severe anterior resection syndrome. The patient should undergo stoma site marking and education, preferably by an enterostomal therapist. A preoperative consult with a plastic surgeon should be considered if a large pelvic defect will result, as flap closure may be indicated.

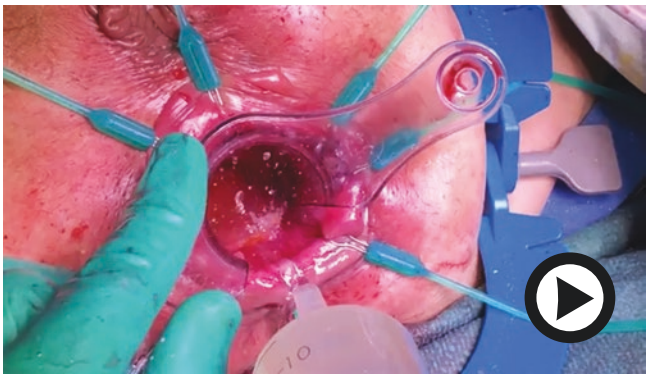

Fig. 36.18 Air leak test. https://doi.org/10.1007/000-33m

Surgical Technique

Abdominal Approach

The abdominal steps for APR are the same as for laparoscopic LAR. One of the two left-sided trocars should be positioned at the colostomy site (preoperatively identified and marked), and a suprapubic trocar can be utilized (instead of having two ports on the left site). After mobilization of the left colon and rectum, the sigmoid colon is divided, and the proximal end of the colon is brought through the abdominal wall to fashion an end colostomy. Ports are closed and the drain (if needed) is placed.

Laparoscopic Perineal Approach

The steps of the traditional perineal procedure are described in the chapter devoted to the principles of rectal cancer surgical treatment. However, another option is to perform the perineal part of the operation via a laparoscopic technique as well. The theoretical advantage of this retrograde method relates to the creation of the dissection plane in the pelvis before entering into the peritoneal cavity, thus avoiding having other pelvic structures impede exposure. As the literature on this approach is still in its infancy, there are little data on feasibility, safety, and outcomes of this approach. Our preferred approach is as follows. The patient is in lithotomy position. The anus is sewn closed and dissection is initiated in the ischiorectal space/extrasphincteric plane. Once the levator ani muscles are divided, a single-port laparoscopic surgery or transanal endoscopic microsurgery device is positioned within the dissected space and secured to the skin to

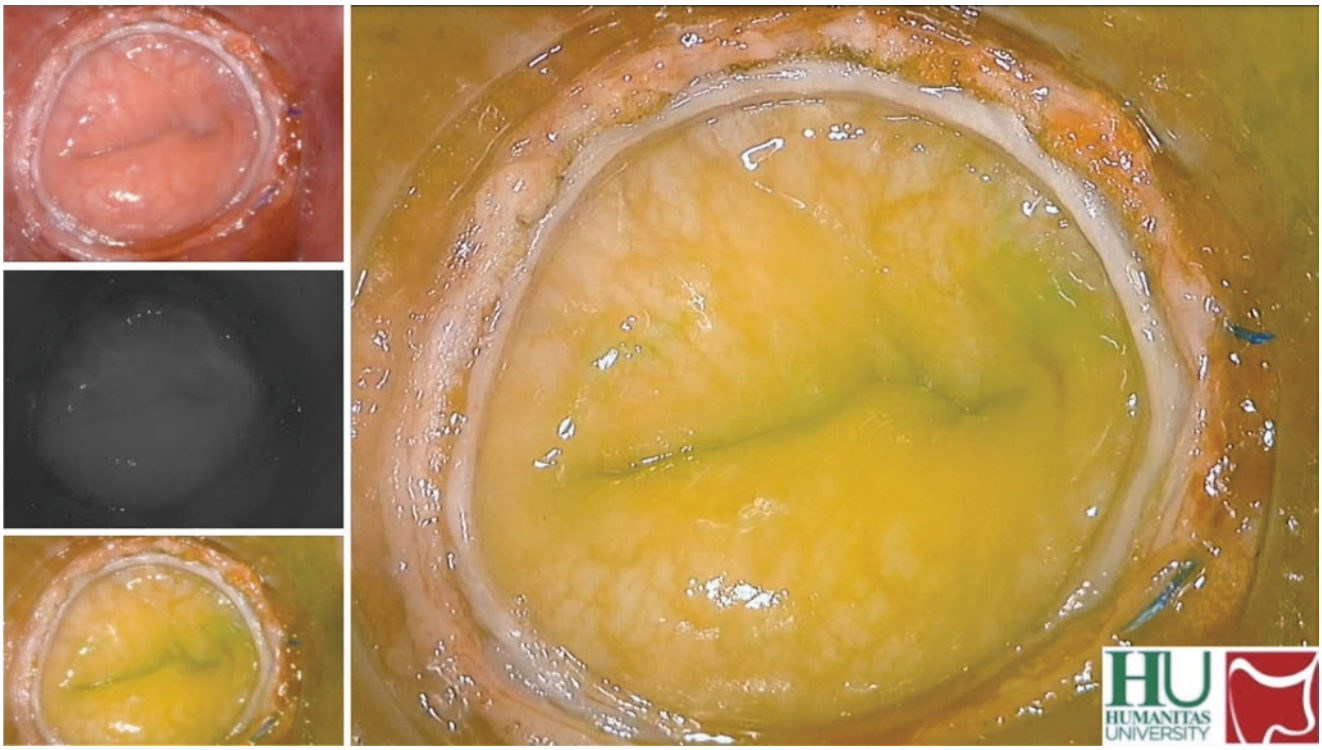

Fig. 36.19 Assessment of the colorectal anastomosis perfusion with real-time indocyanine green intraoperative fluorescence angiography (ICG-IFA)

prevent CO2 leakage and dislodgement of the access device. The space is insufflated to 15 mmHg, which will put the tissue on tension, thereby retracting the anus/rectum into the pelvis and helping to provide a working space with exposed wispy fibers in the mesorectal dissection plane. Laparoscopic hook cautery is used for dissection, and a suction irrigator is used both for smoke evacuation and countertraction. The small working space fills easily with smoke and quickly collapses with suction. This challenge can be overcome by connecting two separate CO2 insufflation lines to the access device or by switching to a system that allows for continuous smoke evacuation and CO2 exchange. The dissection proceeds to the level of the cervix in women and to the seminal vesicles in men or until the prior mobilization plane from above is reached (if the abdominal portion was performed first). The specimen is then removed through the perineal defect.

Robotic Rectal Cancer Surgery

The first robotic proctectomy for cancer was described in 2006 [68]: a magnified 3D view, improved ergonomics and overall dexterity with 7 degrees of freedom, stable camera holding, tremor filtering, motion scaling, and shorter learning curve seemed all promising features to overcome the limits of laparoscopic rectal surgery. Disadvantages of robotic surgery can be attributed to the lack of haptic feedback, longer operative time, and cost [69]. In addition, the potential benefits of the robotic approach for the surgeon seem not to have translated into demonstrable improved outcomes for the patient.

As noted above, laparoscopic proctectomy can be very challenging, especially in males who are obese with irradiated low tumors. Using the nonarticulating laparoscopic instrumentation and obtaining an optimal surgical view can be difficult and lead to high conversion rates [42, 70]. The abovementioned advantages of the robot could overcome these challenges and potentially lead to lower conversion rates [71, 72]. However, the ROLARR RCT [73], which used conversion to open as the primary outcome variable, failed to demonstrate that the robotic approach was associated with a lower conversion rate. Additionally, the ROLARR RCT [73] did not find any difference in short- and long-term outcomes between the robotic and the laparoscopic approaches. Lastly, robotic surgery was on average £980 more expensive than laparoscopic surgery, even when the acquisition and maintenance costs were excluded. Other RCTs [74–76] reported similar short-term, long-term, and functional outcomes between the laparoscopic and robotic approaches. The most time-consuming aspect of robotic surgery is docking, especially when multiple dockings are required. However, recent meta-analyses showed a similar operating time for robotic and laparoscopic proctectomy as a result of gained experience by the surgical team [71, 77].

Robotic proctectomy can be performed using a fully robotic or a hybrid laparoscopic/robotic technique [68, 78] in which the robot is docked only to perform the proctectomy. The choice of approach is up to the surgeon, as there are no studies demonstrating that one is superior to the other. A total robotic approach can be used in low anterior and abdominoperineal resections. For proctectomy with splenic flexure mobilization, a fully robotic approach can be time-consuming and may require two dockings, although the need to re-dock may be obviated by advances in robot technology [79, 80]. The hybrid approach implies that the mobilization of the splenic flexure and left colon and vessel ligation are performed laparoscopically. The robot is docked for rectal mobilization. This approach allows for the robot to be used for maximal benefit, which becomes evident in the narrow pelvis.

While there continues to be a debate regarding the cost-effectiveness of the robot, especially given the current lack of clinical evidence demonstrating its superiority to the laparoscopic approach, it appears to have an expanding role for colorectal surgeons, particularly with the advent of the single-port platform which may have utility in transanal procedures [81].

Robotic Proctectomy

Preoperative Considerations

There are no specific indications and no absolute contraindications for robotic proctectomy. The use of the robot is at the discretion of the surgeon, and indications are those indicated for laparoscopic rectal resection for cancer. The operating room setup should provide adequate space for staff and large equipment and allow the surgeon to have a direct view of the patient from the surgeon's console. The room should also allow docking from several angles.

Surgical Technique

Abdominal Robotic Approach

Port positioning with the da Vinci Xi® and Si® platform is shown in Figs. 36.20 and 36.21.

We describe the operating steps of a totally robotic proctectomy using the Xi platform.

The robot is docked from the patient left side and instruments are inserted under visual control. After a complete exploration of the abdominal cavity, the transverse colon is lifted up with the R1 arm (Fig. 36.22). The lesser sac is entered through an incision through the bare area at the root of the transverse mesocolon at the level of the anterior pancreatic border. Splenic flexure mobilization is carried out with a medial-to-lateral approach along the pancreatic body.

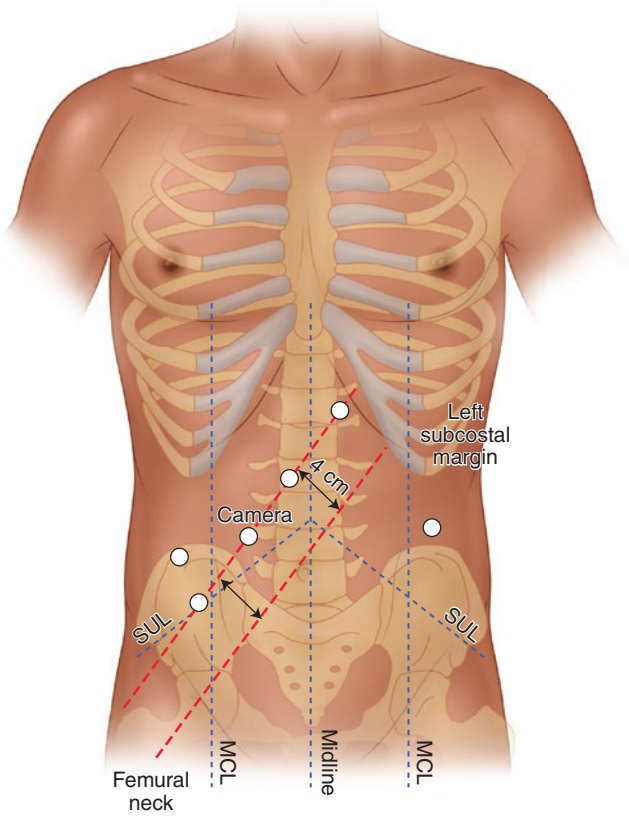

Fig. 36.20 Trocar placement for a fully robotic proctectomy with the da Vinci Xi® platform

A gauze is placed underneath the transverse mesocolon, and the splenic flexure is retracted medially by the assistant. Splenic flexure mobilization is completed in a lateral-to-medial fashion along the white line of Toldt up to the inferior splenic pole, and the plane previously developed is reached.

The next step is the ligation of mesenteric vessels. During this phase, R2 and R4 are the operative arms, whereas R1 is used for stable retraction. A 30°-down robotic camera is mounted on robotic arm R3. The trocar of the assistant in the right flank is used for suction/irrigation, clip applier, gauze introduction, or additional retraction if needed. The assistant grasper and the robotic grasper in R1 lift anteriorly and laterally the sigmoid colon and upper rectum to expose the root of the sigmoid mesocolon and the upper mesorectum. The peritoneum is then incised at the level of the sacral promontory to obtain the avascular presacral plane, and the hypogastric nerves are identified. The robotic monopolar hook on R4 and bipolar grasper on R2 work synergistically for the dissection of the IMA, which is freed from the surrounding lymphatic tissue, providing a wide locoregional lymphadenectomy and preserving the main trunks of the hypogastric plexus at the IMA origin. Before IMA division, Toldt's fascia is identified deep to the IMV in a medial-to-lateral fashion, and left gonadal vessels and left ureter are identified and preserved.

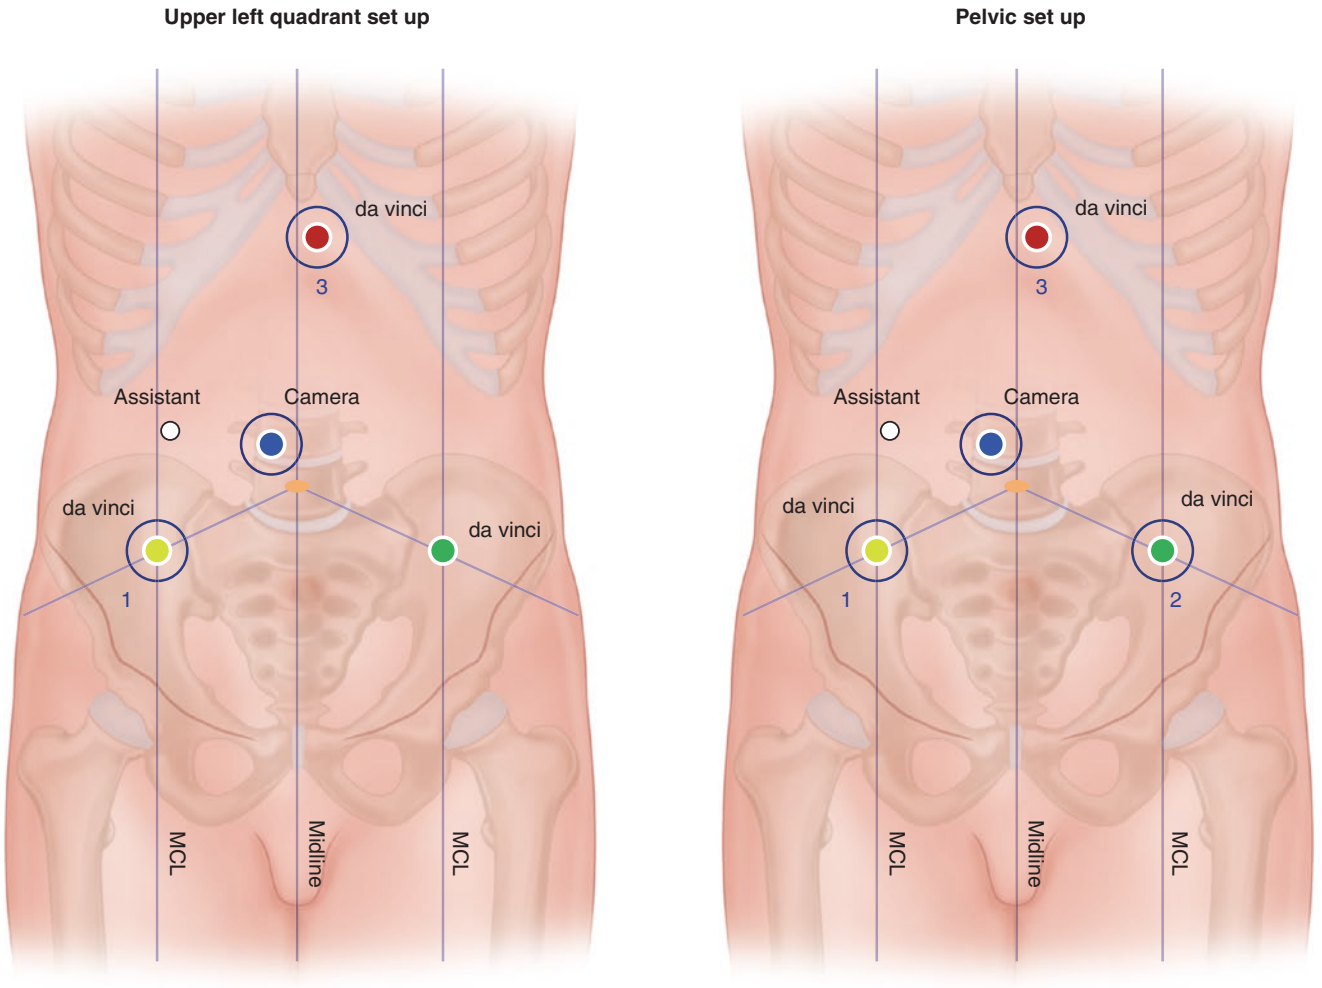

Fig. 36.21 Upper left quadrant setup and pelvic setup to perform a proctectomy with the da Vinci Si® platform

A high ligation of the IMA is then performed. The dissection along the Toldt's fascia, which has been previously identified cranially and caudally to the IMA origin, is completed to a medial-to-lateral fashion preserving the retroperitoneal structures. The IMV is then isolated and divided between clips (or using an energy device) at the inferior border of the pancreas.

Robotic Proctectomy

The canonical principles of TME are followed, emphasizing minimal manipulation of the rectum, identification of embryologic planes, and tumor clearance with negative margins. Bulky anterior tumors close to the vagina or prostate and seminal vesicles are more challenging, especially given the lack of haptic feedback from the robotic arms. In these cases, the identification of proper planes can be more difficult.

During this step, R1 is moved and connected to the left flank 8-mm trocar to achieve optimal access to the mesorectum, whereas R2 and R4 remain in their original position (Fig. 36.23). An additional 8-mm epigastric trocar is placed to maximize the assistance with cranial retraction on the sigmoid colon and simultaneous suction/irrigation or gentle pelvic sidewall retraction. Robotic R2 and R4 are the operative arms, whereas R1 is used to expose the pelvic area with lateral traction on the pelvic sidewall or anterior/upward traction on the Douglas peritoneal reflection, vaginal wall, or seminal vesicles/Denonvilliers' fascia. Frequent repositioning of R1 is fundamental to maintain the adequate countertraction that will allow the dissection to continue to the level of the pelvic floor. Mesorectal mobilization is carried out starting from the posterior plane: whereas the assistant retracts the sigmoid colon anteriorly and superiorly, the surgeon follows the areolar plane deep to the superior hemorrhoidal artery along the presacral fascia, toward the coccyx proceeding as distal as possible. Laterally, the hypogastric nerves are identified and preserved. Dissection is last carried anteriorly; Denonvilliers' fascia/pouch of Douglas is entered by incising the peritoneal reflection between the anterior wall of the rectum and the posterior wall of the vagina or seminal vesicles. R3 can be used as an anterior retractor to

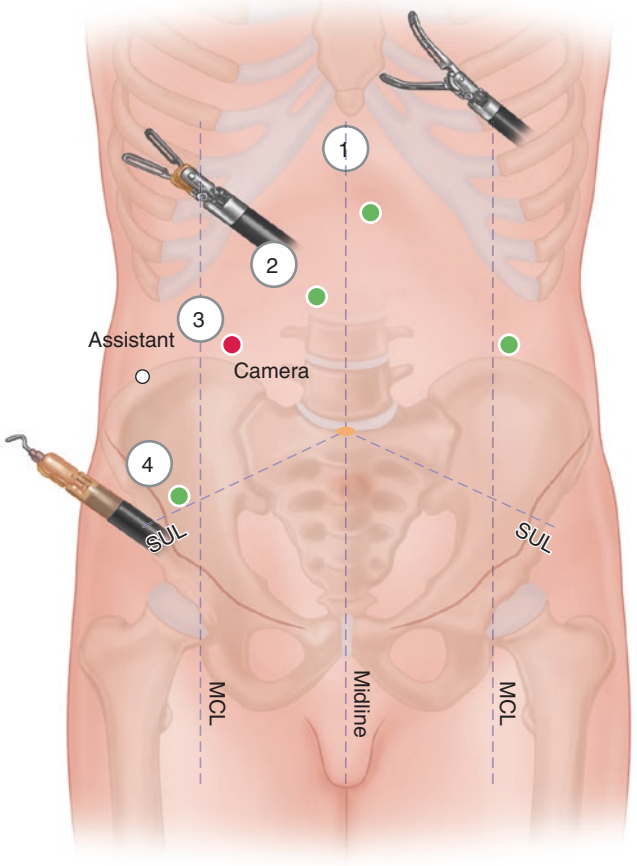

Fig. 36.22 Instrument setup during splenic flexure mobilization with the da Vinci Xi® platform

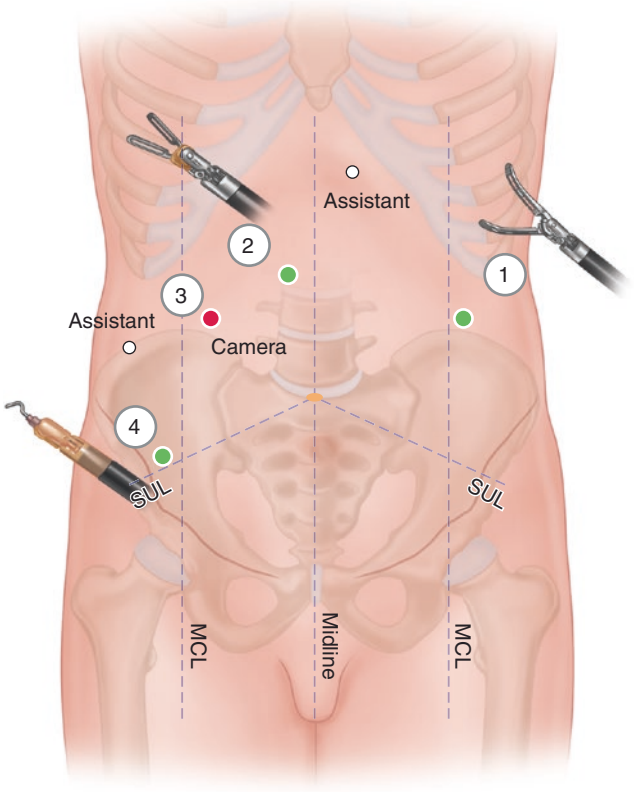

Fig. 36.23 Instrument setup during proctectomy with the da Vinci Xi® platform

keep the bladder, uterus, vagina, or prostate out of the field of dissection. It is important to point out that the left hand of the robotic surgeon (arm 2) should not grasp the mesorectum during the dissection because the robotic instruments are particularly powerful and can lacerate the mesorectal fascia. Dissection is carried out down to the pelvic floor where the levators can be identified. For tumors located at least 2–3 cm from the anorectal ring, a double-stapled colorectal anastomosis can be performed. The bowel is divided via either R1 or R2, using the robotic stapler or by the assistant using a laparoscopic approach, depending on the amount of retraction needed to expose the surface of the rectum. After undocking the robot, the bowel is extracted through a Pfannenstiel incision, and the proximal colon is divided extracorporeally. After insertion of the anvil, the double-stapled anastomosis is performed under laparoscopic vision. The technical aspects of performing the anastomosis are the same as described in the laparoscopic paragraph (see above). Transanal extraction is also possible. After placing a wound protector, the specimen is delivered through the anus, and extracorporeal resection is performed before fashioning the anastomosis. For tumors that are located less than 2–3 cm above the anorectal ring, not invading the external sphincter or levators, a double-stapled anastomosis may be difficult to accomplish under robotic or laparoscopic control without compromising the distal resection margin. In properly selected patients, an ISR with transanal extraction and hand-sewn coloanal anastomosis may be performed.

Robotic APR

The robotic approach can also be applied to APR or extralevator abdominoperineal excision (ELAPE). Once proximal mesorectal mobilization is completed, the dissection is carried distally, taking care to avoid "coning in" at the level of the levators creating a "waist" in the specimen. Rather, a wide resection of the levators near their origin is carried out, extending the dissection distally into the ischiorectal fat as far as feasible just before encountering the perineal skin. Once this is accomplished, the robot is undocked and the perineal phase is started. The few published studies of robotic APR show it is safe and feasible in select patients operated upon by experienced surgeons, with functional outcomes comparable to the laparoscopic approach [82–88]. One study reported lower conversion rates but higher total hospital

charges with the robotic approach compared to laparoscopy [89]. When compared to the open approach, robotic APR showed faster bowel recovery and a trend toward reduced CRM+ [83], although the vast majority of studies are not randomized, and thus selection bias may influence outcomes.

Transanal Total Mesorectal Excision (TaTME)

The concept of TaTME was proposed to overcome the technical challenges encountered with the transabdominal approaches (open, laparoscopic, robotic) in the more difficult cases such as obese, male patients with mid-low rectal cancers. There are concerns that such patients with a narrow, radiated pelvis and bulky mesorectum may currently be undergoing sphincter-sparing resections with an involved CRM, a poor-quality TME, or even an unnecessary abdominoperineal resection (APR). It has been recently claimed that TaTME offers three potential advantages: (1) a longer distal resection margin, thanks to the distal transection under direct visual control, reducing the risk of distal margin tumor involvement, (2) a decreased rate of positive CRM, and (3) improved quality of TME [90]. Additionally, rectal transection performed under visual control avoids multiple stapling and dog ears that together with the single-stapled anastomosis can potentially reduce the risk of leak, even if the comparative benefits of single-stapled over conventional double-stapled anastomosis are still unproven [91]. However, the utilization of TaTME remains controversial, because of the lack of RCTs comparing TaTME to open, laparoscopic, and/or robotic proctectomy and because of concerns regarding safety. Several non-randomized studies, including the results from the TaTME registry group [92], have suggested that TaTME is an oncologically safe and effective technique in select patients, resulting in comparable short-term and oncologic outcomes when compared to the abdominal approaches [90, 92–98]. Recently, a number of criticisms have been raised over the TaTME technique, including concerns about complications such as urethral damage or carbon dioxide embolism [91, 99–101] and multifocal local cancer recurrence potentially related to the use of pelvic insufflation and spread of cancer cells [102], very rarely previously reported in other approaches. However, results from a recent study including six tertiary referral centers focused on local recurrence (LR) after TaTME showed a 2-year LR rate of 3% and no multifocal pattern of recurrence, indicating good locoregional control after TaTME [103]. Standardization of surgical technique, implementation in daily practice, and strict selection criteria are required to further clarify the role of TaTME in the treatment of rectal cancer. Hopefully, the COLOR III multicenter RCT will better define the relative short- and long-term oncologic outcomes after TaTME [104].

Transanal TME

Surgical Technique

Abdominal Approach

The patient is placed in the lithotomy position. Standard steps of the abdominal dissection are performed: left colon and splenic flexure mobilization, division of IMA and IMA, and then mobilization of the proximal mesorectum, paying attention not to injure the urethra and hypogastric nerves during dissection. The transanal mobilization can be performed before, after, or synchronous with abdominal mobilization.

Transanal Approach

Setup and Start

The patient is placed in the lithotomy position, in Trendelenburg, and tilted to the right. A pudendal block with local anesthetic is performed. A self-retaining retractor is then placed to visualize the dentate line. The hooks are placed at the level of the anal verge, retracted, and fixed on the plastic frame (Fig. 36.24). Anal dilators are used to facilitate the placement of the transanal platform. This author's preference is to use a flexible platform which is firstly folded in a U-shaped manner to facilitate its introduction in the lubricated anal canal. The device is adjusted with the introducer beyond the levators and two stitches placed laterally to fix it in place. In cases of very low rectal lesions, it may be desirable to leave the platform unfixed or secured loosely to manipulate the access channel. While positioning the platform, release the tension on the hooks to prevent prolonged dilation of the anal canal. The anal platform should fit snugly on the anal wall in order to prevent air leakage (Fig. 36.25). Trocars are placed in the gel cap at 2, 6, and 11 o'clock. If a continuous insufflation system is used, the trocar is usually placed at 2 o'clock. The cap is then placed on the transanal platform and the lid is closed (Fig. 36.26). At this point, a purse string should be performed using a 0 PDS or Prolene suture on a 26 mm needle, starting at 5 o'clock and continuing clockwise, leaving a 1–2-mm space between stitches. The needle should enter at a 90-degree angle performing small full-thickness bites. The exit point should be the entry point of the next suture, and a constant distance should be maintained from the access channel. Once completed, the purse string should be tied down—I suggest to leave some length when cutting ends for an easier manipulation of the stump (Fig. 36.27). In women, the anterior stitches must be carefully placed to avoid grasping the vaginal wall. While performing this step, the abdominal team clamps the colon at the level of the rectosigmoid junction to prevent colonic distension. The TaTME technique allows for clear identification of the distal edge of the tumor, and then, at the desired distance, the purse-string suture is placed in order to achieve a

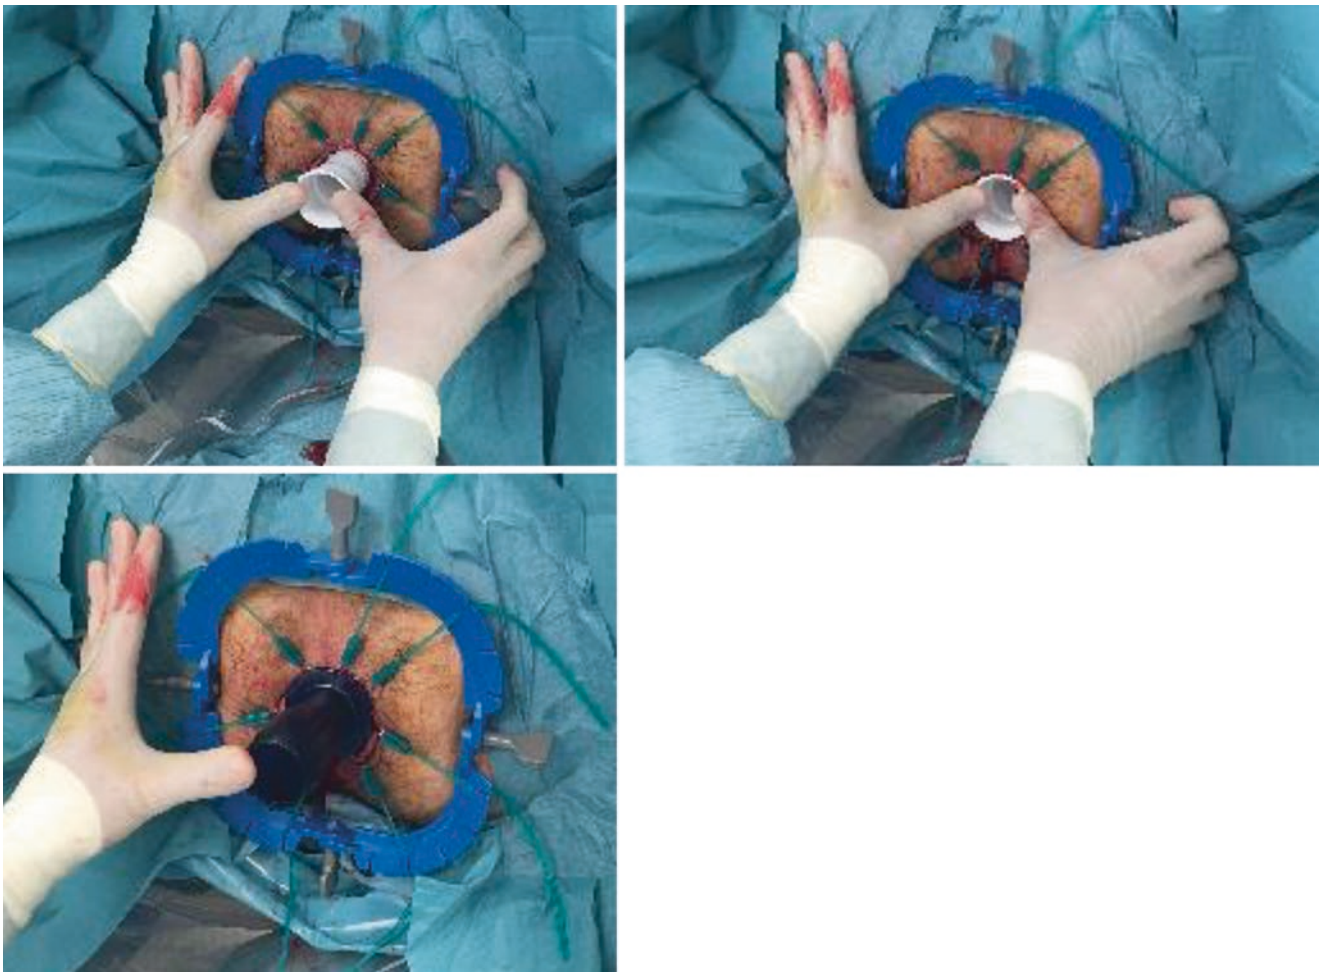

Fig. 36.24 First steps of a transanal total mesorectal excision (TaTME): after pudendal block, a self-retaining retractor is placed to visualize the dentate line. The hooks are placed at the level of the anal verge, retracted, and fixed on the plastic frame. Anal dilators are used to facilitate the placement of the transanal platform

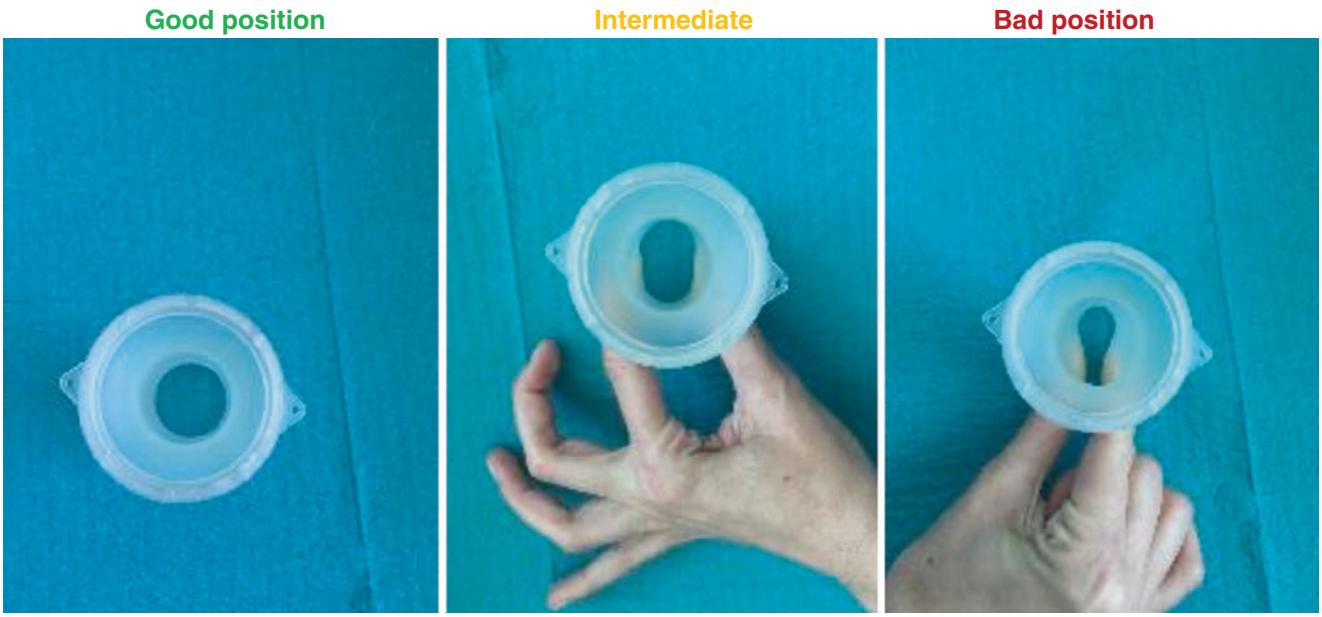

Fig. 36.25 Correct positioning of the anal platform into the anal wall in order to prevent air leakage

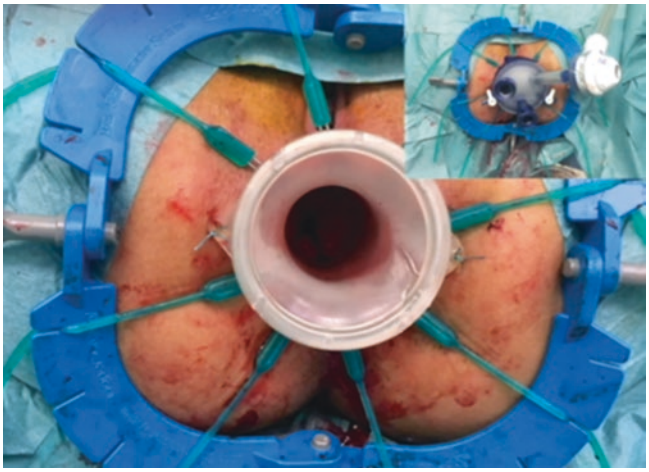

Fig. 36.26 Anal platform positioning and trocars setup on the gel cap

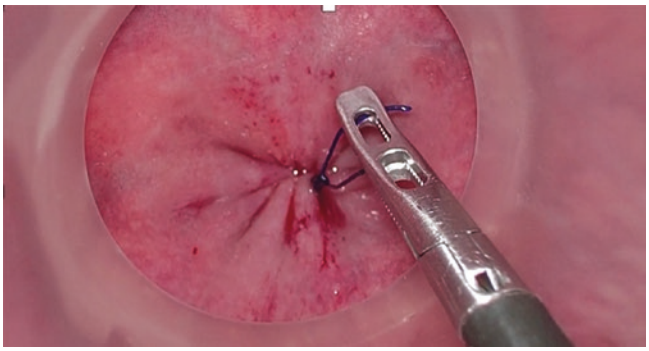

Fig. 36.27 Purse string completed and tied down

distal resection margin. After the purse string is tied, I usually perform a rectal washout. The rationale for performing this maneuver is that it should reduce fecal contamination and potentially lose tumor cell implantation, although there is no clear data that support this contention. Once the purse string is tied down, the cap is placed back on the platform, and the pneumorectum is established. The rectal mucosa is marked circumferentially with electrocautery (hook), about 1 cm from the purse string knot, where the mucosal folds end. A 360° full-thickness rectal wall incision starting at posterolaterally is performed (Fig. 36.28), transecting the rectal wall to continue along the mesorectum. During this phase, it is helpful to maximize the angulation of the hook to achieve the best dissection. If the distance between the tumor and the anorectal junction (ARJ) is >4 cm, place the purse string 3 cm from the anal verge; if the distance between the tumor and the ARJ is 2–4 cm, place the purse string 1 cm distal to the tumor; if the distance is <2 cm, dissection is started without the platform: division of the rectal wall is performed first, and then the rectal purse string is performed before introducing the platform.

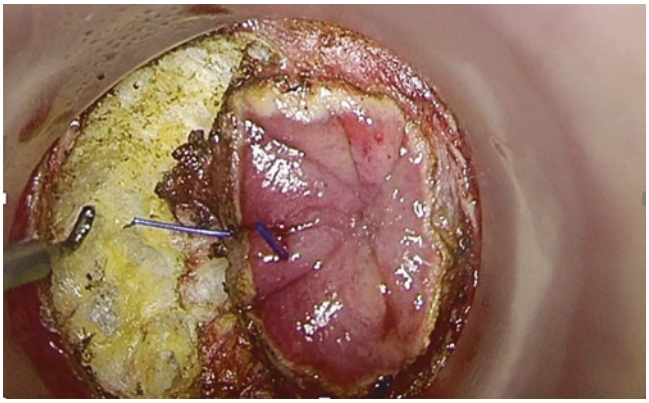

Fig. 36.28 Right lateral dissection during transanal total mesorectal excision (TaTME)

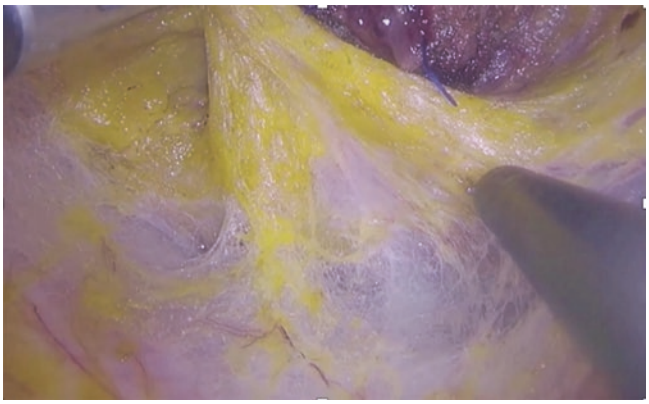

Fig. 36.29 Posterior plane of dissection during transanal total mesorectal excision (TaTME)

Mesorectal Mobilization

Dissection should progress circumferentially, avoiding to tendency to create a funnel. The avascular presacral space posteriorly is the safest area to start the procedure. Lift up the specimen with a grasper to find the posterior plane (Fig. 36.29). Dissection starts posterolaterally. The posterior midline is avoided initially as the anococcygeal ligament may impede progress. Follow the muscle layers of the pelvic floor to localize the correct plane, particularly in males who may have a tight pelvic floor around the rectum. If the dissection deviates too posteriorly, the presacral vessels can be injured with subsequent bleeding. Anteriorly, dissection proceeds in the rectovaginal or rectoprostatic planes which are usually straightforward to find. Pushing against the tissue with the grasper allows the pneumopelvis to reveal the plane (provided that the abdominal mobilization was performed first). Then, the specimen is pulled down with the grasper to find the avascular anterior plane. Dissection starts anterolaterally, paying attention at the urethra in male patients (in the anterior midline), and stops

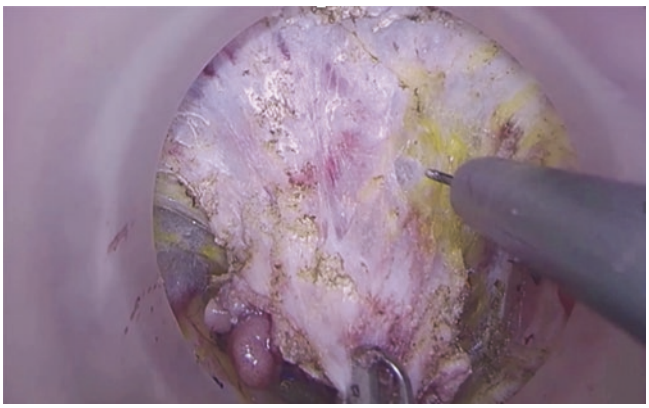

Fig. 36.30 Anterior plane of dissection during transanal total mesorectal excision (TaTME)

close to the neurovascular bundle (2 and 10 o'clock) (Fig. 36.30). Placing a vaginal retractor or palpating the vagina helps to find the plane. In males, it is critical that the dissection stays posterior to the prostate and urethra to avoid prostatic bleeding and urethral injury. On the lateral sides, the parietal fascia should be the landmark; as if dissection is performed too far laterally, nerves and vessels can be injured at 2 and 10 o'clock. This step is easier if performed with synchronous transabdominal and transanal approaches.

Specimen Extraction

The specimen is extracted transabdominally or transanally. The transanal extraction should be performed only if the bulk of the mesorectum is limited. Transabdominal extraction can be performed through a Pfannenstiel incision, on the left or right iliac fossa, or at the stoma site.

Anastomosis

The proximal colon should reach the pelvis with no tension and without torsion. Before transecting the colon, vascular supply is assessed. The proximal purse string is performed, and the detachable anvil of the end-to-end stapler is positioned and secured. A tubular drain can be positioned on the tip of the anvil as a temporary handle, and the colon is repositioned in the abdomen (Fig. 36.31).

At this point, the tension of the elastic bands on the anal retractor is released to get better exposure while performing the Prolene 0 distal purse string on the rectal stump. The rectal cuff purse-string suture should be performed with full-thickness bites without imbricating too much the rectal wall in each bite but avoiding gaps. The first and last stitch should overlap. While performing the distal purse string, pay attention not to imbricate the vagina or the sphincter muscle. The

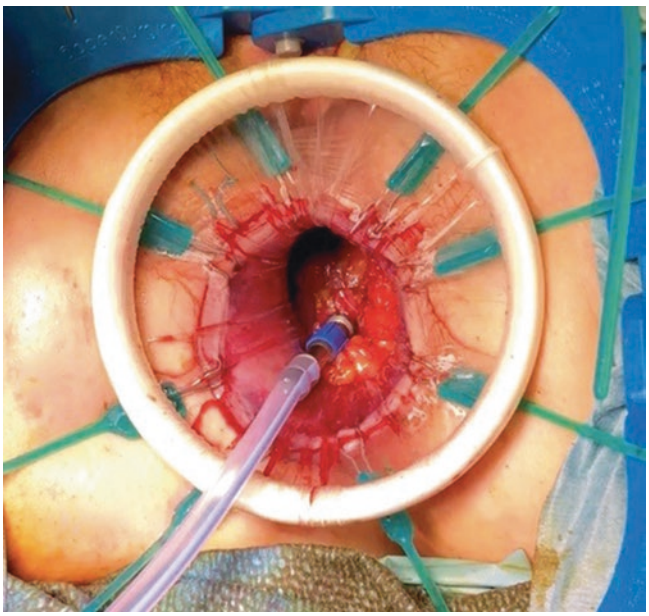

Fig. 36.31 A tubular drain is positioned on the tip of the anvil before repositioning the colon in the abdomen

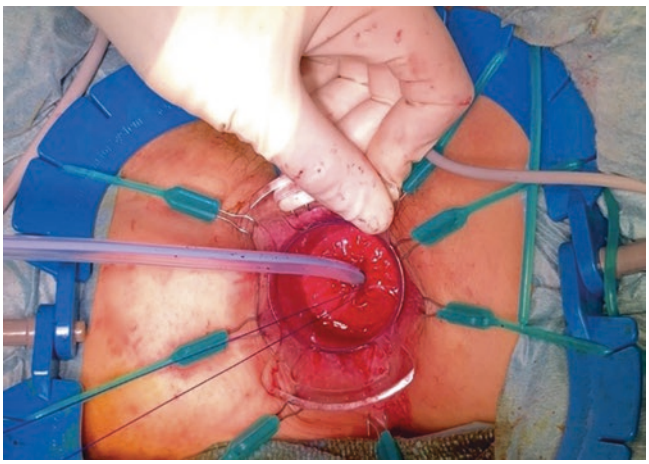

Fig. 36.32 The drain on the tip of the anvil is pulled through the distal purse string. When the spike has gone completely through the purse string, it is tied down

drain on the tip of the anvil is easily grabbed with a clamp introduced through the rectal stump and pulled through the distal purse string. When the spike has gone completely through the purse string, the purse string is tied down (Fig. 36.32). The anvil is then attached to the spike under abdominal monitoring, and a single-stapled colorectal end-to-end or side-to-end anastomosis is performed using the circular stapler. Air leak test (standard or reverse) is performed. Proximal fecal diversion with loop ileostomy of colostomy is typically then performed.

Hand-Assisted Rectal Cancer Surgery

Hand-assisted colorectal laparoscopic surgery (HALS) techniques were developed in the late 1990s [32] with the aim to overcome some of the limitations of the laparoscopic approach. When considering laparoscopic proctectomy in general, excluding those cases in which transanal specimen extraction is performed, an abdominal incision of 4–8 cm is used to extract the specimen. This incision can also be utilized to perform mesentery division and anastomosis directly, provided that adequate mobilization of the colon has been accomplished intracorporeally. If such an incision is to be made at the end of the operation, why not make it at the start of the procedure and utilize it throughout? This incision can be used to perform mobilization of the mesorectum directly if the patient's body habitus is favorable ("hybrid" approach), which may allay fears of compromising quality of mesorectal mobilization by using a laparoscopic approach. The current generation of hand-assisted devices allows this concept to be put into practice to facilitate the performance of laparoscopic colectomy and proctectomy. The optimal device includes a stable, sturdy platform base that crosses the abdominal wall and provides circumferential retraction of the wound with a low vertical profile and a self-sealing membrane that allows for rapid and easy hand exchange and accommodates trocar or stapler placement through the device while maintaining pneumoperitoneum.

The main findings of studies comparing open, straight laparoscopic, and hand-assisted low anterior resection (HALAR) can be summarized as follows [105–115]:

1. HALAR retains many of the benefits of a pure laparoscopic approach.
2. Complication rate and length of stay following HALAR comparable with straight laparoscopic approach.
3. Oncologic outcomes following HALAR comparable with straight laparoscopic or open approaches.
4. Shorter operative time and lower conversion rate with HALAR.
5. Slightly longer incision than straight laparoscopic approach, although of unclear clinical significance.
6. Increased level of inflammatory markers compared to straight laparoscopic approach, although of unclear clinical significance.

Given the concerns with oncologic outcomes following laparoscopic proctectomy as outlined previously, hand-assisted technology allows for the benefits of laparoscopy to be realized while not violating the recommendation to avoid laparoscopic proctectomy for rectal cancer. Mobilization of the proximal colon can be performed laparoscopically, and mesorectal mobilization can be accomplished directly via the base of the hand-assisted device in open fashion, provided the patient's body habitus is not extremely unfavorable.

Hand-Assisted Laparoscopic Proctectomy

Preoperative Considerations

There are no specific indications and no absolute contraindication for hand-assisted proctectomy. Preoperative assessment and indications are similar to those indicated for the previously described approaches.

Surgical Technique

Access to the Abdomen and Vessel Ligation

Access to the abdomen can be performed through a periumbilical port, so that occult unresectable metastatic disease that would prompt the surgeon to abandon proctectomy can be ruled out prior to making a larger incision. Care should be taken to place this port superior enough to avoid planned position of the skirt of the hand-assisted device. Alternatively, a Pfannenstiel or lower midline incision for the hand-assisted device can be performed initially and only 5-mm ports utilized during the operation. The length of the incision depends on the hand size of the surgeon. A general rule is to perform an incision the same length as the surgeon's glove size in centimeters.

For cases where the likelihood of conversion to open operation is high, a lower midline incision for the hand-assisted device is preferred, allowing for easier conversion to a midline laparotomy if necessary. This incision can be made prior to opening any laparoscopic or disposable instruments and extended directly to laparotomy if indicated prior to creating pneumoperitoneum. Used selectively, this technique is associated with an overall low rate of conversion from laparoscopy to laparotomy [116]. The other ports are then placed: typically two 5 mm on the right side and one or two 5 mm trocars on the left side, lateral to the rectus muscle on both sides to avoid the epigastric arteries.

The operating surgeon can stand on the right of the patient using the right hand through the hand-assisted device and the left hand with a dissecting tool. The first step is to place the omentum over the liver and the small bowel to the upper right quadrant of the abdomen. It is often helpful to drape a moist laparotomy pad over the small bowel. The left colon mesentery, the IMA, and IMV are then exposed. The hand is used to identify and follow the sacral promontory and put traction on the IMA. The peritoneum along the inferior aspect of the pedicle is incised, starting at the sacral promontory and working toward the origin of the IMA and IMV. The IMA is isolated at its origin, taking care not to injure the ureter and the main trunks of the hypogastric nerves, and the IMV is isolated adjacent to the ligament of Treitz. During the operation, dexterity with the hand and ensuring that it does not obstruct the field of vision are a must. In general, it is important to keep the hand away from the camera, in a "C-shape" position.

Splenic Flexure and Left Colon Mobilization

The lateral attachments to the colon are taken down using the dissecting tool through the left-sided port, and splenic flexure mobilization is performed (if needed) according to the principles already described. This is sometimes facilitated by having the operating surgeon stand between the legs and utilize the left lower quadrant port for dissection and the left hand in the hand-assisted device for retraction.

Mesorectal Mobilization

The principles of TME remain the same irrespective of the specific technique used. The hand-assisted device offers multiple options in carrying out mesorectal mobilization. The specific technique used is dependent on the preference of the surgeon and the specific characteristics of the patient and tumor:

1. *Open* technique through the hand-assisted port: the lid of the device is removed. Laparotomy pads can be used to pack the small bowel out of the pelvis. Pelvic retractors can be placed to obtain a better view of the pelvis. After mesorectal mobilization is completed, transection of the rectum can be performed using a stapler.
2. *Laparoscopic technique*: the dissection is carried out laparoscopically with or without hand assistance. In this phase, the hand can be used as a retractor. The proximal bowel can be divided with a laparoscopic linear stapler or performed with an open stapler through the hand-assisted device.
3. *Laparoscopic technique pulling the specimen through the hand-assisted device as a retractor*: the colon is divided through the Pfannenstiel incision at the proximal margin, and the divided colon stump is exteriorized through the gelatinous cover of the hand-assisted device to provide traction and help to complete posterior mesorectal dissection.

The distal transection is then performed, and an end-to-end or side-to-end double-stapled colorectal anastomosis is performed as previously described.

Minimally Invasive Complete Mesocolic Excision with Extended Lymphadenectomy for Colon Cancer

37

Patricia Sylla

Key Concepts

- Complete mesocolic excision and central vascular ligation (CME + CVL) refers to en bloc dissection of the colon and mesocolon along the embryologic planes with preservation of the mesocolic envelope, central ligation of the feeding vessels, extended lymphadenectomy, and adequate bowel resection.
- CME + CVL most closely matches Japanese D3 lymphadenectomy which requires en bloc resection of paracolic (D1), intermediate (D2), and central (D3) nodal stations along the feeding vessels.
- CME + CVL/D3 dissection increases the risk of potential organ injury, particularly during right colectomy where nodal tissue is dissected off the anterior surface of the superior mesenteric vein and its tributaries. Thorough knowledge of variations in vascular anatomy at the root of the mesentery is needed.
- In experienced hands, the minimally invasive surgical (MIS) approach to CME + CVL/D3 dissection results in acceptable conversion rates and perioperative and oncologic outcomes equivalent to that of open CME.
- The lack of standardized operative assessment for CME + D2 vs D3 dissection, and limited adoption of quality indicators to assess CME specimens, has made direct comparison of long-term oncologic outcomes between the groups challenging.
- There is no conclusive evidence to support routine use of CME + CVL/D3 versus CME + D2 dissection for colon cancer. It should be considered in cases were nodal metastasis is suspected based on preoperative staging and/or intraoperative assessment.
- Several ongoing randomized controlled trials comparing outcomes between CME + D2 and CME + D3 dissection for colon cancer incorporate video-based assessment of CME techniques and morphometric assessment of CME specimens.
- There is increasing enthusiasm for MIS CME in Europe and in the USA. Standardization of performance assessment and adoption of CME quality indicators will be needed in order to assess the impact of CME + CVL on long-term oncologic outcomes of right and left colon cancer resections.

Introduction

The concept of dissection in the avascular plane surrounding the mesorectum and removal of the mesorectum at risk for nodal metastases was given a moniker ("total mesorectal excision (TME)" and popularized by Bill Heald. Dissection along the embryologic planes also increases the chances of R0 resection for tumors which has not broached the mesorectal fascia. These techniques have universally been adopted as standard of care for the curative resection of rectal cancer. Implementation of TME techniques, combined with improvements in staging modalities and neoadjuvant/adjuvant treatment regimens, have led to substantial reduction in local recurrence rates [1–3]. Over the last two decades, these principles have been adapted to minimally invasive approaches, including laparoscopic and robotic-assisted techniques and, most recently, transanal endoscopic TME (taTME).

The same surgical principles have been increasingly applied to curative resection of colon cancer, with growing interest in the extent of nodal harvest and anatomic details of excision of the mesentery. It has long been known that the number of lymph nodes removed in colorectal cancer speci-

mens directly correlates with improved staging and prognosis, and there is ample evidence that extended nodal dissection improves survival for stage I–III colon cancer [4–7]. In their seminal publication in 2009, Hohenberger et al. promoted the concept of extended lymphovascular clearance described by Jamieson in 1909, advocated by Enker in 1979, and already in routine practice in Japan since the late 1990s [4, 8–10]. Hohenberger et al. termed this technique "complete mesocolic excision" (CME) which included (1) sharp en bloc dissection of the colon and mesocolon with complete removal of the mesenteric envelope along the embryologic plane between the mesocolic and parietal fascia; (2) extirpation of all lymphovascular tissue extending from the pericolic area to the lymph nodes at the base of the feeding arteries; (3) central vascular ligation (CVL) or high vascular tie at the most proximal extent of the feeding arteries and veins; and (4) adequate length of bowel resection in order to ensure adequate lymph node dissection [9]. Although the original description of CME with CVL for right colon cancer inferred that a Kocher maneuver be performed in order to expose the base of the mesenteric vessels, modern CME practice has evolved toward a modified approach that closely matches the Japanese Society for Cancer of the Colon and Rectum (JSCCR) definition of D3 lymphadenectomy, whereby only anterior dissection of the superior mesenteric vein (SMV) is required [11–13].

As opposed to the Japanese definition of D2 and D3 dissection which implies complete mesocolic dissection en bloc with the anatomically defined lymph node station(s), the term CME + CVL is a misnomer in the literature, where the extent of lymphadenectomy completed is variable and subject to interpretation. This has led to lack of consistency with regard to surgical techniques and assessment of CME specimen quality and challenges interpretation of oncologic outcomes across studies [14]. In order to align CME terminology throughout this chapter, the term "CME + CVL" refers to CME performed with radical lymphadenectomy which corresponds to the JSCCR definition of D3 lymph node dissection (CME + D3).

The difference between "conventional" and CME + CVL dissections is not analogous when considering left versus right colectomy. Many surgeons routinely ligate the inferior mesenteric artery (IMA) at the aorta during proctectomy for rectal cancer (CME + D2 dissection); thus the concept of CME + D3 for left-sided colon tumors, which requires exposure of the aortic wall in order to remove additional nodal tissue at the base of the IMA, has not been a dramatic step up in complexity. However, the same cannot be said for CME + D3 for right-sided tumors. The anatomical challenge posed by safe exposure and dissection of SMV tributaries and trunk of Henle and added risk of injury and long learning curve has added to surgeons' reluctance to adopt this approach for right and transverse colectomy, especially in the absence of high-level evidence demonstrating long-term oncologic benefits relative to standard CME + D2 resections. This chapter will review the rationale for CME + D2 or D3 dissection, highlight relevant anatomical landmarks, and describe surgical techniques for right- and left-sided resections, with a focus on minimally invasive approaches. Short- and long-term outcomes will also be critically assessed with emphasis on current gaps in knowledge.

CME and Extended Lymphadenectomy: Definitions

Lymph Node Classification

The level of nodal dissection is best described using the Japanese classification of colonic regional lymph nodes, which describes three levels. Lymph nodes are classified as epicolic or paracolic (D1) located along the marginal artery, intermediate (D2) along major arterial branches, and main/central (D3) at the origin of the superior mesenteric artery (SMA) or IMA. The scope of lymph node dissection is also based on lymph node classification and graded as D1, D2, and D3 dissection (Fig. 37.1 and Table 37.1) [12, 13].

D1, D2, and D3 Lymphadenectomy

The 2005 JSCCR guidelines and subsequent 2010 and 2019 updates are based on the latest results from the JSCCR colorectal registry. Levels of dissection are defined as follows:

D1 dissection refers to complete dissection of epiploic lymph nodes attached to the colon and paracolic lymph nodes along the marginal artery in the relevant colon segments and no or incomplete dissection along the tumor-supplying arteries (Fig. 37.1).

D2 dissection is defined as complete removal of epicolic, paracolic (D1 nodes), and intermediate (D2) lymph nodes along the tumor-supplying arteries (ileocolic, right colic, middle colic, left colic, sigmoid, and IMA from the origin of the last sigmoid artery to the origin of the left colic artery). For right-sided colonic tumors, D2 dissection includes ligation of the ileocolic artery (ICA) at its root, at the level of the lower border of the duodenum. If the right branch of the middle colic or main middle colic artery is to be ligated as part of extended right colectomy (for ascending colon/hepatic flexure tumors), high ligation could be performed without exposing the SMV. For left-sided tumors, D2 dissection includes ligation of the IMA just proximal to the left colic artery origin (Fig. 37.1).

Table 37.1 Definitions of location and dissection of mesocolic lymph nodes

D1	Complete dissection of epicolic lymph nodes attached to the colon and paracolic lymph nodes along the marginal artery in the relevant colon segments and no or incomplete dissection along the tumor-supplying arteries
D2	Complete dissection of D1 and intermediate lymph nodes along the tumor-supplying arteries (ileocolic, right colic, middle colic, left colic, sigmoid, or inferior mesenteric arteries from the origin of the last sigmoid artery to the origin of the left colic artery)
D3	Complete dissection of D1 to D2 and central lymph nodes, for left-sided tumors along the inferior mesenteric artery between the aorta and the left colic artery and for right-sided including mid-transverse tumors, lymph nodes along the superior mesenteric vein and lateral to the superior mesenteric artery
D4	Complete D1 to D3 and along aorta and inferior vena cava or superior mesenteric artery/superior mesenteric vein central to the origin of the middle colic artery
Alternative definition of location of lymph node metastases (JSCCR)	
n(1)(+)	Lymph node metastasis in D1 area, but within 5 cm proximal or distal from the tumor edges
n(2)(+)	Lymph node metastasis in D1 area >5 cm proximal or distal from the tumor edges or in D2 area
n(3)(+)	Lymph node metastasis in D3 area
n(4)(+)	Lymph node metastasis in D4 area (considered distant metastases)

Suffixes + and – added to the D-area designation refer to the status of the lymph node metastases reported by the pathologist. Suffixes (p) and (c) added to D2 to refer to peripheral and central part of D2, where D2p in some studies is included in the specimen in conventional resections
JSCCR Japanese Society for Cancer of the Colon and Rectum

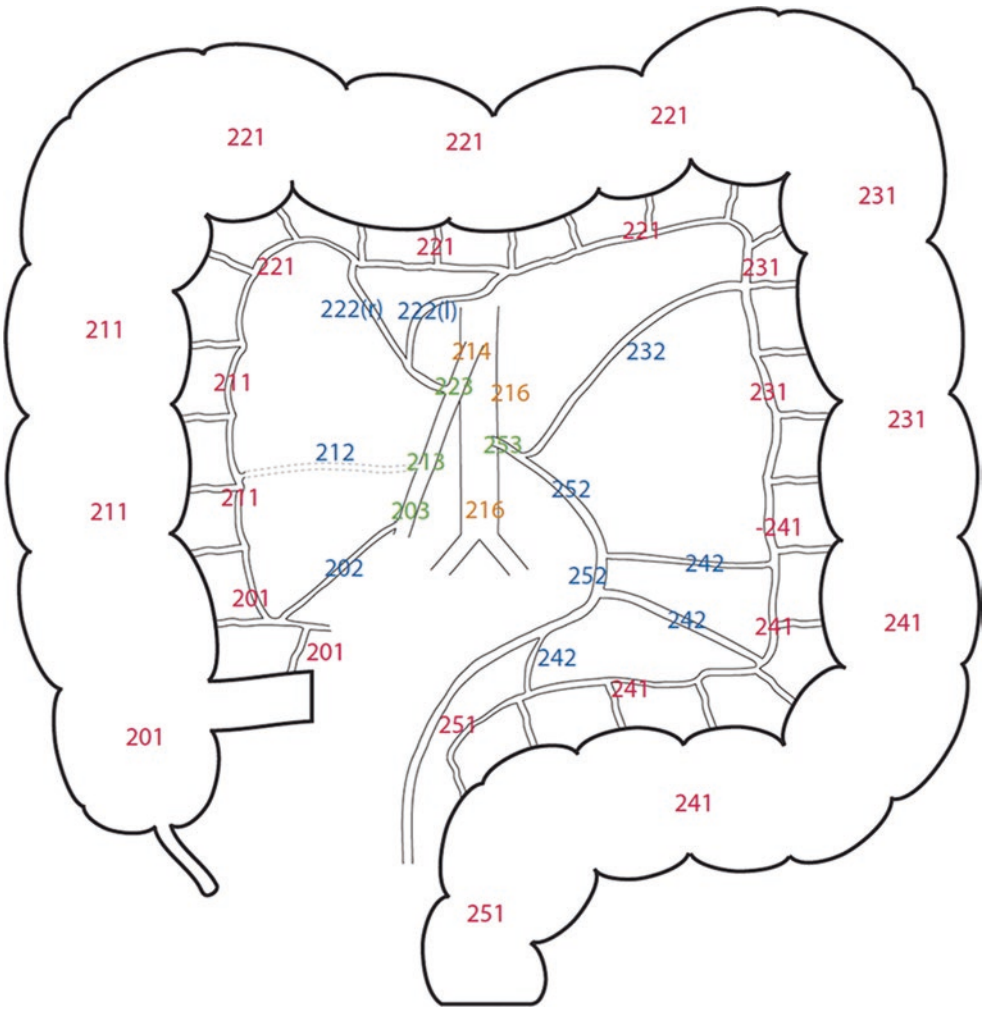

Fig. 37.2 Mesocolic lymph node stations according to the Japanese Society for Cancer of the Colon and Rectum. D1-D4 defined by colors: D1 red, D2 blue, D3 green, and D4 yellow. Right colic artery (dotted). (Reused with permission [27]. Copyright © Wolters Kluwer)

D3 dissection is defined as complete removal of D1, D2, and central (D3) lymph nodes. For right-sided tumors, the anterior surface of the SMV is exposed (dissection of the SMA is not required), and vessels are transected at their origin with removal of all nodal tissue along the SMV and lateral to the SMA including nodal groups 203 and 213 (Figs. 37.1 and 37.2). En bloc resection of nodal group 223 is also removed for extended right colectomy. For left-sided tumors, the IMA is divided at its base from the aorta, and the aortic wall is exposed (dissection deeper than the embryonic layer), with removal of all nodal tissue between the aorta and the left colic artery including nodal group 253 (Fig. 37.2). With extended left colectomy, removal of nodal group 223 is also required, with exposure of the SMV.

The scope of lymph node dissection with CME is based on preoperative clinical staging and/or intraoperative assessment of visible/suspected lymph node metastasis (Table 37.1). In Japan, in addition to standard radiologic staging by either computed tomography (CT) scan or magnetic resonance imaging (MRI), endoscopic assessment of the depth of tumor invasion plays an important role in clinical T staging (cT). Advanced endoscopic techniques including chromoendoscopy and narrow-band imaging (NBI) are routinely used to predict depth of invasion, with occasional use of endoscopic ultrasound [11, 15–17]. For pTis tumors completely removed endoscopically, lymph node dissection is not typically required, but if bowel resection is elected, D1 dissection can be performed. For pT1 tumors removed endoscopically, D2 dissection is recommended due to an approximately 10% risk of D1/D2 lymph node (LN) metastasis and 1.9% risk of D2 node metastasis based on JSCCR registry data [11]. For cT2 cancer, at least D2 dissection is recommended, although D3 dissection can be considered given the 0.7–1% risk of central/main node metastases and lack of accuracy of imaging-based preoperative cT staging. For cT3/T4 tumors, D3 dissection is the standard of care. In the 2000–2004 JSCCR registry that reviewed 25,617 patients treated for colorectal cancer, lymph node metastasis around the origin of the feeding vessel (main/central/D3 node) was found in 0.9%, 2.3% and 5.7% and 6.7% for pT2, pT3, and pT4a and pT4b tumors, respectively [11, 12].

It should be noted that outside of centers with expertise in endoscopic assessment of depth of tumor invasion, recom-

mendations for level of nodal dissection based on standard preoperative radiology-based tumor staging are difficult to utilize clinically, as this assessment can only be determined with certainty postoperatively, after histologic evaluation of the resected colectomy specimen. The only exception would be patients with superficial tumors undergoing complete endoscopic removal prior to colectomy.

Quality Indicators of CME Resections

Analogous to proctectomy specimen grading with photodocumentation of the anterior, lateral, and posterior surface, quality indicators in CME resection include (1) documentation of mesocolic plane dissection; (2) number of lymph nodes harvested (which may include classification of lymph nodes based on the JSCCR classification of lymph node stations); (3) specimen morphometry, which documents the distance from the vascular tie to the tumor, the distance from the vascular tie to the colon, and the area of mesentery resected (in mm^2); and (4) large bowel length/small bowel length [10, 18]. Grading of plane of mesocolic dissection and specimen morphometry can be documented based on high-resolution specimen photographs taken of the front and back of the unfixed unopened specimen, with the mesentery laid out flat without stretching, placed alongside a ruler (Fig. 37.3). In Japanese practice, and especially since publication of the JSCCR guidelines, it is a standard practice for Japanese surgeons to map lymphatic stations directly onto surgical specimens, which not only validates completion of D2 vs D3 lymphadenectomy but permits precise evaluation of the pattern of lymphatic spread in colon cancer and correlation to oncologic outcomes [11, 19]. Since publication of the 2005 JSCCR guidelines recommending D3 dissection for stage II/III colorectal cancer, adoption of D3 dissection among Japanese surgeons has increased 58.4% in 2001 to 75% in 2010 as assessed by photodocumentation of D3 specimens in the JSCCR tumor registry [9].

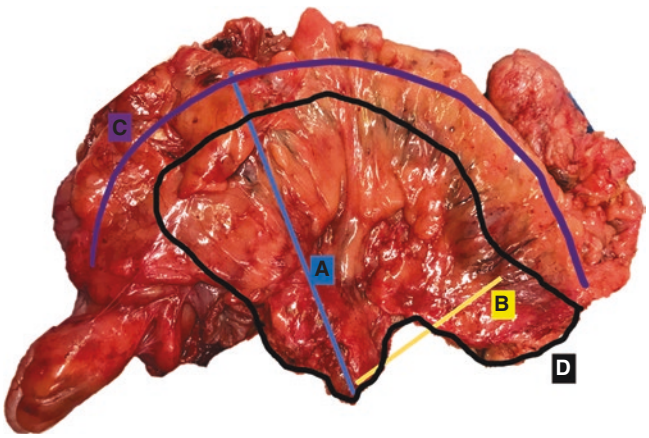

Fig. 37.3 Morphometric assessment of CME + D3 right colectomy specimen. (**A**) Distance from the high vascular tie to the tumor. (**B**) Distance from the high vascular tie to the closest bowel wall, (**C**) length of large bowel, (**D**) surface are of mesentery

Differences between tissue morphometry of colon cancer specimens resected using non-CME (NCME, England), CME with CVL (Germany), and D3 dissection (Japan) were evaluated based on review of specimen photographs. There were no significant differences in tumor location, pT, and pN stage between the groups. The length of resected bowel and area of mesentery were significantly greater in the NCME and CME + CVL specimens. The distance from the vascular tie to the bowel wall was similar between the CME + CVL and D3 specimens; all were longer than in NCME specimens. The rates of mesocolic plane surgery and number of lymph nodes were highest in the CME + CVL group, followed by D3 resection specimens [20]. These differences reflect the JSCCR guidelines that promote the concept that when the tumor has an associated distinct main mesenteric vessel, bowel resection should proceed 5 cm beyond a feeding vessel in the direction of the lymph flow and 10 cm away from the tumor in the opposite direction [12]. This is based on Japanese studies that have shown that longitudinal spread >10 cm beyond the tumor occurs rarely (0% for left-sided, 1–4% for right sided tumors); hence bowel resection margins are rarely >10 cm in Japanese D3 specimens [21, 22]. This is in contrast with the principles of CME, which advocates removal of the next feeding vessel beyond the 10 cm bowel margin, to ensure adequate lymphovascular clearance [22]. The differences in absolute length of resected specimens may also reflect differences in body habitus between the populations.

When assessing and comparing studies that evaluate the impact and NCME and CME techniques with CVL/D2/D3 dissection, it is critical to understand which CME quality indicators were used to validate completion of good-quality CME. Currently, there is no consensus on which of the above quality indicators are the most critical when evaluating/comparing the quality of CME resections. While the number of lymph nodes in surgical specimens has been used as a surrogate for quality of surgical resections, that variable must be interpreted with caution, as the number of nodes harvested can be impacted by variability in both patients and pathologic processing techniques and diligence and is thus subject to bias. As described by West and Hohenberger in 2009, documentation of the grading of the plane of surgery (into the muscularis propria plane, intramesocolic plane, or mesocolic plane) and tissue morphometry (area of mesentery removed, distance from the vascular ties to the tumor and to the closest bowel wall, length of large and small bowel) should be included in order to achieve uniformity across studies [18]. Using the above quality indicators, West and Hohenberger were able to demonstrate that CME with cen-

tral ligation removed significantly more tissue than NCME resections, in addition to increasing the number of lymph nodes harvested [18]. Standardized pathologic quality control is critical in the appraisal of the impact of CME techniques on long-term oncologic outcomes. Contemporary trials evaluating outcomes of CME + D2/D3 dissection have incorporated assessment of CME quality indicators in order to validate completion of CME + D3 by participating surgeons [23]. Likewise, in the JCOG 0404 RCT comparing open and laparoscopic D3 dissection for stage III colon cancer, quality control for D3 dissection was ensured by central peer review of photodocumentation of the completed D3 dissection surgical field, and of the surgical specimen, highlighting surgical margins [24].

Rationale for Adoptions of CME for Colon Cancer

As noted above, there is not universal agreement as to what constitutes "CME," "CME + CVL," or "conventional" dissection, which hampers comparisons of outcomes. In addition, it is nearly impossible to perform randomized studies of CME vs conventional colectomy, as surgeons would be unlikely to alter their techniques substantially between patients, with the possible exception of level of nodal harvest at the root of the mesentery. Thus, most published studies of CME versus conventional colectomy utilize historical controls or compare outcomes between hospitals or geographic regions, which introduce the likelihood of hidden cofounders and substantial bias. In addition, some studies retrospectively subgroup patients by stage, which does not have a clinical correlate as it is difficult to reliably differentiate stage III versus stage II disease preoperatively. While removing the colonic mesentery in its fascial envelope and achieving negative circumferential margins of resection for the primary tumor are clearly of benefit to the patient, determining the optimal level of vascular division at the root of the mesentery has been more difficult. Lastly, in an ideal world, patients with true stage I and stage II disease should garner no benefit from lymphadenectomy. Extended lymphadenectomy would thus pose excess risk in these patients and provide no benefit. "Improved" oncologic outcome from extended lymphadenectomy in patients with stage I/II disease would therefore reflect stage migration, or inherent inaccuracies in histologic staging, the magnitude of which may be co-linear with differences in basic surgical techniques, further confounding the analysis.

Impact of CME on Mesocolic Dissection Grade

Regardless of the exact extent of lymphadenectomy performed, CME dissection, which dictates that colon and mesocolon resection proceeds along the embryologic mesocolic plane with preservation of intact fascial layers, has been associated with good outcomes. Similar to Quirke's grading of the quality of TME dissection, dissection of the colonic mesentery can occur along the muscularis propria (poor plane), intramesocolic (intermediate plane), or mesocolic resection plane (good plane). When comparing CME specimens with those from "standard" oncologic resection for colon cancer, West et al. demonstrated significantly greater amount of mesentery and colon length, a higher lymph node yield, and a higher proportion of specimens with mesocolic plane resection among the CME group [18]. Furthermore, based on a review of 399 specimens photographed and graded according to the plane of mesocolic dissection, mesocolic dissection was confirmed in 32% of specimens and was associated with a 27% 5 year survival advantage rate in stage III colon cancer relative to dissection along the muscularis propria plane [25]. Notably, a higher rate of mesocolic resection plane was achieved during left-sided CME than right-sided or transverse CME, which may again be related to the higher complexity of vascular dissections for right-sided and transverse colon lesions. The Danish Colorectal Cancer Group (DCCG) compared outcomes of CME adoption in 2008 at one institution relative to outcomes of NCME performed at three other hospitals. Relative to NCME procedures, CME was an independent predictive factor for higher DFS, especially for stage I/II disease [26]. In an ongoing prospective non-randomized trial comparing CME + D3 with NCME colon resection, where specimen morphometry was assessed based on photodocumentation of surgical specimens, CME was associated with improved 3-year local recurrence-free survival in stage II and III patients [23]. Overall, current evidence supports adoption of tumor-specific mesocolic excision for colon cancer, similar to tumor-specific TME, with complete resection of the mesocolic envelope and lymphadenectomy beyond paracolic nodes (D2 or D3 dissection).

The Impact of CME on Lymph Node Harvest, Central Node, Skip, and Occult Metastases

CME has consistently demonstrated an association with increased lymph node harvest, which improves the accuracy of staging, and can upstage tumors and prompt consideration of adjuvant chemotherapy. A recent systematic review of retrospective studies comparing outcomes between colectomy performed for colon cancer with or without CME demonstrated that in 10 of 12 studies, lymph node harvest was significantly higher in the CME group [14]. In addition to increasing lymph node harvest, CME with D3 dissection may remove clinically suspicious nodes detected intraoperatively, as well as lymph node micrometastases not otherwise detectable pre- or intraoperatively. Likewise, extended

lymphadenectomy would permit removal of skip metastases, i.e., tumor metastases found in central lymph nodes in the absence of pericolic or intermediate lymph node involvement, which is reported in 0–19.8% of stage III colon cancers [27–29].

The pattern of locoregional lymph node metastasis in colon cancer remains poorly understood, with two opposing theories. In the Halsted model, progression of metastasis occurs in a stepwise fashion from the primary tumor to pericolic, intermediate, and central nodes and ultimately to distant organs. In the Fisher model, metastatic progression is non-linear and can bypass proximal nodal basins altogether [30–33]. Pattern of nodal spread has different implications on the theoretical impact of radical D3 lymphadenectomy. In the Fisher model, removal of all lymphatic tissue at all three nodal stages is unlikely to impact oncologic outcomes. However, in the Halsted model, systematic removal of central lymph nodes in stage III disease during D3 dissection, including potential skip metastases, may improve staging and local disease control and impact long-term oncologic outcomes, independently of adjuvant treatment.

While the incidence of pericolic, intermediate, and central lymph node metastases increases with tumor stage, the incidence of occult central node metastasis in clinically staged II colon cancer, traditionally treated with CME + D2, is not considered negligible in the JSCCR guidelines that currently recommend D3 dissection for stage II and III colorectal cancer. The incidence of D3 nodal metastases based on pT stage among 23,579 stage I–III colorectal cancers was 0.9% in pT2 and up to 2.3% in pT3 tumors based on results from the 2000–2004 JSCCR cancer registry [12]. Based on these results, the JSCCR guidelines indicate that D3 rather than D2 dissection can be considered for cT2 tumors because "about 1% of cT2 cancer is accompanied by main lymph node metastasis and preoperative diagnosis of depth of invasion is not very accurate" [11, 12]. Implementation of these guidelines are facilitated by the widespread use of advanced endoscopic techniques in Japan to improve preoperative staging of colorectal lesions, including chromoendoscopy, image-enhanced endoscopy (NBI), and/or endoscopic ultrasound assessment of depth of tumor invasion [15–17].

As would be expected, the incidence of D3+ metastasis increases with tumor stage. In stage III disease, the incidence of apical/central node metastasis has been reported as high as 19.7%, as in a series of 244 stage III right colon cancers treated with CME + D3 (with a rate of skip metastasis of 19.8%) [28]. Among 1355 stage III colon cancers treated with D3 dissection across 71 Japanese centers and with a minimum of 5-year follow-up from the 2000–2002 JSCCR registry, the rate of D3+ nodes was 8.3% [34]. In an ongoing prospective non-randomized trial comparing 220 CME + D3 with 110 non-CME right and left colon cancer resection, with validation of D3 completion based on photodocumentation, the incidence of central node metastases in D3+ specimens was 13.8% in stage III disease, with a rate of skip metastasis of 2.7% [23].

With respect to the oncologic implications of central node metastases, in that same JSCCR registry of 1355 stage III colon cancers, after adjusting for tumor and node classification and other prognostic factors, central node metastasis was independently associated with cancer-specific death (HR 2.29; 95% CI 1.49–3.52) [34]. Similarly, the presence of metastatic central lymph nodes at the origin of the IMA has been shown to correlate with advanced tumor stage and has been associated with worse disease-free survival, despite adjuvant treatment [35–38]. Some authors argue that these findings support high ligation of the IMA at the aorta with CME and D3 dissection in order to reduce the risk of residual unsuspected metastatic IMA lymph nodes, and optimize nodal staging [37]. A recent review of the 1999–2007 JSCCR database of 4034 stage III tumors treated with D3 dissection demonstrated significant differences in the pattern of central node metastasis between right- and left-sided stage III colon cancer and the impact of the rate of D3+ metastasis on survival [19]. Although the number of lymph nodes harvested was equivalent between right and left colon cancer resections (20.3 vs 19.2, respectively), the rate of D3+ nodes (8.5% vs 3.7%) and skipped node metastases (13.7% vs 9%) were significantly higher in right- vs left-sided tumors, respectively. The 5-year disease-free survival (DFS) was similar between right- and left-sided cancer, but the 5-year unadjusted overall survival (OS) was significantly worse in right-sided cancers (77.4% vs 80.9%). By multivariate analysis, although D3+ status was associated with worse OS in left-sided cancer, neither DFS nor OS were affected by the pattern of lymph node metastasis in right-sided cancer. These findings suggested differences in the prognostic significance of D3+ nodes based on tumor location and suggest that D3 dissection may have a greater impact on survival in stage III left-sided colonic cancer [19].

Overall, these results support the recommendation of extended right colectomy with CME + D2 dissection at a minimum, with consideration for CME+ D3 dissection for suspected clinical stage III cancer based on the 3.7–19.7% risk of central node metastasis and potential prognostic significance of this finding in stage III disease. This recommendation takes into account the shortcomings of preoperative staging by CT scan in predicting nodal involvement. It has been argued that CME + D3 dissection may help upstage tumors and improve local control by reducing the risk of residual metastatic or unsuspected micrometastatic lymph nodes and may improve survival relative to D2 dissection alone, particularly in stage III colon cancer. However, there are no definitive data to support that contention. As one might expect, there is a limit to the benefits of lymphadenectomy. At some distance from the tumor, finding involved

lymph nodes is simply a marker for disseminated disease, instead of local disease that can be surgically removed. To date, it has been difficult to quantify the potential benefit versus risk of extending lymphadenectomy beyond the level of the commonly named vessels at the root of the mesentery.

Anatomical Considerations

Surgeons looking into adopting CME+CVL must have thorough knowledge of the common and less common variations in central vascular anatomy, especially as it relates to variations in the arterial and venous anatomy near the SMV and SMA. Several anatomical reports in cadavers and radiologic reviews have mapped out variations in configurations of the gastrocolic trunk of Henle and its tributaries (GCT), the confluence of the right gastroepiploic vein (RGEV), superior (or accessory) right colic vein (SRCV) and anterior superior pancreaticoduodenal vein (ASPDV), tributaries of the SMV, as well as the variable relationships between the ileocolic, middle colic, and superior mesenteric vessels. This knowledge is critical to safely complete D3 dissection during right colectomy, lower the risk of inadvertent ligation of incorrect vessels, and avoid bleeding from direct vascular injury or inadvertent traction injury to venous tributaries.

Several classifications of this anatomy have been described, mostly based on cadaveric dissections but more recently derived from intraoperative review of minimally invasive cases [38, 39]. Most classifications focus on delineating common and less common variations in the presence or absence of a GCT/GPCT and the configurations of its tributaries (confluence of the RGEV, SRCV, and ASPDV); the anatomy of the SMV tributaries (ileocolic, right colic, and middle colic vein); and the anatomy of the SMA branches (ileocolic right colic and middle colic artery) and their crossing relationship with the SMV. This simple classification can help surgeons correctly identify common and less common variations in the vascular anatomy near the SMV and recognize anomalous configurations, but requiring careful reappraisal of surgical anatomy and landmarks.

Variations in Configuration of the GCT/GPCT

The majority of anatomic classifications refer to the GCT as the confluence of the RGEV, ASPDV, and colic veins, although in others, this confluence is referred to as the gastro-pancreatico-colic trunk (GPCT) [38]. When present (37.8–89% of cases), subtypes of the GCT are based on the presence and location of the SRCV [39] or on whether 1, 2, or 3 right colic veins (RCV) merge with the trunk. In the most common configuration, a single colic vein joins the RGEV and ASPDV (55.8% [38], while other configurations include additional colic veins). In 20.7–21.6% of cases, there is no common trunk between the colic and gastroepiploic vein.

Variations in the Anatomy of SMV Tributaries

One, two, and three middle colic veins can be found in 72.1–74.1%, 22.4–26.1%, and 1.8–3.5% of patients, respectively [38, 39]. In cadaveric and clinical studies, the MCV drains directly into the SMV in 86–89%. Although a SRCV can be identified in 28.8–83.6% of cases, a RCV is only identified in 19–24.3% but always drains directly into the SMV. A single ICV is found in 100% of cases, which drains directly into the SMV in 92.8–100% of cases or alternatively into the GCT or the jejunal truck [38, 39]. In few cases, the ICV may not travel with the ICA and may enter the SMV 3 cm cranial to the base of the ICA.

Variations in Arterial Anatomy and Relationship to SMV

A single ileocolic artery originates from the SMA in 100% of cases and crosses the SMV either anteriorly or posteriorly [38, 39]. A right colic artery (RCA) is identified in 10–63% [38]. It originates from the SMA in 33% or alternatively from the ICA or middle colic artery (MCA) and crosses the SMV anteriorly in 87–97%. The SMA typically courses just left and posterior to the SMV. The MCA arises from the SMA in 100% of cases and is a single artery in 88%, double (11.7%) with finding of three MCAs exceedingly rare.

During SMV dissection, variations in anatomy that are critical for surgeons to identify in order to avoid injury include whether the ICA crosses anteriorly or posteriorly to the SMV and where the ICV drains into the SMV, which could be a few centimeters cranial to base of the ICA. The surgeon should also; and identify the ASPDV, SRCV, and RCV as the first venous tributaries of the Henle trunk, as the dissection proceeds to separate the right mesocolon from the head of the pancreas. Early identification will reduce the risk of inadvertent venous tearing from overzealous traction.

The anatomy of the IMA is more consistent. The IMA splits into left colic artery and superior rectal (hemorrhoidal) artery 2–3 cm from its origin at the aorta. The left colic artery courses superiorly toward the splenic flexure and the superior rectal artery courses inferiorly toward the rectum at the root of the sigmoid mesentery. It should be noted that there is no universally agreed upon nomenclature regarding the IMA and its branches, as some surgeons assert that the IMA becomes the superior rectal artery when it "crosses the common iliac artery," after it has given off some of the sigmoidal branches.

Laparoscopic Approach for CME + D3 Dissection

Applying CME+CVL principles to laparoscopic or robotic colectomy can be challenging, primarily due to the technical difficulty of vascular dissection and skeletonization at the root of the mesentery. There is an associated increased operative time, risk of vascular injury, and long learning curve [40]. Conversion rates range in the literature from 5% to 22% [26, 41, 42]. However, as with other complex MIS procedures, when performed by surgeons with the appropriate training and expertise, laparoscopic CME + D3 dissection is associated with equivalent OR time, morbidity rates, and oncologic outcomes relative to the open approach. The MIS approach may improve short-term outcomes, including incision-related postoperative morbidity, bowel function recovery, and length of hospital stay [41]. Relative contraindications to the laparoscopic or robotic approach to CME + CVL are similar to those for conventional cancer surgery and include the emergency setting, hemodynamic instability, inability to tolerate pneumoperitoneum, prior extensive abdominal surgery, T4 disease when en bloc resection is anticipated to be difficult, and large/bulky tumors.

In the European literature, experience with laparoscopic CME is growing rapidly. Based on the largest and oldest experience from Denmark, adoption of laparoscopic CME increased to 49% based from the 2008 to 2013 Danish DCCG dataset, with conversion rates dropping slightly during the course of the study, from 22% to 19.9% [26, 42]. For right colectomy with CME, laparoscopic adoption was 33% with a 21% conversion rate, reflecting the difficulties unique to CME + D3 dissection and often necessitating an open approach to achieve adequate exposure of the vascular anatomy near the SMV [43].

In a recent systematic review and meta-analysis of one randomized trial and seven case-control trials comparing laparoscopic with open CME with central lymphadenectomy, despite significant heterogeneity in the data from lack of consistency in reported outcomes and of standardized perioperative protocols, a trend toward longer operative time and shorter length of hospital stay was noted with the laparoscopic approach. Laparoscopic CME was associated with a significantly lower wound infection rate. No differences could be found with respect to lymph node yield, local and distant recurrence, or overall survival [44]. With respect to training, when performed by supervised trainees, laparoscopic colon cancer resection with CME and CVL/D3 dissection was equivalent to open CME with respect to the macroscopic specimen assessment and mesocolic plane resection rate [45].

A large multicenter randomized trial compared open vs laparoscopic CME + D3 dissection enrolling patients from 2004 to 2009 across 30 Japanese centers, with procedures performed by surgeons with a minimum of 30 open and 30 laparoscopic CME + D3 operations previously completed. When comparing 521 open versus 527 laparoscopic CME + D3 for stage II/III right- and left-sided cancer, the conversion rate was 5.4%, with longer OR time and a higher rate of intraoperative organ injury in the laparoscopic CME group, although not statistically significant (3.6% vs 1.7%). Injuries that occurred during laparoscopic surgery and not during open procedures included injuries to the duodenum, arterial injuries, and gastrocolic trunk injuries [41]. The laparoscopic approach was associated with lower blood loss, faster resolution of ileus, and shorter length of hospital stay relative to open [41]. Postoperative morbidity was also lower with laparoscopic CME (14.3% vs 22.3%) with similar median number of lymph node harvested. Overall, 86% of stage III patients in each group received adjuvant chemotherapy, with no differences in 5-year OS (90.4% vs 91.8%, open vs lap) or DFS (80% vs 79%, open vs lap) [46]. Central review of procedural videos and intraoperative photographs were used for quality control, and all specimens were processed according to the Japanese classification of colorectal carcinoma. Overall, in the hands of highly experienced surgeons, laparoscopic CME + D3 dissection was demonstrated to be safe for patients with stage II/III colon cancer, and the laparoscopic approach was associated with improved short-term outcomes and equivalent oncologic outcomes relative to the open approach.

With respect to anticipated difficulties for surgeons to transition from D2 to D3 dissection, studies comparing outcomes between laparoscopic or robotic D2 and D3 resections have not identified increased surgical risks or worse outcomes with MIS D3 dissection. Analysis of the first 100 patients accrued in the ongoing COLD trial (D2 vs D3 dissection), where 79–84% of procedures were completed laparoscopically, demonstrated no differences in OR time, blood loss, conversion rates (12% vs 13%, respectively), or 30-day complications (47 vs 48% Clavien-Dindo grade I–IV, respectively) between the groups [29], which supports the notion that experienced D2 surgeons can transition to D3 dissection with excellent results. There were three injuries during D3 dissection that included left gonadal artery transection and two small bowel injuries, the latter requiring conversion. Participating surgeons were required to have a minimum of 20 case experience with D2 and 20 cases with D3 lymphadenectomy and to have submitted unedited videos for technique assessment as a requirement for study participation [29]. Similarly, In the USA, Sammour et al. recently described their institutional experience with laparoscopic and robotic CME + D3 performed in 141 patients compared to 56 CME + D2 cases. Although D3 dissection was preferentially used in patients with favorable anatomy and based

on preoperative staging, CME + D3 was associated with a lower conversion rate (1% vs 3.5%) and similar blood loss, perioperative complication rate (10.6% vs 17.9%) and lymph node harvest [47].

Several additional reports describe the use of the robotic approach becoming increasingly used in these complex procedures [48, 49]. In a recent retrospective comparison of 101 laparoscopic vs 101 robotic-assisted CME for stage I–III right colon cancer over a 10 year period, Spinoglio et al. demonstrated longer OR time with the robotic approach but lower conversion rates (0% vs 6.9%) and no differences in complications, lymph node harvest, and 5-year OS or DFS [50], although reporting of the extent of lymphadenectomy or other quality indicators of CME resection was not provided.

Techniques of MIS CME + D3 for Right-Sided and Transverse Colon Cancer

Medial to Lateral Approach

Similar to conventional oncologic resection for right colon cancer, i.e., CME + D2 dissection, the avascular plane between the mesocolon and the retroperitoneum is dissected with intact visceral peritoneum until the second portion of the duodenum and head of pancreas are exposed medially and the mesocolon has been mobilized all the way toward the right and proximal transverse colon. Attention is then turned to the anterior aspect of the SMV which is exposed as the mesocolon package is entirely dissected off these vessels. The ileocolic vessels are ligated at the root of the SMV and SMA, respectively, and the dissection continues cephalad, anterior to the SMA and SMV, heading cephalad toward the right colic vessels, the CGT, and the middle colic vessels. The right colic vessels (if present) are dissected and transected at their base, and the CGT is carefully dissected with preservation of the ASPDV and RGEV. The RCV and/or SRCV are transected. Finally, the middle colic vessels are dissected at their base of the SMA and SMV. Following D3 dissection, the principles of tumor-specific CME are subsequently followed with respect to extent of colonic mobilization and division of the middle colic vessels, based on tumor location. Arterial flow from the IMA retrograde to the transverse colon should be assessed prior to division of the main trunk of the MCA, especially in patients of advanced age or with a history of atherosclerotic disease. For cecal and ascending colon tumors, the main and left branch of the middle colic artery are spared, and only the right branch of the middle colic artery and vein are divided. For tumors of the hepatic flexure or transverse colon, the middle colic vessels are usually divided at their base (Figs. 37.4 and 37.5, courtesy of Dr. Ito Masaaki and Dr. Hiro Hasegawa). For distal

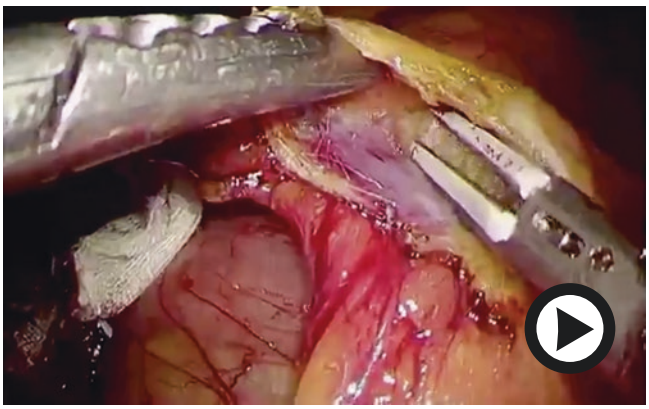

Fig. 37.4 Medial to lateral approach for laparoscopic right colectomy with CME + D3 dissection for tumor at the hepatic flexure. (Courtesy of Dr. Masaaki Ito and Hiro Hasegawa and Takeshi Sasaki). https://doi.org/10.1007/000-33p

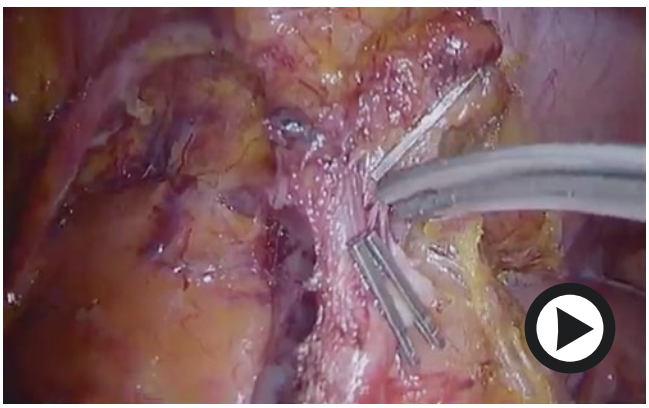

Fig. 37.5 Medial to lateral approach for laparoscopic left colectomy with CME + D3 dissection for tumor in the distal transverse colon. (Courtesy of Dr. Masaaki Ito and Dr. Hiro Hasegawa and Takeshi Sasaki) https://doi.org/10.1007/000-33n

transverse colon tumors, left colectomy is performed with sparing of the right branch of the middle colic artery. The IMV is also ligated with takedown of the splenic flexure (Figs. 37.6 and 37.5). Omentectomy is performed inferior to the gastroepiploic vessels which are preserved unless infiltrated with tumor. The plane below the mesocolon and the lesser sac is merged, and the hepatocolic ligament is divided. Finally, the lateral peritoneal attachments of the right colon are mobilized in order to complete mobilization of the right colon in preparation for specimen exteriorization. Intracorporeal or extracorporeal reconstruction can then be planned, based on surgeons' preference.

Alternatively, a "SMV-first approach" has been popularized with robotic CME + D3 dissection [29, 46]. The base of the mesocolon is exposed, the transverse colon retracted superiorly, and an incision is made inferior to the ileocolic vessels and extending it more proximally until the SMV is identified. All lymphatic/areolar tissue anterior to the surface of the SMV is dissected en bloc,

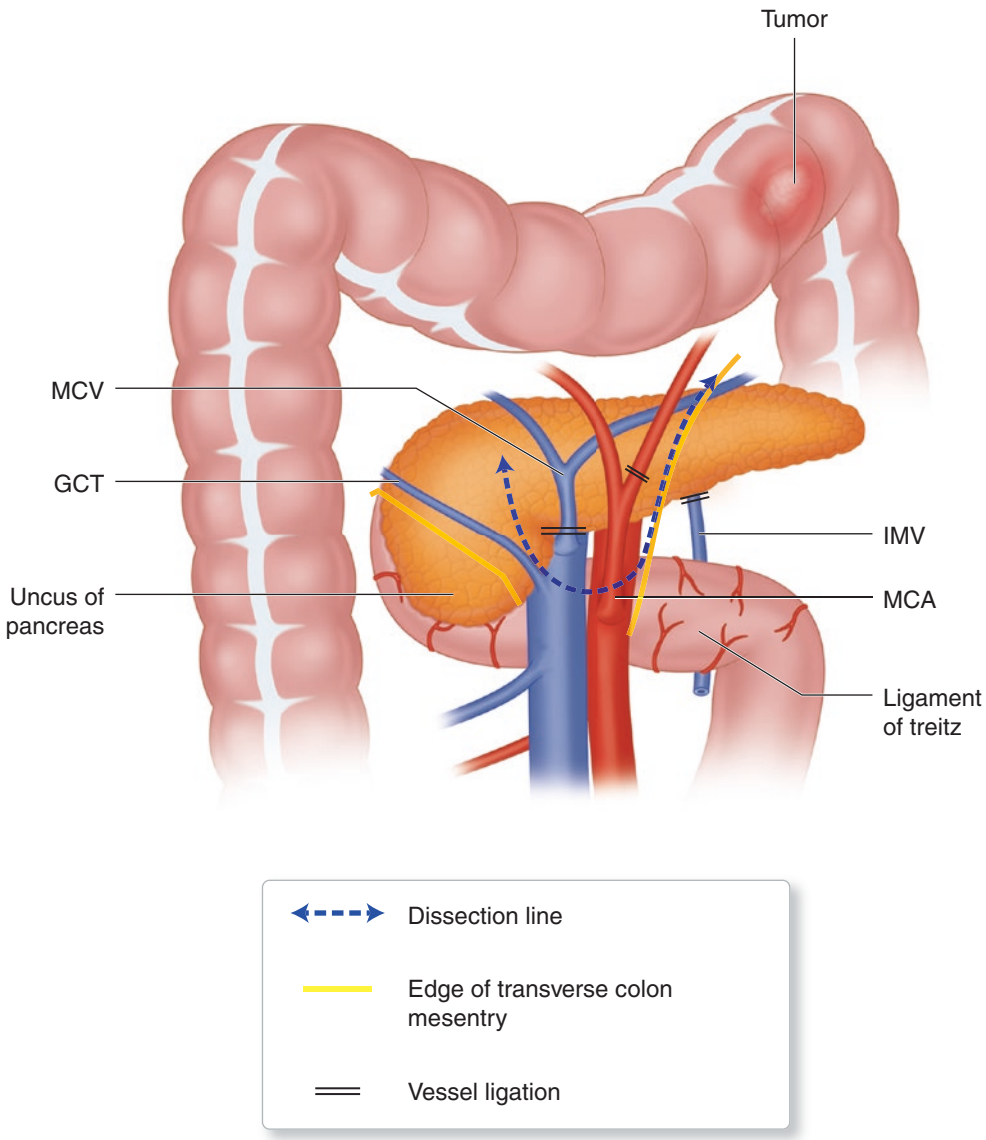

Fig. 37.6 Left colectomy with CME + D3 for a distal transverse colon cancer. The main feeding vessel to be ligated is the left branch of the middle colic artery (MCA) with preservation of the right branch of the MCA

heading cephalad. Then the tributaries of the SMV are sequentially divided, starting with the ICV, followed by ligation of the ICA off the base of the SMA. Medial to lateral mobilization of the mesocolon off the retroperitoneum may be carried out then or subsequent to completion of the SMV dissection. Otherwise, cephalad dissection along the SMV is continued until the middle colic vessels are identified. A right colic artery may be identified and divided, followed by ligation of the MCA or its branches, based on tumor location. The GCT is subsequently identified and dissected along the right anterolateral aspect of the SMV.

Retrofascial Uncinate First Approach This technique was developed by Stefan Benz et al. and is based on an open-book model to best understand the vascular and meso-/fascial anatomy of the operation. In this model, the different planes (mesogastric, mesocolic, and ileocolic) are depicted as pages of a booklet with the GCT serving as the vertical axis and the pancreas serving as the back of the book [51]. The avascular plane between the pages must be dissected according the principles of CME and prior to dividing the vessels in order to avoid vascular injury. Following standard laparoscopic port placement, nine steps are described to complete CME + D3, with associated "critical views" that help provide guidance on satisfactory completion of each step (Figs. 37.7 and 37.8).

Step 1 The small bowel is retracted into the right upper quadrant, exposing the duodeno-jejunal flexure. The peritoneum is incised at the inferior/posterior border of the visible duodenum (Fig. 37.9a). Dissection of the duodenum is carried out in a medial to lateral fashion, and this retromesenteric dissection is extended caudally along the entire

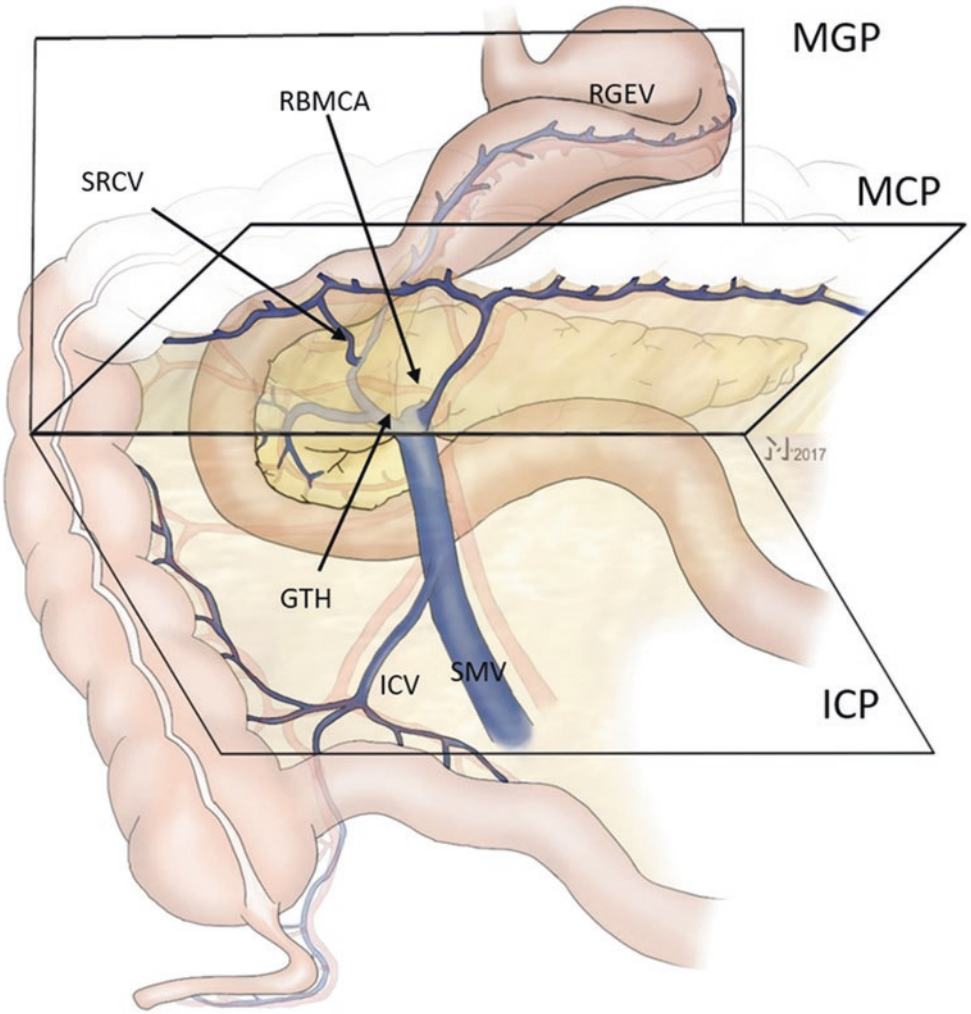

Fig. 37.7 CME + D3 approach using the retrofascial uncinate first approach. This technique is based on an open-book model to best understand the vascular and meso-/fascial anatomy of the operation. In this model, the different planes (mesogastric, mesocolic, and ileocolic) are depicted as pages of a booklet with the GCT serving as the vertical axis. The avascular plane between the pages must be dissected according the principles of CME and prior to dividing the vessels. RGEV right gastroepiploic vein, GTH gastrocolic trunk of Henle, RBMCA right branch of the middle colic artery, SRCV superior right colic vein, MCV middle colic vein, SMV superior mesenteric vein, ICV ileocolic vein, MGP mesogastric page, ICP ileocolic page, MCP mesocolic page [51]. Fig. 37.10 Step 2 of the retrofascial uncinate first approach for CME with central ligation. (**a**) Incision point between the ileocolic and mesenteric vessels [51]. (**b**) Critical view 2: The incision point is highlighted after placing tension on the ileocolic pedicle. (Courtesy of Dr. Stefan Benz)

ascending mesocolon. The right ureter and gonadal vessels are separated from the mesocolon. Cranially the hepatic flexure is usually reached, and Toldt's fascia is incised along the lower border of the duodenum and the anterior surface of the uncinate process is separated from mesocolon (Critical view 1: Figs. 37.9b and 37.8).

Step 2 The small bowel is repositioned to the left, and the ileocolic vessels are placed on tension. A V-shaped configuration between the ileocolic and the superior mesenteric vessel can be identified (Critical view 2: Figs. 37.10a, b and 37.8).

Step 3 The peritoneum is incised approximately 3 cm distal to the ileocolic root, between the ileocolic and superior mesenteric vessels. The dorsal dissection plane is entered and the pancreatic head and the duodenum can be clearly identified. The dissection is continued in the direction of the SMV, which should be dissected to about 180–270° of its circumference. The incision line along the edge of the mesenteric root up to the root of the transverse mesocolon is marked with monopolar cautery. Dissection along the SMV is extended superiorly and 360° dissection of ICV at its confluence with the SMV is carried out (Critical view 3: Fig. 37.8). The ICV is then divided.

Step 4 The ICA is identified crossing either anterior or posterior to the SMV and is dissected entirely 360° at least at the level of the SMV (Critical view 4: Fig. 37.8). In most patients the SMA can be readily identified during this dissection, and all lymphatic tissue on the right side of the SMA is resected. After division of the ICA, the SMV is dissected toward the GCT which is usually the major vein running into the SMV from the right side and cranial to the ICV.

Step 5 Following the principle that the pages of the open-book model should be dissected before vessels are divided, the mesogastric page is now separated from the mesocolic page. Thus, the stomach is retracted cranially, and the gastrocolic ligament is incised approximately 5 cm to the left of the midline, in this way preserving the gastro-omental arcade. The slightly left-sided incision is important because the lesser sac is usually obliterated on the right side of the middle colic vessel which is located approximately in the midline. The lesser sac is entered and the dorsal aspect of the stomach is visualized (Critical view 5: Fig. 37.8).

Step 6 The gastrocolic ligament is divided in a medial to lateral fashion. The vessels running into the omentum need to be transected. Dorsal to these vessels, the avascular plane between the transverse mesocolon and the dorsal mesogastrium (containing the gastroepiploic vessels and infrapyloric lymph nodes) is identified and dissected. This plane crosses the second part of the duodenum and can be followed laterally toward the hepatic flexure and merges with the previously completed step 1. The separation of mesocolon and mesogastrium creates a sulcus, and the colic veins (usually the SRCV) in the mesocolon and the RGEV in the mesogastrium can be identified merging at the base of this sulcus (Critical view 6: Fig. 37.11a, b and 37.12). Because the SRCV often runs outside this axis, excessive tension will result in major bleeding (bleeding point).

Step 7 The operation continues inferior to the mesocolon. The mesocolon is retracted cranially and the transverse mesocolon is incised directly anterior to the SMV. The mesocolon is then divided stepwise from cranial to caudal, dissecting the origin of the right branch of the middle colic artery which is usually found at the base. The origin of the right branch is mobilized 360° ensuring the preservation of the integrity of the left branch (Critical view 7, Fig. 37.8). The vessel is divided, and the middle colic vein is only divided if it impedes adequate lymphadenectomy.

Step 8 The anterior surface of the trunk of Henle is exposed, and all the veins that merge with it from the mesocolon can be divided including the SRCV/RCV. The gastroepiploic vein can usually be identified and must be preserved, as well as the ASPDV. Central dissection is now complete (Critical view 8: Fig. 37.12a, b).

Step 9 The lateral attachments of the right colon can be divided. If extracorporeal anastomosis is planned, the specimen can be exteriorized at this time. If intracorporeal anastomosis is performed, the colon and the terminal ileum are divided. Care must be taken to preserve the ileocolic lymphatic drainage.

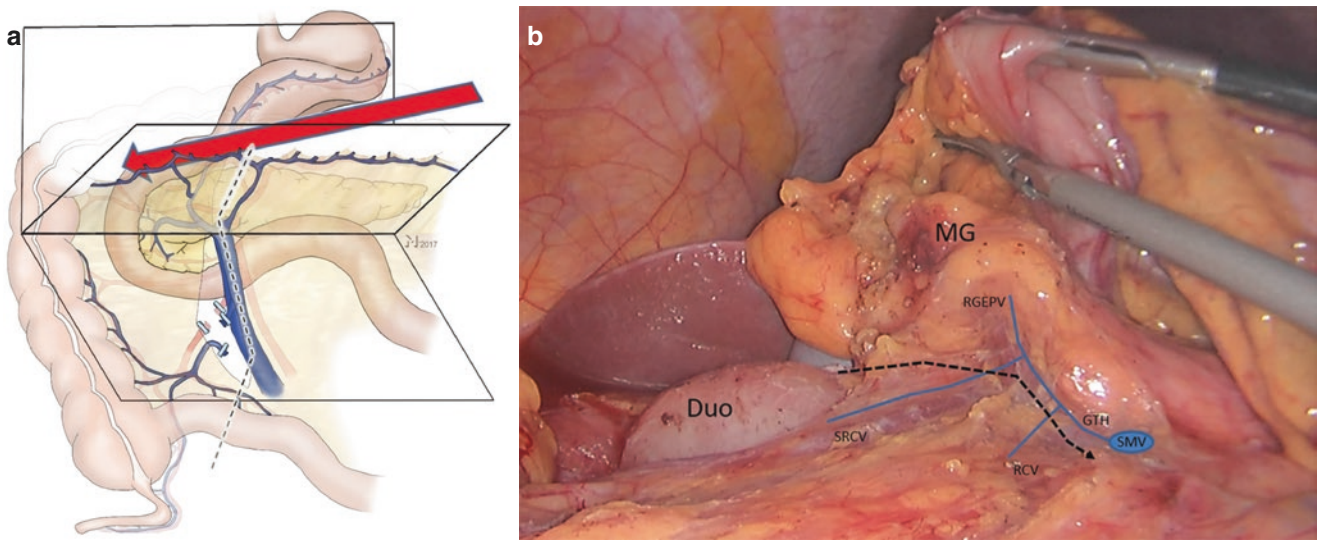

Fig. 37.11 Step 6 of the retrofascial uncinate first approach for CME with central ligation. (**a**) Dissection of the mesogastrium from the mesocolon [51]. (**b**) Critical view 6: The lesser sac is dissected; the sulcus between the mesogastrium and mesocolon is visible. (Courtesy of Dr. Stefan Benz)

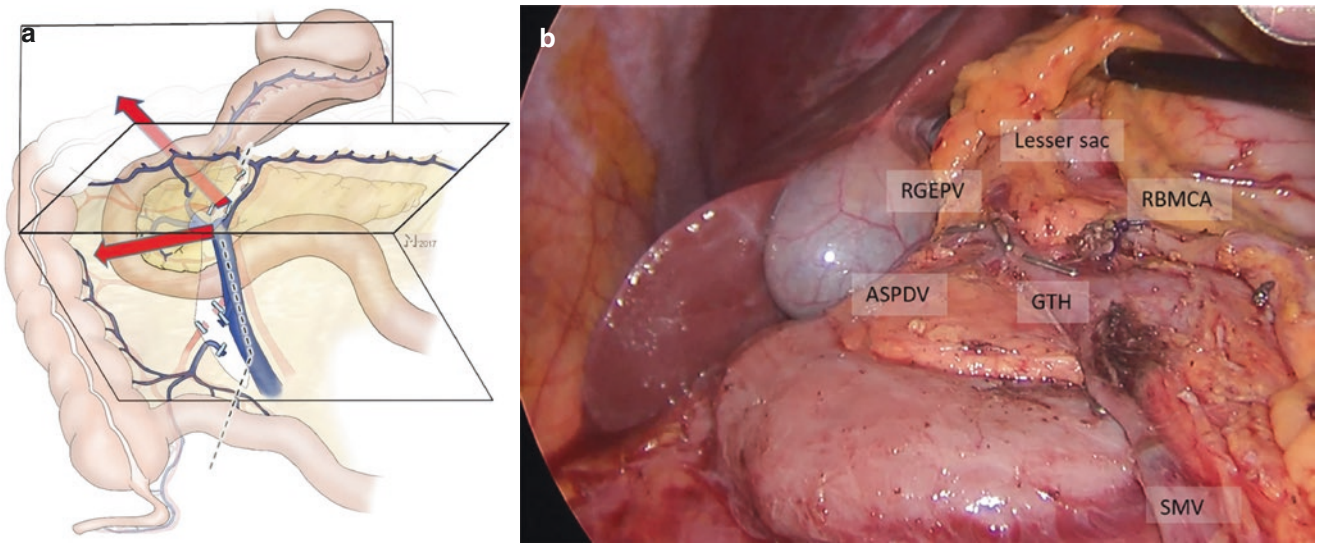

Fig. 37.12 Step 8 of the retrofascial uncinate first approach for CME with central ligation. (**a**) The remainder of the mesocolon is dissected by dividing the colic branches of the GCT while preserving the RGEV and ASPDV [51]. (**b**) Critical view 8: Completed CME with central ligation. (Courtesy of Dr. Stefan Benz)

Lateral to Medial Approach

This alternative approach is preferred in the event the base of the ileocolic pedicle is difficult to identify. The white line of Toldt's is incised along the right gutter, and the embryological plane between the right mesocolon and Gerota's fascia is dissected sharply, taking care to avoid injury to the right ureter, kidney, and right gonadal vessels. This dissection is extended medially toward the duodenum. The base of the ileocolic pedicle is exposed and dissected with exposure of the SMV and dissection of the lymphatic tissue on SMV. The ileocolic pedicle is dissected at its base followed by sharp dissection along the SMV up to the root of the middle colic vessels. After dissection of all lymphatic tissue at the base of the middle colic pedicle, with skeletonization of each branch, arterial and venous ligation is performed based on tumor location. The transverse colon is retracted caudally, and the gastrocolic ligament is divided along the right gastroepiploic vessels.

Cranial to Caudal Approach

This approach has been increasingly adopted in Asia and proposes early and easy access to and exposure of the pancreas, GCT and SMV [52]. With this approach, the omental bursa is opened with exposure of the GCT using the right gastroepiploic vessel and superior (accessory) right colic vein as landmark. After dividing the latter, the SMV and middle colic vein are identified and the latter is divided at its root. Complete dissection of the lymphatic tissue along the SMV proceeds in a cranial to caudal direction. In addition, the middle colic artery is dissected and the MCA or its right branch is divided at its base. The transverse colon is then pulled ventrally and dissection of lymphatic tissue continues along the SMV in a cranial-caudal approach. The ileocolic and right colic vessels are dissected and divided at their origin, and the ascending and transverse mesocolon is dissected off Gerota's fascia, the retroperitoneum, pancreatic head, and duodenum using a medial approach.

MIS CME for Left Colon Cancer with D3 Dissection

A medial to lateral approach to the sigmoid mesentery is preferred. The medial aspect of the sigmoid mesocolon is incised just above the level of the sacral promontory, and medial to lateral mobilization of the mesocolon is carried out sharply through the avascular plane as during standard medial to lateral approach for proctectomy. The IMA is elevated and skeletonized at its base, with dissection of the entire lymphatic and areolar tissue at its root. Care is taken to avoid injury to the superior hypogastric plexus at the level of the aortic bifurcation and the left ureter and gonadal vessels during medial to lateral mesocolic dissection. Following D3 dissection, the principles of tumor-specific CME are subsequently followed with respect to extent of colonic mobilization and division of the IMA or left colic artery, based on tumor location. For proximal left colon tumors, the left colic artery may be divided at its origin, and the root of the IMA and superior rectal artery

are preserved if anastomosis to the distal sigmoid is contemplated. If the entire sigmoid colon is to be resected, as for mid-left sided, sigmoid, and rectosigmoid tumors, the IMA is ligated at its origin on the aorta. In either situation, the IMV is typically divided just inferior to the border of the pancreas, which will allow the proximal colon to rotate inferiorly, when combined with complete mobilization of the splenic flexure. The ligament of Treitz serves as the landmark to identify the IMV. It is important to ensure that there is no arterial branch in the tissues adjacent to the IMV prior to dividing the IMV, as occasionally the dominant arterial flow from the left branch of the middle colic artery runs at the root of the mesentery. If this artery is inadvertently divided, arterial flow to the proximal colonic conduit may be compromised. The left mesocolon is dissected away from Gerota's fascia, the lesser sac is entered, and the root of the transverse mesocolon is freed from the inferior border of the pancreas. The splenic flexure can also be mobilized using the medial to lateral approach. Once completed, the lateral attachments of the left colon are taken down as is the splenocolic ligament. Omentectomy is completed just below the gastroepiploic vessels with preservation of the left gastroepiploic vessels, unless infiltrated by tumor.

Short-Term Outcomes of CME

In a 2019 systematic review of studies comparing outcomes between CME and non-CME resections for right and left colon cancer, two of three eligible studies demonstrated longer operative time with CME [14]. The pooled perioperative morbidity rate among 6 studies was 22.5% vs 19.6% in CME vs NCME groups. The majority of older institutional reports include no information regarding the occurrence of intraoperative adverse events during CME dissection.

The more recent Danish Colorectal Cancer Group (DCCG) published short-term outcomes from 529 patients who underwent CME/D3 for stage I–III colon cancer at a single institution between 2008 and 2013, soon after a short implementation period, and were performed or supervised by a "specialist." A laparoscopic approach was attempted in 48.8% of cases with a 19.9% conversion rate. This is the only study documenting a higher rate of intraoperative organ injury with CME relative to a non-CME historical cohort (9.1% vs 3.6%) with injuries including splenic and SMV injuries [42].

In the Japanese JCOG0404 laparoscopic vs open RCT comparing 521 open to 527 laparoscopic CME + D3 for stage II/III for right- and left-sided cancer, the conversion rate was 5.4%, with longer OR time and a higher, albeit not significant, rate of intraoperative organ injury in the CME group (3.6% vs 1.7%). Intraoperative events included injuries to the small bowel and rectum, arterial supply, portal vein, bladder and ureter, portal vein and gonadal vein, and gastrocolic trunk [41].

In a recent interim analysis of 3-year outcomes of a prospective non-randomized trial comparing 220 CME with 110 non-CME open colon cancer resections, no difference in perioperative complications was noted between the groups. However lower blood loss, faster resolution of ileus, and shorter length of hospital stay were noted in the CME group [23]. These differences likely reflect the vast experience of Japanese surgeons with D3 dissection that preceded the description of CME/CVL by Hohneberger et al. in 2009 by at least a decade [10]. As reflected by three ongoing Chinese RCT's evaluating CME vs D2/D3 dissection, D3 dissection has also been embraced by Chinese surgeons.

There are limited data on the learning curve required for CME. Melich et al. described excellent lymph node harvest, low rate of major complications (3.6%), and no conversion during their initial 81 laparoscopic CME cases with central ligation. However, OR time only decreased from 250 minutes to under 200 minutes after 81 cases completed over 3 years [40].

With respect to complications specific to CME, the most concerning is increased risk of vascular injury to the SMV and its tributaries and the roots of the ICA, RCA, and MCA that need to be dissected in order to achieve adequate D3 lymphadenectomy. Inadvertent ligation of the SMV or tributaries of the GCT can lead to bowel ischemia and necrosis. The risk of injury is likely highest for surgeons early along their learning curve, who must gain extensive understanding of the vascular anatomy around the Trunk of Henle and SMV. The risk of vascular injury is difficult to estimate. Freund et al. reported a 1.6% injury rate over 159 open and 145 CME cases performed for right colon cancer over a 10-year period [53]. The mechanism of injury was attributed to errors related to misperception and lack of understanding of variations in the venous and arterial branches at the root of the mesentery and avulsion of the middle colic vein due to excessive traction.

Other potential injuries related to CME includes organ injury, chyle leak from extensive nodal dissection, severe diarrhea from injury of the superior mesenteric plexus, and genitourinary dysfunction during left-sided dissection near the IMA (injury to the inferior mesenteric plexus and superior hypogastric plexus). As mentioned in the section on MIS CME + D2/D3, there are no documented additional procedural risks when performing CME using laparoscopic or robotic assistance when performed by experienced high-volume surgeons [22].

Long-Term Outcomes of CME with D3 Dissection

In a recent 2019 pooled analysis of eligible studies comparing long-term oncologic outcomes between CME and NCME resections, five studies demonstrated no differences in 3- or 5-year overall survival (OS), and one study demonstrated a lower 5-year cancer-specific survival (CSS) in the CME + D3 vs CME + D1/D2 [14, 54]. Four studies demonstrated higher disease-free survival (DFS) or cancer-specific survival (CSS) with CME [26, 55–57], although interpretation of results was limited given historical biases, significant heterogeneity in study design, procedures performed, extent of lymphadenectomy (D1, D2, D3/CVL), and pathologic assessment of CME specimens. The authors concluded that the limited quality of the evidence did not consistently support the oncologic superiority of CME.

In their 2009 seminal article reporting on outcomes from 1329 consecutive patients with stage I–III CRC from the ERCRC registry, Hohenberger et al. reported that adoption of a standardized approach for CME with central ligation resulted in a decrease in 5-year locoregional recurrence rate (6.5–3.6%) and improvement in 5-year cancer-related survival (82.1–89.1%) between the 1978–1984 and 1995–2002 time periods [10]. It is important to note that only 5.6% of patients received adjuvant chemotherapy in that timeframe. The results from the updated 1978–2014 ERCRC registry by the same authors were contrasted between the pre-CME, CME development, implementation, and CME practice time periods. The authors documented a rise in achievement of ≥12 lymph node harvest from 84.8% to 100% and R0 resection rate from 97% to 100%. Significant reduction in the 5-year locoregional recurrence rate (14.8–4.1%) and improvement in 5-year CSS (61.7–80.9%) and 5-year OS (53.1–68.6%) was reported among stage III patients between 1978 and 2009, in the background of increased use of adjuvant chemotherapy (0–79%) between 1978 and 2014 [55].

While this oncologic benefit was likely confounded by historical changes in adjuvant therapies, this survival advantage was confirmed in a population-based study by the DCCG [23]. The Danish 2008–2011 dataset compared 364 CME performed at a single specialized center to 1031 non-CME performed at 3 other centers and demonstrated a higher 4-year DFS in the CME group, especially for stage I/II stages [26]. In the 2008–2013 dataset for right colectomy, 256 CME from the same specialized center were compared with 813 non-CME cases from 3 other centers in Denmark. The 5.2-year recurrence rate for stage I–III colon cancer was significantly lower in the CME vs non-CME group (9.7% vs 17.9%) [43].

Another cohort study of 189 consecutive patients with stage I–II colon cancer treated with CME + D3 at one hospital vs CME + D2 at 3 other institutions between 2007 and 2008 demonstrated significant improvement of 3-year OS (88.1% vs 79%) and DFS (82.1% vs 74.3%) in the CME + D3 group [56].

Finally, a smaller institutional study comparing 45 CME with a historical control group of 58 patients treated with non-CME resections for right colon cancer also demonstrated that CME was associated with a significantly lower local recurrence rate (0% vs 20.6%) and higher 5-year CSS in stage III patients [50], despite the fact that similar portion of patients underwent adjuvant chemotherapy (47% vs 43% in CME vs NCME).

Much of the criticism of the above studies relate to flaws in study designs and reliance on historical cohorts as control groups. In several of the above studies, NCME procedures were localized at hospitals that never adopted CME and compared with CME performed at a single specialized institution, which introduces significant bias [26, 43, 56]. In addition, two studies reported inexplicably high rates of local/locoregional recurrence in the historical NCME cohort (14.8% and 20.6%) [55, 57], which raises concerns about baseline surgical techniques and outcomes [14]. Finally, the majority of these studies did not report the use of quality indicators to demonstrate/validate the adequacy of CME resections, other than the number of lymph nodes. As a result, the extent/quality of CME and D2 vs D3 dissection could not be validated [18, 43, 54–57].

With respect to more recent studies, interim analysis of an ongoing prospective non-randomized double blind trial comparing outcomes of 220 vs 110 patients who underwent open CME + D3 vs non-CME for right and left colon cancer, respectively, demonstrated improved 3-year local recurrence-free survival in stage II and III cases but no differences in OS or DFS [23]. Long-term outcomes form the ongoing COLD trial (multicenter randomized trial comparing mostly laparoscopic D2 vs D3 dissection), which so far demonstrated an equivalent number of lymph nodes harvested in each group among the first 100 patients accrued, will provide more insight regarding long-term outcomes of CME with D3 dissection [29]. Three other RCTs are currently underway in China to evaluate long-term outcome of laparoscopic CME + D2 vs CME+D3 for right colon cancer (RELARC, SLRC trials) [29, 58] and right- and left-sided cancer (LCME) [29].

Few groups in the USA have published their experience with CME + D3 dissection. Sammour et al. recently reported their short-term results with laparoscopic and robotic CME + D3 performed in 141 patients with right colon cancer (including 98 stage II/III patients) with favorable anatomy and in whom D3 dissection was preferred based on preopera-

tive staging [40]. Relative to a CME + D2 cohort of 56 patients performed during the same time period, no significant difference in short-term outcomes were identified with the exception of a higher median number of lymph node retrieved with CME + D3 (31 vs 27) although the number of positive nodes did not differ between the groups. It was not possible to determine the incidence of centrally positive nodes in this study since nodal stations are not routinely recorded on pathological analysis in the USA, nor is the level of vascular ligation based on mesenteric and pedicle length between the vascular tie and the tumor and/or bowel wall recorded.

In the USA, American cancer societies including American Society of Clinical Oncology (ASCO), the American College of Surgeons Commission on Cancer (ACS CoC), and National Collaborative Cancer Network (NCCN) have endorsed the recommendation that a minimum of 12 lymph nodes be used as a quality indicator for colorectal cancer resections, along with the oncologic principles of high ligation and negative margins. There are no guidelines or expectations regarding the optimal distribution of lymph nodes to be harvested relative to major vascular pedicles, or expected amount of mesentery to be removed. In sum, these recommendations could be translated to mean that CME with D2 lymphadenectomy is considered standard of care, with consideration for selective D3 lymphadenectomy based on preoperative detection of suspicious central lymph nodes in select patients.

It has become essential when designing prospective trials to evaluate outcomes of D2 versus D3 resection during CME for colon cancer, for the surgical community to standardize anatomic definitions, surgical principles and procedural milestones, as well as quality indicators of CME specimen assessment. As for mesorectal specimen grading, colon mesentery specimen grading should be externally validated using pathological parameters with high interrater agreement. Studies evaluating the safety and oncologic outcomes of CME will need to define the exact parameters of the operation, especially with respect to extent of lymphadenectomy, using standardized video-based assessment of procedures and review of intraoperative photographs highlighting prespecified anatomic landmarks.

With respect to adoption of CME + D2/D3 resection, it is hoped that based on the evidence presented in this chapter, and in light of the emerging evidence from well-designed ongoing trials, surgeons will become engaged and eager to reflect on their own surgical techniques when performing colectomy for cancer and strive to optimize CME + D2 dissection. CME + D3 resection can be considered in select cases, although at present there are no definitive data to support its use.

Conclusions

Although the published evidence supports completion of CME for colon cancer based on global improvement in surgical quality, prognostic and survival advantage provided by higher lymph node counts achieved, routine D3 lymphadenectomy for stage II/III colon cancers remains highly controversial, especially given the lack of direct and high-level evidence demonstrating long-term oncologic benefits. While in experienced hands, CME + D3 has an acceptable risk profile; when applied to right colectomy in particular, it requires thorough knowledge of the anatomy of the superior mesenteric vessels and their tributaries. These are technically challenging procedures with added risk of organ and vascular injury during the early learning curve. Recently, laparoscopic and robotic approaches for CME + D3 dissection have been increasingly described, with acceptable conversion rates, improved short-term results, and non-inferior oncologic outcomes in experienced hands and at high volume centers. Several ongoing prospective observational and randomized trials are currently underway to evaluate the oncologic impact of CME + D2/D3 resection in stage II/III disease. Unlike older trials, these trials incorporate video-based standardized assessment of the quality of CME resections, as well as standardized pathologic assessment of quality indicators for CME specimens using photodocumentation. Until then, the current evidence only supports selective use of CME + D3 for tumors with high risk for lymph node metastasis, based on preoperative imaging, tumor location, and/or clinical T stage. The same published evidence however should serve as a reminder to the surgical community of the importance of adopting CME + D2 dissection and adopting procedural and pathological quality assessment measures.

Part IV

Benign Colorectal Disease

Colonic Diverticular Disease

38

Jason F. Hall and Willem A. Bemelman

Key Concepts

- Our understanding of the pathophysiology of diverticular disease is evolving.
- Many behavioral and environmental factors may influence the development of diverticular disease.
- Some patients with early uncomplicated diverticulitis can be treated without antibiotics.
- The decision to perform elective surgery after several episodes of recurrent uncomplicated diverticulitis should be individualized.
- The decision to perform elective surgery after successful non-operative management of a diverticular abscess should be individualized.
- Laparoscopic lavage can be employed in some patients with Hinchey III diverticulitis.
- Minimally invasive surgery is an acceptable option for managing diverticulitis and its complications.

Introduction

Diverticular disease of the colon is one of the most commonly diagnosed gastrointestinal conditions [1, 2]. Symptomatic diverticular disease represents a spectrum of disease ranging from mild abdominal symptoms to free perforation with peritonitis and sepsis. In the past few decades, there has been renewed enthusiasm for research in this area, and many practice patterns have been challenged. Presentations of diverticulitis are stratified into complicated or uncomplicated diverticulitis.

Complicated disease includes diverticulitis associated with free perforation, fistula, abscess, stricture, or obstruction. Uncomplicated diverticulitis is defined as diverticulitis which is not associated with any of the aforementioned features. Microperforation with small amounts of contained extraluminal gas, in the absence of a systemic inflammatory response, is considered uncomplicated diverticulitis [3]. Symptomatic uncomplicated diverticular disease (SUDD) is defined as diverticulosis associated with chronic abdominal pain. These patients do not have clinically overt colitis [4].

This chapter focuses on the pathophysiology, evaluation, and treatment of left-sided colonic diverticulitis. Diverticular hemorrhage is associated with diverticulosis and not diverticulitis. The management of diverticular bleeding is covered in the chapter on lower gastrointestinal bleeding.

Epidemiology

The prevalence of diverticula-related illness has risen in the United States over the past few decades [5, 6]. A recent report utilizing information from the National Inpatient Sample (NIS) suggested that the rate of hospitalization for diverticulitis increased from 74.1/100,000 in the year 2000 to 96.0/100,000 in 2008 [1]. Peery recently examined data from the National Ambulatory Medical Care Survey and the National Hospital Ambulatory Medical Care Survey. In 2010, there were more than 2.7 million discharges in the ambulatory setting associated with a diagnosis of diverticular disease. In 2012 there were >340,000 emergency department visits for diverticulitis [7]. More recent data revealed that in 2014, there were 1.92 million patients diagnosed with diverticular disease in the ambulatory setting [2]. The estimated aggregate national cost of caring for patients with diverticular disease in the emergency setting was $1.6 billion in 2013 [8].

S. R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, https://doi.org/10.1007/978-3-030-66049-9_38

Histology and Pathology

Many of the microscopic features of diverticulitis include thickening of the lamina propria, mucin depletion, and Paneth cell hyperplasia. Crypt abscesses and ulceration are also observed in some cases [9]. Many of the histologic features are similar to those associated with inflammatory bowel disease [10]. Hinchey developed pathologic criteria to classify the severity of diverticular disease. This classification has been used and is divided into Stages I–IV [11]. Stage I includes patients with diverticulitis and a pericolic abscess. Stage II represents patients with distant abscesses such as a pelvic or retroperitoneal. Stage III and IV are patients with purulent and feculent peritonitis, respectively. A number of attempts have been made to extend the Hinchey criteria to preoperative staging based on CT scan [12].

Role of Fiber

A number of authors have postulated that diverticular disease is related to fiber deficiency. Painter and Burkitt studied colonic transit times and fiber contents in patients in Uganda and the United Kingdom. Patients with a higher fiber intake had more frequent bowel movements, faster colonic transit times, and larger stool volumes. They postulated that a progressively more processed diet removes a large source of fiber from the Western diet [13]. These observations are confounded by a number of factors, including differing life expectancies in industrialized and non-industrialized countries [14]. It is interesting to note that as non-industrialized societies have adopted a more Western diet, a number of authors have noted an increasing prevalence of diverticular disease [15].

A number of studies have examined dietary factors in large patient populations with and without diverticular disease and found an inverse association between incidence and fiber intake [16, 17]. The relative risks associated with fruit and vegetable fiber intake were 0.62 and 0.55, respectively [16]. Fiber found in fruits and vegetables conferred the most protective effect (compared with fiber from cereal) and a high intake of fat and red meat increased the incidence of diverticular disease.

Manousos et al. [17] compared individuals who ate a vegetarian diet to those who predominantly ate meat. The risk of developing diverticular disease was 50-fold greater in meat eaters. In a more recent cohort study of 47,228 male health professionals, popcorn, nut, and seed consumption were inversely correlated with diverticulosis or diverticular complications. This study refutes the adage that "nuts, corn, seeds and popcorn" cause diverticulitis and should be avoided in patients who have had an attack of diverticulitis [18].

Recent data has examined the association between eating a "Western" diet (high in red meat, refined grains, and high-fat dairy) and the risk of developing diverticulitis. In a study of men from the Health Professionals Follow-Up Study, Western diet was associated with an increased risk of diverticulitis when compared to a "prudent approach" (high in fruits, vegetables, and whole grains). Men who had the highest consumption of a Western diet had a multivariate hazard ratio of 1.55 (95% CI: 1.20–1.99) for diverticulitis compared to men in the lowest quintile. The authors suggested that this association was related primarily to the intake of less fiber and more red meat [19].

Another group demonstrated a similar pattern when they studied 907 incident cases of diverticulitis. The cohort was divided into patients with low- and high-risk lifestyles. The components of a low-risk lifestyle are an average red meat intake (<51 g per day), dietary fiber intake in the top 40% of the cohort (about 23 g per day), approximately 2 hours of exercise weekly, normal BMI, and never smoked. These authors demonstrated an inverse linear relationship between the number of low-risk lifestyle factors and the incidence of diverticulitis (p for trend <0.001). Although there were numerous contributors to the lower risk of disease, it appears that fiber has an important role to play in the pathogenesis of this disease [20].

Pathophysiology

Genetics

The progression of normal colonic architecture to diverticulosis and subsequent diverticulitis is not well understood. Multiple lines of evidence suggest that this progression is multifactorial and may involve diet, the microbiome, lifestyle, and genetics [21, 22].

A hereditary basis for diverticular disease was suggested by a number of sources. Hall demonstrated that a family history of diverticular disease is associated with a higher risk of recurrence in patients with an incident case of diverticulitis [23]. Two large, twin studies compared the risk of diverticular disease in monozygotic and dizygotic twins. The risk of developing diverticular disease in a twin pair was significantly higher among monozygotic as opposed to dizygotic twins. These authors estimated that heritability accounted for 40–50% of the risk for diverticular disease [24, 25].

Although these clinical observations have been important in establishing a hereditary predisposition to the disease, localization of a specific gene is still in flux. A recent genome-wide association study identified several gene variants (COLQ, ARHGAP15, and FAM155A) that may contribute to diverticular disease [26]. Many of these genes are thought to influence important cellular functions such as

regulation of immunity, cell adhesion, membrane transport, intestinal motility, and immunity [21].

Other authors have detected several single-nucleotide polymorphisms in the TNFSF15 gene in a cohort of patients with diverticular disease who required surgery [27]. Variations in this gene have also been implicated in the pathogenesis of Crohn's disease [28]. Coble used whole exome sequencing to examine genes that are associated with early onset diverticulitis. LAMB4, a gene localized to the colonic myenteric plexus, was found to alter the function of the enteric nervous system and was proposed as a potential contributor to early onset diverticular disease [29].

Microbiome

The human gastrointestinal tract contains a variety of microorganisms, which harbor approximately 10^{12} to 10^{14} genes. The size of this genome is estimated to be at least 100 times larger than the size of our own genome [30]. The aggregate of these varied microorganisms is referred to as the microbiome. Several authors have postulated that an altered microbiome could influence the pathogenesis of diverticulitis [31].

The human metabolism and inflammatory response can be influenced by genetic information outside our genome. However, insights into the influence of microorganisms on gastrointestinal function and diverticular disease are in their infancy and rely on extrapolation from other disease states. Patients with obesity, colon cancer, irritable bowel syndrome, and inflammatory bowel disease have all been proposed to have altered microbiomes [31–34].

There have been a few small studies that examined the role of the microbiome in the pathogenesis of diverticular disease. There is some evidence that patients with diverticular disease have lower levels of bacteria that metabolize fiber into short-chain fatty acids (SCFA) [35]. SCFA are thought to increase the production of antimicrobial and mucus peptides in the gut. In this way they help to regulate intestinal barrier function and cell proliferation [36].

Other authors have demonstrated that patients who had colonic resections for diverticulitis had higher levels of *Bifidobacterium* when compared to patients with colon cancer or IBD [37]. Another group compared the microbiome of patients with diverticulitis undergoing colonoscopy to asymptomatic controls. They found that the diversity of *Proteobacteria* was higher in patients with diverticulitis [38]. Other studies have demonstrated lower levels of Clostridial organisms in patients with a history of diverticulitis when compared to controls with asymptomatic diverticulosis [39, 40].

The fecal microbiome appears to be important to normal gut function. Its role in the pathogenesis of diverticular disease is still to be determined. It is not clear whether the aforementioned changes are causal or simply associated with the development of the disease.

Risk Factors for Disease

Age

Diverticular disease tends to affect patients during middle age; the incidence rises from 5% at age 40% to 80% by age 80 [3]. Historically, diverticulitis in patients under the age of 50 years was thought to be more virulent and associated with more complications [3]. More contemporary data suggests that young age is not associated with worse clinical outcomes.

Younger patients do have higher recurrence rates compared with older patients. However, younger patients do not seem to have more complicated recurrences [41–43]. This observation is bolstered by data from multiple national databases and systematic reviews, which demonstrate that younger patients are more likely to require repeat hospitalization for diverticulitis, but are not more likely to undergo emergency surgery [44–46].

Sex

Diverticulitis is more common in men. Previous estimates suggest between a 3:2 and 3:1 male-to-female ratio [47]. Others have reported that patients with symptomatic diverticular disease under the age of 65 tend to be male. Hall demonstrated that younger male patients may present with more severe CT findings of diverticulitis than female patients [48]. Etzioni reported that women are at higher risk of treatment failure when managed as outpatients [49]. A similar pattern was noted in a paper examining recurrence of diverticulitis in the National Health Service (United Kingdom) [44].

Physical Activity

Several studies have examined the effect of exercise on the development of diverticular disease [50, 51]. The risk of developing diverticular disease and levels of physical activity appeared to be inversely related. This difference persisted even when the authors adjusted for differences in dietary fiber intake. These findings were later replicated in 2009. Strate demonstrated that men who had >57.4 metabolic equivalent hours per week (MET-h/week) had a RR of 0.75 for diverticulitis and 0.54 for bleeding, as compared with men in the lowest quintile (< or = 8.2 MET-h/week). Vigorous activity appeared to be particularly important and was inversely related to diverticulitis (multivariable RR, 0.66; 95% CI, 0.51–0.86). Nonvigorous activity was not associated with a similar benefit [52].

Smoking

Although the association between smoking and diverticular disease was once considered controversial, more recent data suggests a strong association. One large case-control study demonstrated that smokers had three times the risk of developing complications from diverticular disease compared to nonsmokers [53]. Aune performed a meta-analysis of 5 studies examining 6076 cases of diverticular disease. Current smokers had a much higher incidence of diverticular disease when compared to former smokers and ever smokers. The relative risk associated with developing a complication of diverticular disease (abscess or perforation) was 2.54 for current smokers and 1.83 for ever smokers [54].

Non-steroidal Anti-inflammatory Agents

The use of non-steroidal anti-inflammatory (NSAID) agents has been associated with the development of multiple gastrointestinal complications. A number of cohort studies have consistently demonstrated an association between NSAID use and diverticular disease [55–58]. While the health professionals' follow-up study showed an increased incidence of uncomplicated diverticular disease in patients who used NSAIDs compared with their asymptomatic counterparts, additional studies have also noted an increased risk of complicated diverticulitis with NSAID use [59]. A retrospective study by Corder demonstrated a 23% higher risk of perforating diverticulitis in patients who took NSAIDs regularly compared with patients with diverticular disease who did not take NSAIDs [60]. An additional study of hospitalized patients reported chronic NSAID use to be much higher in patients admitted with diverticular disease than the population as a whole. In addition these patients were four times more likely to develop perforated diverticulitis than patients with no history of NSAID use [61].

Obesity

A number of retrospective case series have noted increased rates of obesity in patients with diverticulitis, particularly patients under the age of 40 [62–64]. In addition, two prospective cohort studies (the Health Professionals Follow-up Study and a Swedish study) have shown an association between body mass index (BMI) and diverticular disease [65–67]. A prospective cohort from the Nurses' health study demonstrated that women who gained ≥20 kg had a 73% increased risk of diverticulitis (95% CI, 27–136%) compared to women who maintained the same weight from age 18 years to the present [68].

Aune examined the role of obesity in a meta-analysis of five studies. They found that the relative risk for an incident episode of diverticulitis was 1.31 for each 5 unit increase in BMI. Similarly, they found that the relative risk for a diverticular complication was 1.20 for each 5 unit increase in BMI [69].

Clinical Manifestations and Physical Findings

Differential Diagnosis

The differential diagnosis for suspected diverticular disease includes appendicitis, bowel obstruction, ruptured aortic aneurysm, colorectal cancer, ischemic colitis, pyelonephritis, gynecologic disease, inflammatory bowel disease, and irritable bowel syndrome. Other diagnoses that should be entertained include endometriosis, tubo-ovarian abscess, pelvic inflammatory disease, ureteral calculi, volvulus, stercoral ulcer, and ovarian torsion. Modern cross-sectional imaging is often helpful in diagnosing many of these clinical entities. An important diagnosis to exclude on initial presentation is colorectal cancer.

History and Physical Examination

Patients with acute diverticulitis typically present with left-sided abdominal pain, fever, and leukocytosis. Physical findings include left lower quadrant tenderness on examination. Patients with free perforation will typically present with diffuse peritonitis and signs of systemic toxicity. When there is a significant phlegmon involving the colon, an abdominal mass may be palpable or appreciated on rectal or pelvic exam. Many patients present with some degree of abdominal distention. Right-sided tenderness can be a presentation in patients who have a redundant sigmoid colon that extends to the right side of the abdomen. Free perforation is associated with diffuse abdominal pain, sometimes referred pain in the shoulder, and shortness of breath.

Many patients often describe changes in their bowel habits such as constipation, or an alteration in stool caliber. Rectal bleeding rarely occurs as a presentation of acute diverticulitis. If present, rectal bleeding is more suggestive of ischemic colitis or inflammatory bowel disease. In complicated presentations, an inflammatory phlegmon can be associated with a small or large bowel obstruction. Patients with an associated obstruction will present with abdominal distention and sometimes nausea and vomiting.

Patients with fistulas may have minimal abdominal complaints and often present initially to a urologist or gynecologist. Colovesical fistulas may present with pneumaturia, pyuria, or fecaluria, while patients with colovaginal fistulas present with vaginal discharge, vaginal air, or stool per vagina.

A number of patients with "chronic" or atypical diverticular disease will present with pain as their predominant symptom in the absence of other physical findings. The pain is typically persistent and boring, and remains constant over long periods of time. It does not tend to be "crampy" in nature as in patients with irritable bowel syndrome, but is difficult to distinguish from this entity [70]. Recently, symptomatic uncomplicated diverticular disease (SUDD) has been used to describe this group of patients. Many patients with SUDD have continuing symptoms and quality of life limitations even after recovery from an acute episode of diverticulitis. Often, there are no imaging findings which correlate with their symptoms [71].

Diagnostic Evaluation

Most laboratory tests are not terribly helpful in the evaluation of acute diverticulitis. Many patients with acute diverticulitis present with leukocytosis. Patients with colovesical fistulas may have an abnormal urinalysis and/or a urine culture with enteric organisms. C-reactive protein (CRP), procalcitonin, and fecal calprotectin have been considered as potential adjuncts in assessing diverticulitis severity [72–74]. In multiple case series, CRP has been examined as a marker of complicated diverticulitis. Much of the available data is limited as the series are small and the suggested cutoff values vary [75–79].

In one study, CRP >150 mg/L significantly discriminated acute uncomplicated from complicated diverticulitis. This study also examined the use of CRP and CT imaging findings. A CRP >150 mg/L and free fluid on CT scan were associated with increased mortality [80]. Another recent study used procalcitonin levels to discriminate between patients with uncomplicated and complicated disease [72]. Although laboratory testing may play an important predictive role in the future, evidence supporting its routine use is limited at present.

Although a number of different modalities have been used to evaluate patients with suspected diverticular disease, computed tomography has emerged as the study of choice. Flat and upright plain films of the abdomen are commonly obtained in the evaluation of the patient with acute abdominal pain to exclude obstruction or free intraperitoneal air. In patients with diverticular disease, the findings of plain films tend to be nonspecific [81]. Ultrasound has not gained wide acceptance in the United States. Contrast enemas are seldom currently used in the evaluation and management of diverticulitis. Water-soluble contrast studies may be useful when an obstructing stricture is suspected.

A CT scan is usually the most useful test in the evaluation of patients with acute abdominal pain. CT findings associated with diverticulitis were first described over 30 years ago. These signs included the presence of diverticula, pericolic fat stranding, colonic wall thickening more than 4 mm, and abscess formation [73]. CT has the ability to stage the severity of disease and may provide a road map for percutaneous drainage of an associated abscess. CT has the added advantage of detecting other intraperitoneal findings including hepatic abscesses, pylephlebitis, small bowel obstruction, colonic strictures/obstruction, and colovesical fistulas.

The first system for classifying the severity of diverticulitis on CT findings to guide clinical management was proposed by Ambrosetti. CT findings consistent with mild diverticulitis included localized wall thickening (>5 mm) and inflammation of the pericolic fat. Severe CT findings were the combination of localized wall thickening and inflammation of the pericolic fat with abscess, extraluminal air, or extraluminal contrast. When the natural history of patients with diverticulitis was stratified by these CT criteria, the authors found that patients with severe CT findings underwent operative intervention more frequently than those patients with mild findings (33% vs. 15%). Patients under 50 years of age with severe findings on CT scan were more likely to have recurrence or complications [74].

In a prospectively collected dataset, patients with findings of severe diverticulitis on CT scan during an index attack treated with antibiotics were more likely to have recurrent attacks of diverticulitis, when compared to patients with mild diverticulitis (39% vs. 14%) [75]. Poletti explored CT and demographic predictors for nonoperative treatment failure in 312 patients with a first episode of left-sided diverticulitis and concluded that the presence of an abscess or extraluminal air >5 cm in diameter was a significant predictor of treatment failure [76].

CT findings which are relevant to clinical management were reclassified based on the Hinchey classification system**.** In grade 0, there is colonic wall thickening but not pericolonic fat stranding. Grade 1a consists of wall thickening and pericolonic fat stranding, while grade 1b includes pericolonic or mesocolic abscess. Patients with grade 2 disease have distant intra-abdominal or pelvic abscesses. Patients with grade 3 and grade 4 disease have purulent and fecal peritonitis, respectively. CT is somewhat limited in distinguishing between patients with grade 3 and grade 4 disease, as purulent and fecal peritonitis often cannot be distinguished on imaging [77].

Kaiser found that disease severity using the modified CT Hinchey classification system correlated with postoperative morbidity and mortality. This group also found that the CT stage correlated with recurrence in patients managed nonoperatively. The presence of a diverticulitis with an associated abscess was one particular factor highly associated with an increased risk of failed nonoperative management [78].

Endoscopic Evaluation

Endoscopic evaluation of the colon is typically recommended following an acute episode of diverticulitis. This

approach is generally advocated to exclude the presence of a malignancy or an alternative diagnosis such as ischemic colitis or inflammatory bowel disease. In actual practice, finding a malignancy is rare. Bryan evaluated 307 patients with flexible sigmoidoscopy (20%) or colonoscopy (80%) following an acute episode of diverticulitis. They found only two patients with colorectal carcinomas [82]. These findings were mirrored by Lau. Of 319 patients who underwent endoscopic evaluation, 26% had polyps (9 polyps >1 cm) and 2.8% were found to have colorectal cancer [83].

Patients with the highest prevalence of malignancy diagnosed after an acute presentation of apparent diverticulitis are those with complicated diverticular disease. A recent systematic review demonstrated that the incidence of malignancy was 7.9% in patients following an attack of complicated diverticulitis and 1.3% following an attack of uncomplicated diverticulitis [84]. Sharma found that the risk of malignancy was 11% in patients with complicated diverticulitis versus 0.7% in those with uncomplicated diverticulitis [85]. A recently published meta-analysis examining 17 studies and 3296 patients demonstrated that the pooled prevalence of colorectal cancer in all patients with diverticulitis was 2.1% (95% CI 1.5–3.1%). In patients with uncomplicated acute diverticulitis, the prevalence of colorectal carcinoma was 0·5 (0·2–1·2) percent [59].

Endoscopic procedures (flexible sigmoidoscopy and colonoscopy) are generally not advocated during an acute episode of diverticulitis. A delay of 6 weeks following resolution of symptoms is typically recommended. This approach is encouraged in order to avoid potential conversion of a sealed microperforation into a free perforation [60]. This position has been questioned by other groups who have demonstrated that colonoscopy during an acute episode of diverticulitis can be safe. However, when colonoscopy is performed in the acute setting, a significant number of the procedures cannot be completed [61, 86].

Cystoscopy or cystography have been used to identify suspected colovesical fistulas associated with diverticulitis. However, in the CT era, the presence of air in the urinary bladder in the absence of instrumentation may be considered diagnostic [87].

Management of Diverticulitis

Acute Uncomplicated Diverticulitis

The number of patients that are admitted for diverticulitis is rising, particularly in the young [1, 88]. Ten percent of these patients develop complications requiring additional management [89]. The vast majority of patients with CT confirmed uncomplicated diverticulitis can be managed without the need for surgery. A number of areas of controversy still exist as new data continues to emerge that influences medical practice.

Antibiotics

Two large randomized trials performed in immunocompetent and stable patients questioned the use of antibiotics for the treatment of uncomplicated diverticulitis (DIABOLO and AVOD). In DIABOLO, a proportion of patients with small abscesses were included. In both trials, there were no differences with respect to development of complicated diverticulitis in the short or long term, nor in rates of recurrent diverticulitis based on antibiotic usage [90–92]. Antibiotic-related complications were reported up to 8% in the DIABOLO trial. Although the aforementioned trials provide level I evidence for non-antibiotic treatment of uncomplicated diverticulitis, there is still not broad agreement in actual practice. The combined SAGES/EAES guideline failed to achieve consensus [93]. The 2020 ASCRS guidelines for the treatment of left-sided diverticulitis are in press and recommend that "selected patients with uncomplicated diverticulitis can be treated without antibiotics/"

Ambulatory Management

Most patients with uncomplicated diverticulitis can be treated in an outpatient setting [94]. General practitioners successfully treat many patients without hospitalization, with low rates of readmission (7%). These patients rarely require percutaneous drainage, and outpatient management is associated with considerable costs savings. Patient selection is paramount. Outpatient treatment candidates should be hemodynamically stable and generally healthy appearing and without major comorbidities or immunosuppression [94, 95].

Dietary Changes

Dietary changes have been applied as non-surgical management of acute uncomplicated diverticulitis. There is little data that suggests that a change in dietary approach can alter the course of diverticulitis. For this reason, the patients should be allowed to have a normal diet as tolerated [96, 97].

Management of Acute Complicated Diverticulitis

Complicated diverticulitis is defined as acute diverticulitis associated with fistula, free perforation, abscess, and/or large bowel obstruction.

Diverticular Abscesses (Hinchey Stages Ib and II)

Literature on the management of diverticular abscesses is difficult to interpret because of significant selection bias. Smaller abscesses (<3 cm) are predominantly treated with antibiotics only, while larger abscesses are treated with percutaneous drainage or even surgery. The failure rates of management of abscesses are therefore difficult to compare.

A recent large multicenter observational study including 447 patients demonstrated a significantly higher rate of treatment failure in the percutaneous drainage group compared to antibiotic treatment (36% vs 24%, $p = 0.013$). In this study, there were more complications in the subgroup of patients with a large or distant abscess (Hinchey 2) [98]. However, the majority of smaller abscesses were treated with antibiotics and the larger ones with percutaneous drainage.

In a systematic review of 7653 patients treated with antibiotics, the overall recurrence rate was 25.5%; in patients treated with percutaneous drainage, the recurrence rate was 15% [99]. Although the optimal role of percutaneous drainage is not completely clear, it may be considered in patients with a diverticular abscess larger than 3 centimeters. Other patients may initially be treated with antibiotics, as may be patients with an abscess inaccessible for percutaneous drainage. Emergent surgery is appropriate for patients who do not respond to standard non-surgical treatments [100–103].

Hinchey Stage III Diverticulitis

Nonoperative Management

Hinchey III diverticulitis is suspected when the CT scan shows free air and free fluid. It is important to tailor the management of perforated diverticulitis toward the patient's clinical condition and CT images. If the patient is clinically stable and without fever, hemodynamic changes, or toxicity, an attempt at antibiotic therapy should be considered. CT scan with the addition of rectal contrast to oral/IV contrast administration can rule out an overt connection between the bowel lumen and the peritoneal cavity (Hinchey IV). There are four case series indicating that in select patients with CT diagnosed perforated diverticulitis, nonoperative management is effective in the majority [104–107].

Laparoscopic Lavage

There have been three randomized trials and numerous cohort studies looking at the efficacy of laparoscopic lavage compared to resectional surgery. In all three trials, the surgical approach was not uniform and the trials examined different primary outcomes [108–110]. In the LOLA trial, the primary outcome was a composite of morbidity and mortality. The primary outcome in the SCANDIV trial was the rate of severe postoperative complications at 90 days (Clavien-Dindo >3a). The DILALA trial compared reoperation rates within 12 months of surgery [108–111].

The LOLA trial was closed early by the data monitoring board because an interim analysis demonstrated an increased rates of serious short-term adverse events in the lavage group (39% vs. 19%, $p = 0.04$) [112]. In addition, the laparoscopic lavage required more surgical re-interventions (20% vs. 7%, $p = 0.12$) and had more abscesses that required drainage (20% vs. 0%, $p = 0.002$). The composite endpoint of morbidity/mortality was comparable between the laparoscopic lavage and sigmoid resection groups at 12 months (67% vs. 60%, $p = 0.58$). Interestingly, 52% of patients in the laparoscopic lavage group did not require any acute or elective surgical intervention, and 74% of patients never required a stoma [112].

In the SCANDIV trial, there was no difference in the rate of severe complications between the groups at 90 days. These results remained consistent at 1 year after surgery [110, 113]. The laparoscopic lavage group had a higher rates of deep surgical site infection (32% vs. 13%, $p = 0.006$) and unplanned reoperation (27% vs. 10%, $p = 0.01$). There were lower rates of superficial wound infection (1% vs. 17%, $p = 0.001$) and stoma formation (14% vs. 42%, $p < 0.001$) in the laparoscopic lavage group. Four patients undergoing laparoscopic lavage were ultimately found to have colon adenocarcinoma.

In the DILALA trial, there was no difference in the rate of early re-interventions (30 days) between the laparoscopic lavage and Hartmann groups (13.2% vs. 17.1%, $p = 0.67$). When long-term results were assessed, the laparoscopic lavage group had a 45% reduction in the risk of undergoing of reoperation within 24 months of surgery [109, 114].

A number of meta-analyses have been performed to summarize the evidence surrounding this technique. Laparoscopic lavage was associated with initial success rate in three out of four patients; similarly, ~3/4 of patients remain stoma free at 1 year. Secondary surgery appears to be necessary in one out of four because of ongoing complaints, who then most often undergo laparoscopic resection. Laparoscopic lavage, however, was associated with a significantly increased risk of intra-abdominal abscess, peritonitis, and future emergency reoperation [108, 110, 111, 115, 116]. Figure 38.1 shows the different outcomes of the three trials at 1 year.

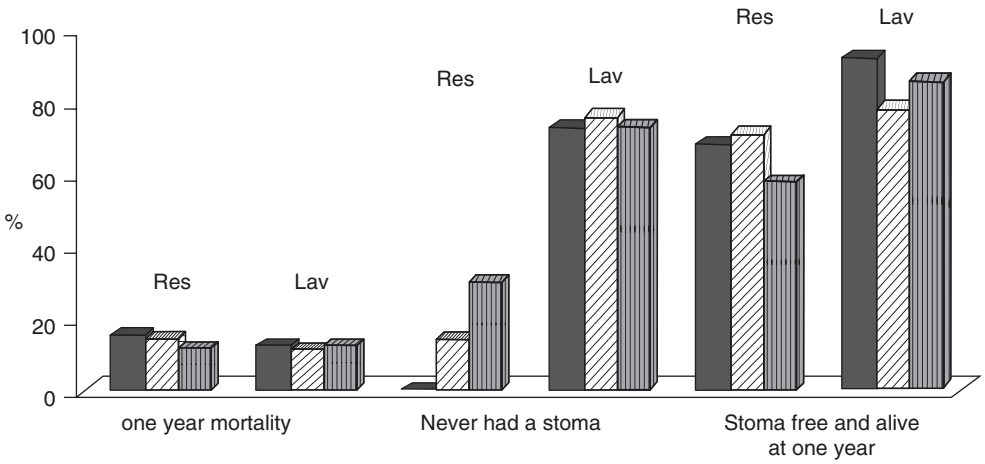

Fig. 38.1 Shows the different outcomes of the three trials at 1 year. (■) DILALA trial [111, 115], LOLA trial [117], (■) SCANDIV trial [110, 116]

The trade-off with lavage is a higher initial re-intervention rate, but overall morbidity and mortality at 1 year and the need for subsequent intervention is similar to resectional surgery. Lavage has been shown to be more cost-effective [118].

Technique: Diagnostic Laparoscopy and Laparoscopic Lavage

During diagnostic laparoscopy, it is important to examine and irrigate the whole peritoneal cavity. When purulent peritonitis is noted, the abdominal cavity is extensively lavaged until the return is clear. Fibrinous exudate may be evacuated if it can be readily removed without damaging the small bowel. The whole peritoneal cavity must be inspected, in particular the pelvis, to ensure there is not an underlying feculent peritonitis. If necessary, the inflammatory mass should be elevated to ensure there is not fecal contamination hidden deep in the pelvis.

Omentum covering the inflamed sigmoid should be carefully removed, but left alone if densely adherent. Laparoscopic lavage for purulent peritonitis is usually effective if the initial diverticular perforation is sealed. Early failure of laparoscopic lavage can be caused by misdiagnosed Hinchey IV diverticulitis or perforated colorectal cancer. Both are conditions that require sigmoid colectomy. Endoscopic insufflation enables detection of a patent perforation.

Hinchey IV Diverticulitis

Hinchey stage IV perforation is characterized by the presence of feculent peritonitis. Resection of the perforated segment is imperative to control sepsis. Segmental resection has been extensively studied in both Hinchey III as well as Hinchey IV perforations. It is important note that in the acute setting, formal mesenteric resection is not necessary unless there is concern for malignancy. If malignancy is suspected, then oncologic resection with high ligation is suggested.

Table 38.1 Randomized trials comparing sigmoidectomy with anastomosis to Hartmann's procedure for Hinchey III and IV perforated diverticulitis (cumulative at 1 year)

	n	Stoma closure		Overall morbidity	
	PA/HP	PA (%)	HP (%)	PA (%)	HP (%)
Oberkoffler [119]	32/30	90	57	84	80
Binda [120]	34/56	65	60	40	69
Bridoux [121]	50/52	96	65	47	48
Lambrichts [122]	64/66	95	72	40	56

In hemodynamically stable and immunocompetent patients, it has been shown that anastomosis after sigmoid colectomy +/− diverting loop ileostomy is safe and associated with a much higher rate of subsequent stoma reversal (Tables 38.1, 38.2, and 38.3). If a definitive anastomosis is to be performed, then a proper diverticular resection should be undertaken to minimize recurrence (see below); if a Hartmann procedure is chosen, only the perforated segment needs be initially resected. When the colostomy is taken down after full recovery of the patient, a proper completion sigmoidectomy can be performed.

Chronic Diverticular Disease

Chronic Uncomplicated Disease

Traditionally, elective sigmoid resection was recommended after the second episode of diverticulitis [124–126]. However, complications of diverticulitis are most likely to occur with a first episode and prophylactic surgery to prevent complicated disease is not justified [23, 127, 128]. Therefore, the decision to perform surgery should be a shared one, which weighs the potential improvement in quality of life against the risks of surgery. The decision for surgery should be individualized, based on severity of symptoms and interference with overall

Table 38.2 Cohort studies comparing sigmoidectomy with anastomosis to Hartmann's procedure for Hinchey III and IV perforated diverticulitis

	N	MR* (%) p<0.0001	MB (%)	MB reversal* (%) p = 0.005	SSI (%)	SSI deep* (%) p = 0.003	Hernia (%)	ReOK (%)	Stoma closure (%)
PA	529	7.9	49	13.5	28	3	11	6	86
HP	366	19.5	41	28.5	29	12	10	16	68

PA Primary anastomosis, *HP* Hartmann's procedure [123]

Table 38.3 Inclusion and exclusion criteria of the trials

	Age limit	Steroids	Pelvic radiotherapy	Dementia	Hemodynamically unstable
Oberkoffler [119]	Not mentioned				
Binda [120]	<18 yrs	–	–	–	–
Bridoux [121]	<18 yrs	–	–	+	+
Lambrichts [122]	<18 >85 yrs	>20 mg	+	+	+

quality of life. Patients should have CT confirmation of the diagnosis of acute diverticulitis, as symptoms from irritable bowel syndrome may mimic ongoing inflammation or recurrent attacks. A randomized study comparing optimal conservative management versus surgery for ongoing complaints or recurrent attacks showed superior quality of life with surgery, despite a relatively high complication rate (DIRECT trial) [129].

The Young

Younger patients do not appear to have more virulent disease than their older counterparts. However, the younger patients have a higher lifetime risk of developing recurrent disease owing to the greater number of remaining years at risk [130]. The relative risk of having an emergent operation in the younger cohort was slightly higher in a systematic review (7.3% vs. 4.9%) [131]. However, this may represent a more aggressive approach to this cohort or a higher rate of misdiagnosis (e.g., appendicitis), rather than the nature of disease.

The Immunocompromised

Complicated diverticulitis may be more aggressive in immunocompromised patients, with a higher incidence of free perforation [132, 133]. However, overall, the incidence of complicated diverticulitis is only slightly higher (1%) in this cohort [134]. The same individualized assessment and approach toward elective resection after an acute episode of diverticulitis appears appropriate.

Fistula

Complicated diverticular disease can be associated with fistulas to adjacent organs. Diverticular fistulas typically form when a diverticular abscess decompresses through a nearby viscus. Colovesical fistulas are characterized by pneumaturia, fecaluria, and recurrent urinary tract infections. Cross-sectional imaging revealing air in the bladder or a urinary culture with a multiple gut microorganism is usually diagnostic in patients with diverticulitis. Colovesical fistulas may also be identified on cystoscopy. Most patients who are medically fit should be offered surgery to avoid recurrent urosepsis.

Colovaginal fistulas typically arise in patients who have had prior hysterectomies. Most patients will complain of passing gas or stool per vagina. Cross-sectional imaging typically is sufficient for diagnosis. Most patients with a significant colovaginal fistula will desire repair because of the associated distressing symptoms and drainage.

Colocutaneous fistula usually results from a longstanding abscess which drains though the abdominal wall. Initially, these can be managed expectantly. As with other fistulas, patients with significant symptoms usually will require or wish to have an elective operation.

Obstruction

Diverticulitis-related obstructions should be treated surgically. Colonic stenting is generally not successful in benign conditions. It is important to differentiate diverticular stricture from colorectal cancer, owing to the need for oncologic resection in the latter circumstance.

Technical Aspects of Surgery

Approach

Three randomized trials and three meta-analyses have evaluated the application of laparoscopy to sigmoid colectomy for diverticulitis. Two of them showed superiority of the laparoscopic approach compared to open surgery [135–138].

Laparoscopy within an enhanced recovery after surgery program is usually the preferred approach in suitable cases and is associated with earlier recovery and less complications [139]. Pfannenstiel incisions are associated with low incisional hernia rates [140]. In emergency surgery, the evidence is accumulating that a laparoscopic approach may also be of benefit [141].

Transection Margins

Most literature regarding the extent of resection is based on retrospective data and is not very robust. The distal margin of the sigmoidectomy should be the proximal rectum. Colorectal as opposed to colocolic anastomoses have a lower frequency of recurrent disease [142–146]. The proximal margin of the sigmoidectomy should be chosen where the bowel is not diseased, as evidenced by the absence of bowel wall thickening. The presence of diverticula per se should not guide the proximal margin of resection.

Inferior Mesenteric Artery Preservation

If there is suspicion of malignancy, an oncologic resection should be done with appropriate proximal ligation of the inferior mesenteric vessels. In cases where malignancy is not suspected, an extensive mesenteric resection is not necessary. One randomized trial showed improved intestinal function when the mesentery is preserved [147]. Another study reported a lower radiological and clinical leak rate [148]. Both systematic reviews and cohort studies have reported that leak rates are either lower or the same with vessel preserving surgery [149–154]. High pedicle ligation seems therefore warranted in cases where cancer cannot be excluded, whereas IMA preservation may otherwise be beneficial.

Splenic Flexure Mobilization

Routine splenic flexure mobilization has not been tested in a systematic way. Nonetheless, creation of a tension-free, well-vascularized anastomosis is desired. In many cases, mobilization of the flexure is necessary to achieve a tension-free anastomosis. The few studies on this topic suggest that splenic flexure mobilization should be done on an individualized basis, depending on the anatomy, disease extent, and the need for additional length to create a tension-free anastomosis [155, 156]. One study suggested that splenic flexure mobilization is associated with increased risk of superficial surgical site infections (10.6% vs. 8.4%, $p < 0.0002$) [157].

Ureteral Stents

Available evidence suggests that routine ureteral stenting in surgery for diverticular disease is associated with a longer operative time, longer length of stay, and higher costs [158–160]. Analysis of the protective impact of ureteral stents against ureteral injury in the literature is always confounded by selection bias, as higher-risk patients are more likely to receive stents. As such, comparable rates of injury in stent vs no stent groups may actually be evidence to support their efficacy. A selective approach appears appropriate.

Anastomotic Leak Testing

Anastomotic leak testing may be simply performed by instilling air transanally while submerging the anastomosis under saline in the pelvis (air bubble test). A positive result identifies patients at higher risk of having a clinical leak [161, 162]. This allows the surgeon to repair or revise and then retest the anastomosis [163]. A randomized trial comparing leak testing versus no leak testing in 145 colorectal anastomoses showed that leak testing significantly reduced the incidence of postoperative clinical and radiological leaks [164].

Right-Sided Diverticulitis

There are distinct differences between left- and right-sided diverticulitis. While left-sided diverticula consist of a protrusion of the mucosa through the bowel wall and are by definition false diverticula, the right-sided diverticula are most often true diverticula consisting of all layers of the bowel wall. They are more common in Asia [3]. The scarce literature on right-sided diverticulitis suggests that right-sided diverticulitis is less often associated with a complicated course. The management of complicated diverticulitis, be it left- or right-sided, is generally similar [165, 166].

Conclusion

Colonic diverticular disease is associated with a wide spectrum of presentations and treatment options. While many of the current treatment methods have been in use for the greater part of a century, new approaches to treatment continue to evolve. The initial goal of therapy is to control inflammation and infection, if present. Increasingly, attenuation of the inflammatory response itself will become a target of medical therapy. Individualized assessment is the key to surgical decision-making.

Large Bowel Obstruction

39

Daniel L. Feingold and Fergal J. Fleming

Key Concepts

- Perforation associated with obstructing colonic neoplasms may either be at the site of the tumor or the cecum based on the law of Laplace.
- Sigmoid volvulus is usually best treated with endoscopic detorsion followed by sigmoid resection.
- Cecal volvulus is typically best managed with urgent right hemicolectomy.
- Neostigmine is often successful in the management of acute colonic pseudo-obstruction.

Introduction

Large bowel obstruction (LBO), a relatively common entity in the practice of colorectal surgery, can be due to any number of underlying pathologies and may be challenging to manage (Table 39.1) The main causes of LBO reviewed in this chapter, colorectal cancer, volvulus, and acute colonic pseudo-obstruction, each have unique operative and nonoperative therapies available; it is important to determine what the ideal intervention is for each individual patient. Patients with LBO are typically older and have comorbidities that influence decision-making. These patients may present along a spectrum of clinical scenarios ranging from subacute, gradual derangements in bowel function that are evaluated in an outpatient setting to life-threatening, complete obstruction with ischemia and even perforation requiring emergency surgery.

Recognizing that a patient is at imminent risk for developing colonic ischemia or perforation requires clinical awareness and a recognition of the underlying etiology. Patients with a more subacute presentation should be counselled about symptoms to watch for that may signify acute worsening of their obstruction (e.g., worsening abdominal distension, clothes not fitting as they had previously, obstipation, abdominal pain, etc.) as these patients may progress to the point of needing emergency intervention and are at risk for worse outcomes. Obstructions due to a diverticular or inflammatory bowel disease stricture, a stercoral process, abdominal wall hernia, or extrinsic compression and obstructions in pediatric patients are not discussed in detail in this chapter.

Table 39.1 Differential diagnosis of large bowel obstruction

Intraluminal	Intramural	Extrinsic
Intussusception	Malignancy	Compressive mass
Impacted material	Colorectal cancer	Neoplasia
Feces (stercoral)	Inflammatory	Abscess
Foreign body	Diverticular disease	Cyst
Bezoar	Ulcerative colitis	Urinary retention
Gallstones	Crohn's disease	Pregnancy
Worms	Iatrogenic/trauma	Cysts
	Radiation	Pseudo-obstruction
	Anastomotic stricture	Volvulus
	Hematoma	Hernia
		Endometriosis
		Pancreatitis

Modified from Gore [77]

Pathophysiology

Bowel obstruction leads to proximal accumulation of gas and fluid, which in turn leads to distension of the gut. This accumulation causes increased intraluminal pressure and bowel distention, which leads to an intermittent increase in peristalsis, followed by a flaccid relaxation as the bowel obstruction persists. Intestinal stasis associated with obstruction facilitates bacterial and endotoxin translocation to the mesenteric lymph nodes and possibly the systemic circulation [1]. LBO

can be classified according to whether it is deemed partial, complete, simple, or complicated. Partial obstruction indicates there is some liquid and/or gas getting through the obstructive process, while complete obstruction implies that there is no passage of fluid or gas. A simple obstruction suggests that the blood flow to the colon is preserved in the presence of either a partial or complete obstruction. A complicated obstruction suggests that there is compromise to visceral blood flow, leading to bowel wall edema, intestinal ischemia, and possibly bowel necrosis and perforation.

The clinical manifestations of a colon obstruction are related, in part, to the competency of the ileocecal valve. If the ileocecal valve is competent, which is the case in approximately 75% of patients, LBO will result in a closed loop obstruction which cannot decompress retrograde into the small bowel [2]. In this situation, both the afferent and efferent limbs of the colon are occluded, leading to a marked rise in intraluminal pressure; this can progress to impair the arterial blood flow to the bowel. Once ischemia commences, necrosis of the mucosal villi can occur within 4 hours and, if the pressure is not relieved, can progress to transmural infarction and ultimately perforation [3, 4].

Laplace's law states that the intraluminal pressure required to stretch the wall of a hollow tube is inversely proportional to the radius of the tube. As the cecum has the largest diameter of the colon, it requires the least amount of pressure to distend. The actual diameter that potentially puts the cecum at risk varies in the literature [2, 5]. In cases of chronic obstruction, the cecum may accommodate, without an imminent risk of perforation. Thus, the acuity of the presentation and the rapidity of cecal distention may be more important in determining the risk of perforation than the cecal size alone [6].

Clinical Presentation

A thoughtful history and directed physical examination can elicit the acuity of the presentation and help formulate a differential diagnosis. LBO can present acutely, with colic-like abdominal pain reflecting increased peristaltic activity. This can be followed by reduced peristaltic activity as the proximal bowel distends and relaxes so that the initially colicky pain transitions to a more constant pain. Markogiannakis reported on the clinical presentation of a series of 150 patients who presented with acute bowel obstruction. Cessation of flatus (90%), cessation of feces (80.6%), and abdominal distension (65%) were the most common symptoms and physical signs [7]. Vomiting tends to occur later in the clinical course of LBO compared to small bowel obstruction [3, 8]. Progression to bowel ischemia may be suggested by continuous abdominal pain, a tender irreducible mass in a hernia, fever, tachycardia, or signs of peritonitis with toxicity on physical examination. Bowel ischemia presentation can be quite insidious; a high index of suspicion should be maintained if there is clinical evidence of sepsis [8].

A complete blood count, renal profile, and electrolyte studies are appropriate first-line laboratory investigations for patients presenting with LBO. Marked electrolyte disturbances, especially with regard to potassium, can be present due to a combination of third-space losses, dehydration, sepsis, and duration of the obstructive process. An arterial blood gas may be a useful adjunct as a low arterial pH, low serum bicarbonate, and/or high lactic acid level may suggest intestinal ischemia; but the absence of these derangements does not exclude the presence of ischemia.

Initial Management

Irrespective of the underlying cause of the LBO, the tenets of LBO initial management are the same and involve bowel rest with appropriate fluid resuscitation. Patients are kept nil by mouth, and a nasogastric tube can be inserted to decompress the bowel. Nasogastric decompression can potentially reduce the risk of aspiration and provide symptomatic relief by decreasing the volume of gastrointestinal secretions in the proximal bowel. Fluid resuscitation with appropriate electrolyte repletion is required to address fluid and electrolyte losses from third spacing and lack of oral intake. Urine output should be monitored, and regular clinical assessment of fluid requirements should be undertaken in addition to laboratory tests to reassess electrolyte requirements.

Imaging

Imaging plays a crucial role in the evaluation of a patient with suspected LBO. In up to one third of cases where the working diagnosis following history and physical examination is LBO, no mechanical obstruction is found. Conversely, 20% of patients thought to have colonic pseudo-obstruction are actually found to have a mechanical LBO [3, 9]. Abdominal plain films are often the first imaging modality obtained. Supine and nondependent (upright or left lateral decubitus) radiographs can aid in the diagnosis of LBO and evaluate for pneumoperitoneum. Abdominal X-rays have a reported 84% sensitivity and 72% specificity in cases of suspected large bowel obstruction [1]. Normal colonic diameter ranges from 3 to 8 cm with the largest diameter in the cecum; the cecum is typically deemed dilated when its diameter exceeds ~9 cm in an acute presentation, and the remainder of the colon is considered dilated with a diameter greater than ~6 cm [2].

CT is often the imaging modality of choice for eliciting the cause of LBO, with a reported sensitivity and specificity of 96% and 93%, respectively [2, 10]. CT can also accurately

identify potential complications of LBO like pneumoperitoneum, pneumatosis, and portal venous gas. Pneumatosis indicates the breakdown of the mucosal integrity of the bowel wall, and while suggestive of intestinal ischemia, it is not pathognomonic, and this finding should be interpreted within the clinical context. The presence of free intraperitoneal air and/or portal venous gas is associated with a higher likelihood of transmural ischemia and necrosis than pneumatosis alone [11]. CT is the superior modality for the detection of intestinal perforation (95% sensitivity and 90% specificity) compared to plain film radiography (53% sensitivity and 53% specificity) and ultrasound (92% sensitivity and 53% specificity) [12, 13].

CT scanning is an integral modality for the assessment of a patient with possible malignant LBO; the two most common sites of obstruction due to colon cancer are the sigmoid colon and splenic flexure [14]. Meanwhile, the most common site of perforation in this setting is at the cecum reflecting Laplace's law, and perforation occurs in about 3–8% of these patients [15]. Typical imaging features of a malignant LBO include dilated large bowel with a transition point across a short segment of colonic thickening with a distally collapsed bowel. An obstructing tumor can often exhibit a shouldering appearance (Fig. 39.1) [2]. The remainder of the colon should also be assessed for synchronous lesions which occur in 2–7% of patients, although conventional CT scanning is not ideal for this purpose. Evidence of local invasion (e.g., into the bladder, small bowel loops, etc.) and metastatic disease should also be assessed as these can impact the therapeutic plan.

Fig. 39.1 CT scan displaying right colon dilation secondary to an obstructing transverse colon cancer. Note the competent ileocecal valve. (Courtesy of Daniel L. Feingold, MD)

While ultrasound can be as accurate as CT in determining the presence of LBO, CT is preferred where available as it provides more information regarding the likely etiology and can inform about relevant clinical factors as described above [16]. MR imaging is comparable to CT in assessing for bowel obstruction and ischemia [17] and is particularly useful in situations that call for omitting ionizing radiation. A water-soluble contrast enema has a 96% sensitivity and 98% specificity in diagnosing LBO but does not commonly elucidate the etiology of the process [18].

Malignant Large Bowel Obstruction

Malignant LBO occurs in up to 20% of patients with colorectal cancer and carries a significant morbidity and mortality. Multiple studies have shown a three- to fivefold higher rate of 30- and 90-day mortality when patients present acutely with colorectal cancer compared with an elective presentation [19, 20]. This reflects the fact that many of these patients are frail with medical comorbidities and present with obstruction often with concurrent sepsis and/or ischemia. Following resuscitation and nasogastric decompression, further management depends on the patient's response to resuscitation and clinical reassessment. Clinical decision-making should incorporate baseline patient medical comorbidities; relevant history; physical examination; presence of sepsis; tumor location (right versus left colon); radiological staging assessment (e.g., primary tumor resectability, presence of metastatic disease, etc.); feasibility of offering endoscopic stenting, if appropriate; and patient treatment goals.

Perforation

Perforation secondary to a colorectal cancer occurs in approximately 2.6–12% of cases [21]. Perforation can occur at the primary tumor site from tissue necrosis or proximal to the tumor due to ischemia related to dilation, most commonly at the cecum, which is referred to as a diastatic perforation [22]. This represents a surgical emergency as patients can rapidly progress to septic shock and multiorgan failure. With concomitant resuscitation underway, the surgical approach typically involves a laparotomy, washout, and identification of the obstructing mass. The site of perforation may be proximal to the obstruction. In some circumstances, damage control surgery principles

might need to be applied such as in hemodynamically unstable patients (e.g., septic shock requiring inotropic support, severe metabolic acidosis, hypothermia with coagulopathy, etc.) [12]. In such situations, the surgeon may limit the initial intervention to washout of the abdomen, placement of drains, and possibly a defunctioning ostomy and leaving the abdomen open with a plan for definitive resection once the patient's condition has stabilized. If the patient is hemodynamically stable, then the surgical procedure can address both the obstructing tumor and the proximal perforation, where applicable.

In the case of a right-sided tumor with perforation, an oncological right hemicolectomy with ileocolic anastomosis can be considered, though the increased rate of anastomotic leak in such situations (estimated at 3–15%) should be considered. A right hemicolectomy with ileostomy may be the safest approach in this situation as it avoids the potential risk of an anastomotic leak. In the scenario where there is a left-sided obstruction with perforation, an oncological resection with end colostomy should be considered with the proviso that the proximal colon appears viable with no concern for compromise of the cecum. In the situation where there is left-sided obstruction with a proximal colon perforation or concern for colon viability, a total abdominal colectomy should typically be performed.

Right-Sided Colonic Obstruction (Cecum to Distal Transverse Colon)

While the right colon's wide diameter and typical liquid contents render it less vulnerable to obstruction, right-sided cancers still account for approximately 30–40% of cases of malignant LBO [19, 20]. In contrast to left-sided LBO, oncological resection and anastomosis have been traditionally undertaken for right-sided LBO due to the perceived relative ease of the procedure and relatively low risk of anastomotic complications. However, contemporary studies should temper this perception. Mege reported on a prospective audit of 776 patients who presented with malignant LBO secondary to right-sided colon cancer; 92% had the primary tumor resected, and 82% had an anastomosis formed. The high postoperative mortality rate (10%) and anastomotic leak rate (14%) have been replicated in other studies [19, 20, 23]. While most patients will do well with resection and anastomosis, there is no robust data to guide the surgeon regarding which patient might be better served with resection with some form of ostomy (either end or covering loop). Surgeons' intraoperative judgment (including an assessment of intraoperative blood supply and tissue quality) remains integral to the decision-making pertaining to restoring intestinal continuity or creating an ostomy in these complex situations.

Left-Sided Colonic Obstruction (Splenic Flexure to Rectosigmoid)

There has been an evolution in the approach to managing LBO secondary to left-sided colorectal cancer (CRC) over the past 30 years. Creation of a loop colostomy had traditionally been the first stage of a two- or three-stage approach to LBO under these circumstances. Colostomy creation allows decompression of the colon with subsequent tumor resection (second stage) followed by colostomy closure (third stage). The downside of this approach is that the tumor is not resected at the time of the first surgery; several studies have shown equivalence in outcomes between patients undergoing defunctioning colostomy alone and primary tumor resection. A randomized, controlled trial comparing defunctioning loop colostomy and primary resection reported no significant differences in terms of morbidity rate or overall survival between the two approaches [24], a finding endorsed by a Cochrane systematic review [25]. Thus, one would advocate for oncological resection when feasible and reserve loop colostomy formation for very frail patients where an expeditious, palliative procedure to relieve the obstruction is required or in those with unresectable disease.

Surgical dogma has dictated that to undertake a primary anastomosis in the setting of colectomy for a left-sided LBO is too hazardous, as a combination of bowel wall edema and an unprepared colon made fashioning an anastomosis ill-advised. Hence, a Hartmann procedure with resection of the obstructing mass, stapling off the distal segment, and creation of an end colostomy has been one of the most common procedures performed in this setting. Intraoperative colonic irrigation or lavage was developed to address the concerns over anastomosis creation in the setting of an unprepared colon. The system can be accessed via an enterotomy or through the base of an amputated appendix to allow for decompression alone or decompression with antegrade, on-table lavage (OTL) of the colon. Lim randomized 49 patients with malignant left-sided LBO to either intraoperative colonic decompression alone or OTL [26]. There was a significant difference in time taken for OTL (31 minutes) versus that for decompression alone (13 minutes, $p = 0.005$). There was no significant difference in overall morbidity between the groups. In the decompression group, 2 of 25 patients developed an anastomotic leak (8%) requiring reoperation, but none (0/24) in the OTL group leaked. However, this difference was not statistically significant [26].

Segmental Versus Total Colectomy

An extended colectomy with either ileosigmoid anastomosis (subtotal colectomy) or ileorectal anastomosis (total colectomy) has been proposed as an alternative to segmental col-

ectomy and stoma creation as a way to avoid creating an anastomosis in a distended, stool-filled colon. This is a preferable approach in the presence of proximal colonic ischemia, cecal serosal tearing not amenable to primary repair, or a synchronous colon lesion. Multiple case series report outcomes after total colectomy and anastomosis with anastomotic leak rates of 0–10% and mortality rates of 0–11% [27, 28]. One major concern raised about this approach is that of medium- and long-term bowel function after a total colectomy and ileorectal anastomosis compared to that of patients undergoing a segmental colectomy. This question was addressed in the SCOTIA randomized trial where 91 patients with LBO were randomized to either segmental colectomy (SC) with or without on-table lavage (OTL) or subtotal colectomy (STC) [29]. No significant differences in anastomotic leak or overall mortality rates were observed between the SC and STC groups. However, patients in the STC group were significantly more likely to report increased bowel frequency (defined as ≥3 bowel motions per day) compared to the SC group (41% versus 9%, respectively, $p = 0.01$), and this difference persisted at 4-month follow-up [29].

Multiple prospective case series show that primary resection with anastomosis for malignant LBO can be performed with reported anastomotic leak rates of 2–12% [20, 30, 31] which is not dissimilar to outcomes reported after elective left-sided resections (2–8%) [28, 32–34]. However, it should be stressed that non-randomized studies are inherently subject to confounding bias, in that surgeons are more likely to fashion an anastomosis when intraoperative parameters are favorable (e.g., no or minimal contamination, healthy proximal colon, good mesenteric blood supply, negative leak test, etc.) in a physiologically stable patient and are more likely to divert when these factors were not present. The potentially disastrous consequences of an anastomotic leak in such a setting cannot be overstated and may lead to life-threatening sepsis and the inability to proceed with adjuvant chemotherapy in a timely fashion. Thus, risk stratification and surgical judgment are crucial in such cases. The Association of Coloproctology of Great Britain and Ireland (ACPGBI) Malignant LBO audit identified that patient age, American Society of Anesthesiologists (ASA) grade, operative urgency, and cancer stage were all significantly associated with in-hospital postoperative mortality [20].

To date, there is no randomized, controlled trial examining whether a diverting loop ostomy is efficacious after resection and anastomosis for malignant LBO. Kube reported the outcomes of 743 patients who underwent resection for malignant LBO; 58% had primary resection and anastomosis, 30% had a Hartmann procedure, and 12% had a primary resection and anastomosis with diverting loop ileostomy [35]. No significant differences were observed between groups who underwent primary anastomosis with or without a diverting ileostomy in terms of anastomotic leak rate (7% and 8%, respectively) or reoperation (5.6% and 5.7%, respectively).

As an alternative to operation, self-expanding metallic stents (SEMS) were originally developed to palliate obstructive symptoms from unresectable tumors or in patients deemed too frail to undergo surgical resection. SEMS involves the endoscopic deployment of a guidewire across the obstructing mass, often facilitated by fluoroscopy, followed by deployment of a stent delivery system (Fig. 39.2). The historically high rate of ostomy formation and morbidity associated with emergent resection for patients with malignant LBO led to studies exploring the deployment of SEMS in these patients to decompress the colon and to act as a bridge to a subsequent elective or semi-elective colonic resection, allowing time for patient optimization before surgery (Fig. 39.3a, b). Observational studies supported the concept that SEMS placement was associated with a reduction in stoma and morbidity rates compared to historical cohorts undergoing surgical resection [36]. However, concerns have been raised about possible tumor cell dissemination after stenting, especially in cases complicated by iatrogenic perforation (Fig. 39.4) [37].

To date there have been eight relatively small randomized, controlled trials comparing SEMS as a bridge to elective surgery compared to emergent surgery. Three of these trials were terminated prematurely due to a higher than anticipated event rate (two in the stenting arm and the third in the surgery arm). The Dutch Stent-In 2 trial was stopped when

an interim analysis revealed a higher than anticipated morbidity rate in the SEMS arm, mainly driven by a high rate of perforation (13%) [38]. The relatively high rate of failure to pass a guidewire across the mass (17%) raised the question whether or not appropriate advanced endoscopic personnel were staffing the trial sites. A second randomized, controlled trial by Pirlet was closed early when an analysis found that the primary outcome of decreased ostomy rate was not achieved in the SEMS group compared to the straight-to-surgery group [39]; this was due to the low rate of successful stent deployment. These studies highlight the advanced endoscopic skill level required to safely and effectively deploy this intervention on a consistent basis. Meanwhile, Alcantara prematurely closed their randomized trial due to a high rate of morbidity in the emergent surgery arm [40]. Arezzo [41] undertook a meta-analysis of eight randomized, controlled trials comparing SEMS as a bridge to surgery to straight to emergent surgery (ES). 497 patients were included, and there was no significant difference in 60-day mortality between the SEMS arm (9.6%) and the ES arm (9.9%, RR = 0.99, $p = 0.97$). However, there was a significant difference in the temporary ostomy rate favoring the SEMS arm (33.9%) compared to the ES arm (51.4%, RR = 0.67, $p < 0.001$).

The United Kingdom-based CREST randomized, controlled trial, the largest to date, randomized 246 patients to SEMS as a bridge to surgery versus straight to emergent surgery and was published in abstract form in 2016 [42]. Stenting workshops were held prior to the trial to standardize technical aspects of SEMS deployment. There was no significant difference in 30-day mortality between the SEMS arm (5.3%) and the surgery arm (4.4%) though the overall

ostomy formation rates were markedly lower in the SEMS arm (45%) compared to the surgery arm (69%, $p < 0.001$).

Covered Versus Uncovered Stents

Uncovered stents were traditionally associated with increased rates of stent occlusion due to overgrowth through the stent interstices, while covered stents were thought to inhibit the rate of tumor ingrowth. However, covered stents may not anchor to the bowel well as effectively as an uncovered stent and may migrate more easily [43]. Mashar undertook a meta-analysis of a single randomized trial and nine observational studies comparing the outcomes of uncovered and covered stents. In this study, rates of successful stent deployment, perforation, and bleeding did not differ between the uncovered and covered stent groups, but the uncovered stent group was associated with a lower risk of tumor overgrowth (RR = 0.29, 95% CI 0.09–0.93, $p = 0.04$), decreased risk of stent migration (RR = 0.29, 95% CI 0.17–0.48, $p < 0.001$), and lower need for stent reinsertion (RR = 0.38, 95% CI 0.17–0.86, $p = 0.02$) [43].

Obstructing Rectal Cancer

It is rare for an extraperitoneal rectal cancer to cause LBO, and a locally advanced tumor is usually encountered. In this situation, emergent resection should be avoided, if possible, due to the higher risk of suboptimal surgical resection leading to poor oncological outcomes. Emergent management should focus on relieving the obstruction to facilitate appropriate clinical staging and neoadjuvant therapy followed by definitive surgical management in the form of a TME. SEMS placement in the extraperitoneal rectum is problematic due to the risk of stent migration and tenesmus [44]. A loop colostomy offers effective decompression under these circumstances but may compromise a future elective restorative procedure by damaging the marginal blood supply to the left colon. A loop ileostomy can be employed instead, though one must be circumspect about its use especially if the ileocecal valve is competent, as proximal colonic distension can persist.

Unresectable Disease

Approximately 10–15% of patients with malignant LBO may have unresectable disease at presentation due to local tumor infiltration [28] or metastatic disease or owing to a debilitated state such that it is not prudent to undertake an oncological resection. In the event there is no evidence of bowel ischemia or perforation, a diverting ostomy or a self-expanding metallic stent can be considered to effectively palliate.

Volvulus

Acute colonic volvulus (from the Latin *volvere* meaning to turn or twist) involves axial torsion of a redundant segment of the colon along its mesentery that results in a closed loop obstruction. Over time, the volvulized segment and the colon proximal to the volvulized segment can distend to the point of developing ischemia and perforation unless the patient experiences reduction of the volvulus either spontaneously or due to therapeutic intervention. While any mobile segment of the colon can volvulize, the condition most commonly occurs in the sigmoid colon (~60% of cases) and the cecum (~40% of cases). For unknown reasons, the twisting of sigmoid volvulus most commonly occurs in counterclockwise fashion, while cecal volvulus tends to twist in a clockwise direction. Volvulus of the transverse colon, splenic flexure, or other segments of the colon is rare.

Risk factors for developing colon volvulus include having amenable anatomy (e.g., redundant colon with a relatively narrow mesentery), constipation or colonic dysmotility, prior abdominal surgery, and prior volvulus. While sigmoid volvulus is more common in patients who are male, > 70 years of age, African American, diabetic, and institutionalized or have neuropsychiatric comorbidities, patients with cecal volvulus are typically younger and more likely female [45]. Colonic volvulus is relatively uncommon in the United States where only about 10–15% of large bowel obstructions and about 3–5% of all bowel obstructions are due to volvulus [45, 46]. In areas like Africa, the Middle East, India, Brazil, and South America (the so-called volvulus belt), volvulus is more endemic and may account for as many as 40% of bowel obstructions. The geographic variability in the incidence of volvulus is thought to be multifactorial and due in part to differences in diet, altitude, cultural factors, and certain kinds of infections [45].

Patients with volvulus often present with abdominal distension, decreased bowel function or obstipation, nausea, and abdominal pain. They may develop a secondary small bowel obstruction due to decompression of the colon through an incompetent ileocecal valve and can also present with vomiting. In cases where volvulus progresses to colonic ischemia and perforation, patients present with an abdominal catastrophe and sepsis. While patients presenting with signs and symptoms consistent with volvulus may have a differential diagnosis that includes the spectrum of etiologies for large bowel obstruction, imaging typically confirms the diagnosis. In emergency cases and cases where the imaging is not clear enough to establish the diagnosis, volvulus is confirmed at the time of exploration.

Given the constellation of symptoms and signs that patients can present with, abdominal radiographs and/or CT scan imaging are usually obtained as part of standard evaluation. Plain radiographs or CT topograms can demonstrate

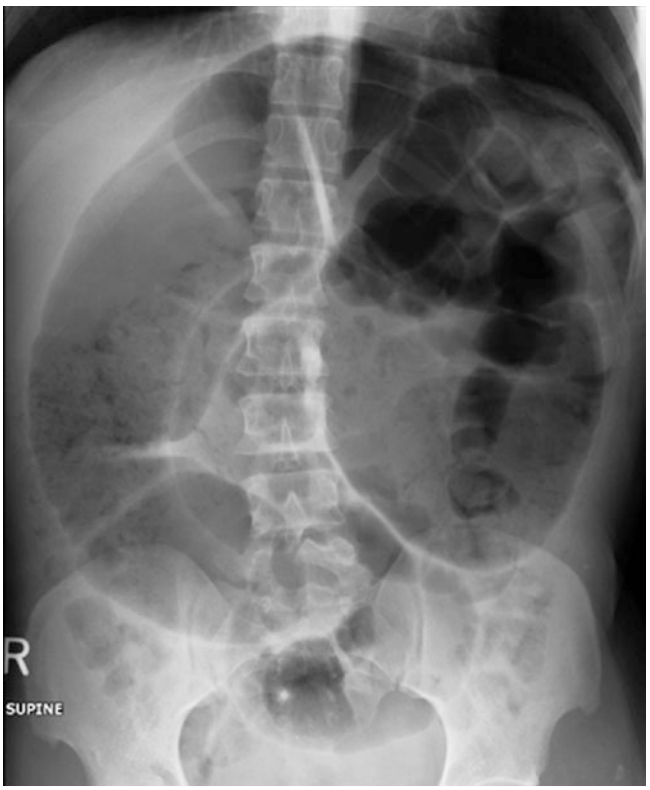

Fig. 39.5 Abdominal radiograph showing a typical sigmoid volvulus prior to decompression. (Courtesy of Daniel L. Feingold, MD)

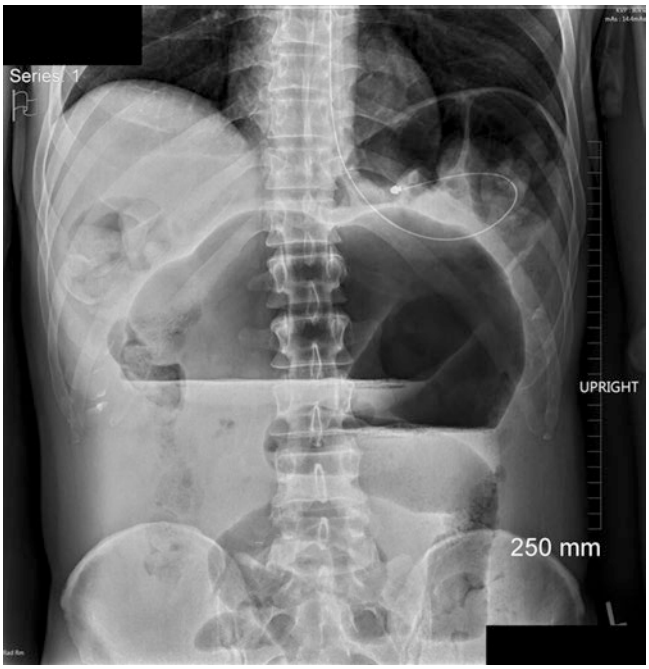

Fig. 39.6 Abdominal radiograph showing typical cecal volvulus. (Courtesy of Daniel L. Feingold, MD)

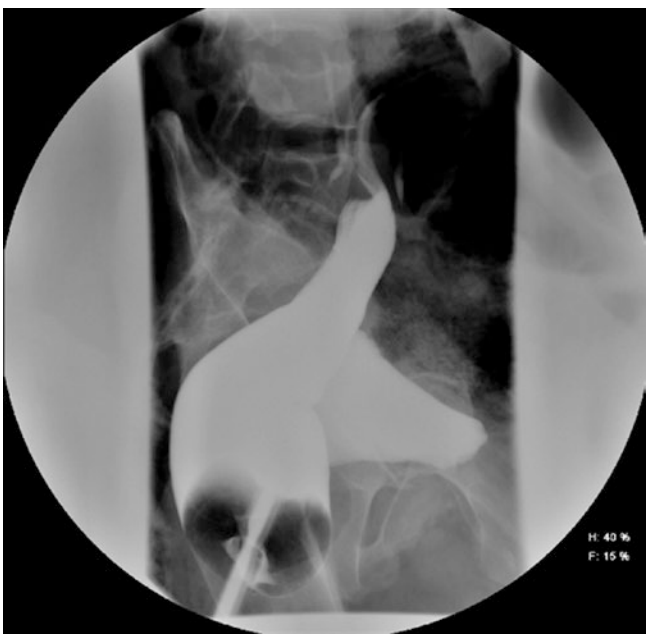

Fig. 39.7 Water-soluble contrast enema demonstrating a bird's beak sign from a sigmoid volvulus. (Courtesy of Daniel L. Feingold, MD)

classic findings consistent with volvulus such as a "coffee bean" or "bent inner tube" which describe the appearance of a massively dilated segment of volvulized colon (Figs. 39.5 and 39.6). The "northern exposure sign" describes the apex of the volvulized sigmoid loop cranial to the transverse colon. Water-soluble contrast enemas can reveal a "bird's beak" sign that reflects the tapering of the colon lumen due to the twisted distal limb of a sigmoid volvulus (Fig. 39.7). CT imaging may also reveal a "swirl" or "whirl" sign depicting the torsed mesenteric vessels due to the presence of a volvulus.

While historically plain radiographs and contrast enemas were used to investigate a possible volvulus, these modalities have effectively been supplanted by CT scanning with multiplanar reconstruction, which can diagnose volvulus with nearly 100% sensitivity and a specificity rate over 90% [47]. Importantly, CT imaging can also identify signs of complicated volvulus related to ischemia or perforation such as intravenous enhancement defects related to arterial occlusion, colon wall thickening related to venous occlusion, pneumatosis intestinalis, free peritoneal fluid, mesenteric or portal venous gas, and pneumoperitoneum. While CT scanning is the preferred modality to diagnose volvulus, depending on the degree of proximal bowel dilation, cross-sectional imaging can be challenging to interpret and may explain why some patients are not diagnosed until the time of exploration.

A cecal bascule is a rare entity distinct from volvulus in that there is no axial torsion across the mesenteric axis; in this situation, the caput of the cecum is displaced anteriorly and folds over the ascending colon closing off the cecum

[48]. In the setting of a competent ileocecal valve, this configuration can cause a closed loop obstruction. Cecal bascule may be demonstrated on cross-sectional imaging but is commonly diagnosed at the time of operative exploration. The evaluation and treatment for a patient with cecal bascule mirror those for cecal volvulus.

Another related anatomic variant that does not meet the criteria for volvulus, mobile cecum syndrome, is a poorly defined entity and postulated to be due to an embryologic abnormality whereby the lateral peritoneal attachments of the ascending colon are absent [49]. It is hypothesized that the resulting mobility of the cecum permits a degree of obstruction that can cause related symptoms. While the proposed treatment for this condition is laparoscopic cecopexy, it is not clear what the criteria are for intervening under these circumstances or what the outcomes are after cecopexy.

There is a paucity of high-quality or population-based evidence detailing the management of this condition. In practice, patients present or are referred in by primary care providers and gastroenterologists with episodic bloating, distension, and pain that resolve after an explosive, decompressive movement and with imaging demonstrating colon dilation but without evidence of volvulus. The concept of a "pre-volvulus" condition is not well described, and operative intervention under these circumstances, despite the insistence of patients or referring doctors, is not generally supported.

Sigmoid Volvulus

Nonoperative Methods for Devolvulizing a Sigmoid Volvulus

Patients with radiographic evidence of sigmoid volvulus without peritonitis, perforation, clinical instability, or sepsis are typically managed with an attempt at detorsion using endoscopy. Patients should be aware that procedures attempting to reduce a sigmoid volvulus risk failure as well as perforation. After obtaining appropriate consent, rigid proctoscopy can be performed at the bedside with the patient in the usual left decubitus position and without sedation. Proctoscopic detorsion is usually well tolerated. The rigid proctoscope is passed under direct visualization to the level of the torsion using air insufflation, as needed. The volvulized mucosa has a typical appearance one would expect from a twisting across the longitudinal axis of the colon which has been described as a pinwheel (Fig. 39.8). With continued insufflation and gentle manipulation of the colon lumen using the tip of the proctoscope, it is usually feasible to untwist the colon and intubate the more proximal sigmoid colon. Once the scope is advanced into what had been the volvulized segment of the colon, the window of the proctoscope is opened to vent the gas and liquid that had been trapped in the obstructed colon. The endoscopist should anticipate this maneuver to produce a dramatic decompression with efflux of the colon contents.

Fig. 39.8 Endoscopic appearance of the mucosa at the level of a sigmoid volvulus. Notice the classic pinwheel appearance of the mucosal folds

Upon successful intubation of the previously volvulized segment, the mucosa of the decompressed colon should be evaluated, and signs of ischemia should prompt a plan for colectomy. In the absence of concerning proctoscopic findings, a transrectal decompression tube should be placed not so much to allow for venting through the tube (this typically clogs with stool) but to stent the previously volvulized segment so that the volvulus does not recur immediately; this affords the patient the ability to continue to decompress and, depending on the individualized plan, to undergo a bowel preparation in anticipation of semi-elective colectomy in the following days. A semi-rigid chest tube passed through the proctoscope and sutured to the perianal skin can adequately function in this capacity. After an apparently successful detorsion, it may be helpful to obtain abdominal radiographs to document the location of the rectal tube and the degree of decompression, as well as to confirm the absence of free air (Fig. 39.9).

As an alternative to rigid proctoscopy or in uncommon cases where the level of the sigmoid volvulus is more proximal than the reach of a proctoscope, flexible sigmoidoscopy can be performed. This procedure may be performed with a water immersion technique or using gas insufflation, as needed, and the rectal tube that is passed is usually thinner and more flexible than rectal tubes that are passed through a proctoscope [50]. In some situations, fluoroscopic guidance

Fig. 39.9 Abdominal radiograph demonstrating the patient in Fig. 39.5 after successful proctoscopic detorsion and rectal tube insertion. (Courtesy of Daniel L. Feingold, MD)

can aid in successfully advancing the flexible scope under these circumstances. Nonoperative detorsion is relatively straightforward and is successful in 60–95% of cases and carries a low morbidity rate [51, 52]. Nonetheless, there is an estimated 3% mortality rate associated with detorsing a sigmoid volvulus which is considered to be a reflection of the patient population typical for volvulus rather than the actual procedure for reducing the volvulus [47].

After successful nonoperative detorsion, patients are observed as they decompress. In general, sigmoid colectomy should be considered after resolution of the acute phase of sigmoid volvulus, specifically in order to prevent recurrent volvulus [52]. The risk of recurrence after a first admission for sigmoid volvulus is estimated at 45–70% or even higher, depending on the length of follow-up, with a majority recurring within the first few months after successful nonoperative decompression [47, 51, 53, 54]. A common teaching and practice is to proceed with semi-elective resection during the same hospitalization, though patients may prefer to return on a more elective timeline, ideally soon after the index hospitalization [52]. Given that the sigmoid volvulus patient population is typically elderly with comorbidities, the decision to proceed with elective, interval sigmoidectomy under these circumstances should be individualized. In addition, it is important to consider the need for colonoscopy, or possibly CT colonography, prior to proceeding with colectomy in the non-emergent setting [55].

Surgery for Sigmoid Volvulus

Patients with evidence of perforation or concern for ischemia should be treated with broad-spectrum antibiotics and intravenous fluid resuscitation as the operating room is being mobilized and typically undergo exploratory laparotomy. Colon ischemia and peritonitis are the main risk factors for mortality related to volvulus; the mortality of volvulus presenting as an emergency may be as high as 33% or even higher [45, 47]. As with elective or semi-elective surgery for sigmoid volvulus, a laparoscopic approach may be utilized depending on the specific patient circumstances and the available expertise. However, even after endoscopic detorsion and decompression, the redundant sigmoid colon typically remains dilated to some degree and has a much larger diameter than a typical otherwise normal sigmoid colon. This anatomy can be difficult to negotiate within the domain of a laparoscopy, and the nature of the redundant colon is such that it usually prolapses out readily, if not spontaneously, through a relatively short midline laparotomy (Fig. 39.10). In addition, the splenic flexure does not typi-

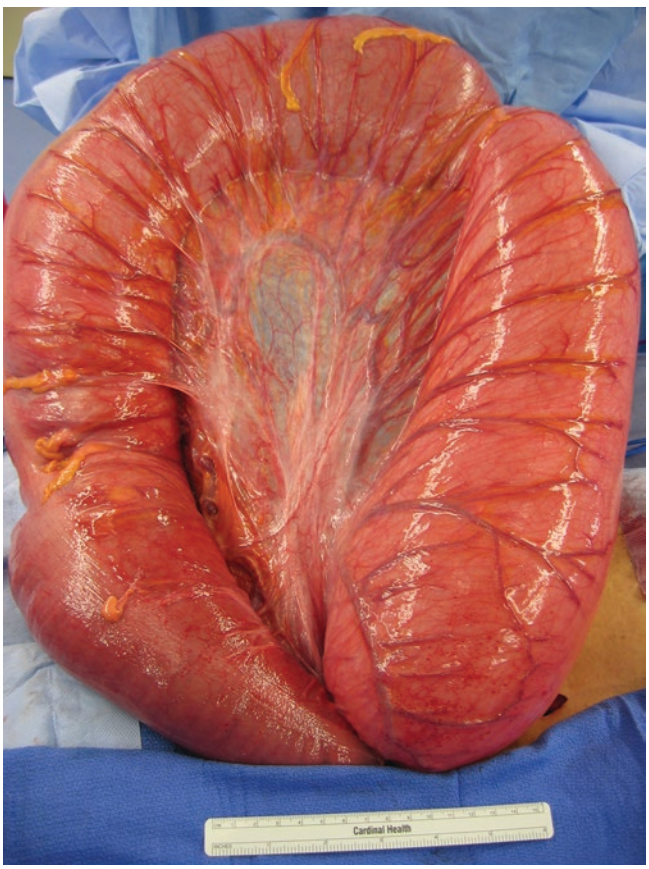

Fig. 39.10 Typical appearance of a sigmoid volvulus prolapsing through a laparotomy incision. (Courtesy of Daniel L. Feingold, MD)

cally need to be released for this operation, obviating the need for operative access to the left upper quadrant. Commonly there is fibrosis observed along the peritoneum overlying the mesocolon which is not thought to be a causative factor in volvulus, but rather a result of prior episodes. While it is relatively common to observe redundancy in other segments of the colon upon exploration, elongation in and of itself is not generally considered an indication for extended resection under these circumstances.

The most common operation performed for sigmoid volvulus is colectomy with the goal of resecting the redundant sigmoid colon in order to minimize the risk for recurrent volvulus [45, 46, 54]. In cases of cecal perforation complicating sigmoid volvulus, a subtotal colectomy is typically performed in order to address the different sites of pathology. Another indication for extended resection is when the colon proximal to the volvulized loop is ischemic due to the colonic obstruction; in these cases, the distribution of the ischemia is often patchy and diffuse, again requiring subtotal colectomy. In patients with sigmoid volvulus and concomitant megacolon, subtotal colectomy can effectively prevent recurrent volvulus at an otherwise retained segment of the colon [52].

The general recommendation for dealing with patients with a gangrenous, volvulized segment of the colon is to resect the loop without reducing the twist in order to try to prevent a load of potassium, bacteria, and endotoxin from entering the circulation and to minimize manipulation of the colon which can lead to perforation of the diseased segment. In practice, the anatomy of a volvulized segment folds the mesentery over itself, making it difficult to control coming across the mesentery without untwisting the colon, though modern-day energy devices are usually capable of coming across this thickness of tissue. While an oncologic operation with a nodal catch is not required under these circumstances, it is usually technically helpful to ligate the main mesenteric pedicle rather than repeatedly come through the mesentery closer to the colon wall. Meanwhile, an unwieldly sigmoid loop can impede dissecting the base of the mesentery and identifying the left ureter. The surgeon should be aware of these options, and it may be preferable to avoid dissecting near the retroperitoneum and use a mid-mesenteric plane of dissection. As with operations for other causes of large bowel obstruction, it may be helpful to decompress the colon in a controlled fashion to facilitate mobilization.

Once the diseased colon has been resected, a decision can be made regarding whether or not to restore bowel continuity. In emergency volvulus operations, the decision is based on individualized risk assessment and the clinical status of the patient. Ideally, patients will have been sited and marked for stoma location preoperatively. In semi-elective or elective operations for previously detorsed sigmoid volvulus, patients will commonly have an anastomosis created. It is common to have a wide diameter end of the colon coming down to the anastomosis which can be suboptimal when seating the anvil of an end-to-end mechanical stapler. In this situation, it may be particularly helpful to close the end of the colon with a linear stapler and perform a side-to-end Baker-type anastomosis.

Non-resectional operations that are alternatives to sigmoidectomy include simple operative detorsion alone, mesosigmoidoplasty, and sigmoidopexy [52]. These approaches spare the risk of morbidity related to stoma creation or creating an anastomosis but are associated with much higher rates of recurrent volvulus [45–47].

Another potential alternative option for treating patients with sigmoid volvulus is percutaneous endoscopic colostomy (PEC) or sigmoidopexy to restrict the mobility of the colon and reduce the risk of recurrent volvulus [56]. Patients considered to have a prohibitive operative risk or who otherwise decline to undergo abdominal surgery may be candidates for endoscopic fixation of the sigmoid colon to the anterior abdominal wall which is usually done under conscious sedation. This procedure can also be combined with laparoscopy to ensure proper alignment of the colon prior to fixation, to guide where along the length of the colon fixation is performed, and to decrease the risk of injury to nearby structures related to the endoscopic procedure [57]. While the approach is relatively straightforward and may even be performed at the time of endoscopic detorsion, there is no universally accepted PEC technique, and questions remain regarding how many points of fixation are used (typically one versus two) and when to remove the devices from the abdominal wall, as early removal has been associated with recurrent volvulus. Furthermore, although this approach is considered minimally invasive, minor and even major complications have been reported, ranging from infection or bleeding at the PEC site to peritonitis from PEC migration or dislodgement due to recurrent volvulus. Given that patients treated with PEC typically have significant comorbidities that preclude abdominal surgery, even minor complications related to an endoscopic procedure can have severe consequences. In reports of PEC that provide follow-up data, this particularly vulnerable patient population has a significantly high mortality rate after PEC from unrelated causes.

Cecal Volvulus

In contrast to sigmoid volvulus, the success of nonoperative detorsion of a cecal volvulus is low, and the general consensus is not to delay operation and risk ensuing ischemia, necrosis, and perforation. Patients diagnosed with cecal volvulus are considered to have a surgical emergency even in the absence of overt sepsis and are typically given broad-spectrum antibiotics and intravenous fluid resuscitation as the operating room is mobilized. As with cases of sigmoid

volvulus, the surgical approach, open versus laparoscopic, depends on the specific clinical circumstances and the available expertise; but the typical size of a cecal volvulus specimen is such that a meaningful extraction incision is usually unavoidable. In addition, as with a sigmoid volvulus, it can be difficult to laparoscopically negotiate the dilated, displaced, and elongated colon.

The most common operation performed to treat and prevent recurrent cecal volvulus is ileocolectomy with anastomosis [54]. In cases where creating an ileocolic anastomosis is considered too high risk, an end ileostomy with or without mucous fistula is performed. In certain circumstances, unstable patients may be resected, left in discontinuity, and brought back for a "second look" with possible anastomosis at that time. As with sigmoid volvulus, there are a number of non-resectional alternatives like simple detorsion alone, cecopexy, or cecostomy that may be considered in cases of cecal volvulus, but these approaches carry risks of morbidity including recurrent volvulus. While there is a role for individualizing the operative treatment in cases of volvulus, consideration of the risks and benefits will most commonly favor resection-based therapy [52, 55].

Ileosigmoid Knotting

While rare in the United States, this entity is more common in areas where volvulus is endemic, such as countries in the volvulus belt. Multiple configurations of knotting have been described, but all involve the ileum and sigmoid colon wrapping around each other in some fashion causing obstruction and frequently progressing to ischemia in one or both segments. This "double-loop" obstruction is associated with a poor prognosis, and patients present commonly with an abdominal catastrophe; the mortality in these cases can be as high as 73% [47, 58]. The diagnosis of ileosigmoid knotting can be made by cross-sectional imaging but is often made at the time of surgical exploration. The combination of imaging demonstrating sigmoid volvulus with a secondary small bowel obstruction and inability to reduce the sigmoid volvulus endoscopically may raise the suspicion of ileosigmoid knotting. Operative treatment depends on the specific anatomic variant encountered and often involves a double resection of the involved anatomy with or without restoration of bowel continuity depending on the anatomy and the circumstances.

Acute Colonic Pseudo-obstruction

Acute colonic pseudo-obstruction (ACPO) is generally considered to result from an imbalance or derangement of parasympathetic inhibition and/or sympathetic stimulation that impairs colonic motility leading to colon dilation in the absence of a mechanical source of obstruction. The prevailing hypothesis is that overall decreased parasympathetic tone in the area of the splenic flexure colon results in a relatively atonic segment that functions like an obstruction [59]. This condition may be referred to by a variety of terms including Ogilvie's syndrome, colonic ileus, acute megacolon, etc. The exact pathophysiologic mechanism underlying ACPO remains unclear, but the autonomic dysregulation involved is likely multifactorial and occurs most often in the setting of predisposing factors [59]. ACPO is rarely a primary diagnosis and is most commonly diagnosed in the setting of patients with some other active illness or state [60]. The dysregulation of the autonomic impulses in the enteric nervous system of the colon is likely part of a syndrome manifesting a more global process as described below [61].

While the exact incidence is unknown, ACPO is considered to be rare and is estimated to occur in 100 of every 100,000 admissions annually in the United States [62, 63]. Patients typically are elderly with medical comorbidities who have been hospitalized for an acute illness, nonoperative trauma, or metabolic disarray or are recovering from a recent surgery (including caesarean section). Many patients predisposed to developing ACPO are also maintained on medications that can affect colonic motility (e.g., opioids, calcium channel blockers, psychotropics, etc.), and these medications may be manipulated to facilitate treatment.

Patients who develop ACPO are typically already hospitalized, have severe or even massive colon dilation, and have symptoms and signs that may include abdominal distension, tympany, nausea, abdominal pain, decreased or absent bowel activity, or diarrhea. The degree of abdominal distension can cause respiratory symptoms by displacing the diaphragm. Right lower quadrant tenderness, signs of sepsis, or diffuse abdominal pain may signify ischemia with impending perforation.

While there is no universally accepted definition or criteria for diagnosing ACPO, patients in the appropriate clinical circumstances with imaging demonstrating a cecal diameter $\geq$ about 9 cm or other colonic segments $\geq$ about 6 cm may be classified as having ACPO. Radiologic imaging by way of abdominal radiographs or cross-sectional imaging typically demonstrates dilated, gas-filled colon with cecal dilation and with a transition to more normal colon in the area of the splenic flexure (Fig. 39.11). Interestingly, in this area of the colon (about where the midgut transitions to the hindgut), there is a transition in colonic innervation, supporting the concept of autonomic dysregulation as part of the underlying etiology of ACPO. When considering the diagnosis of ACPO, it is important to confirm there is no mechanical point of obstruction causing a large bowel obstruction (whether intrinsic or extrinsic to the colon) as these patients are treated according to a different algorithm. While it is usually possible to exclude a mechanical obstruction by reviewing CT scan imaging, in certain cases, it may be helpful to verify the anatomy by obtaining a water-soluble

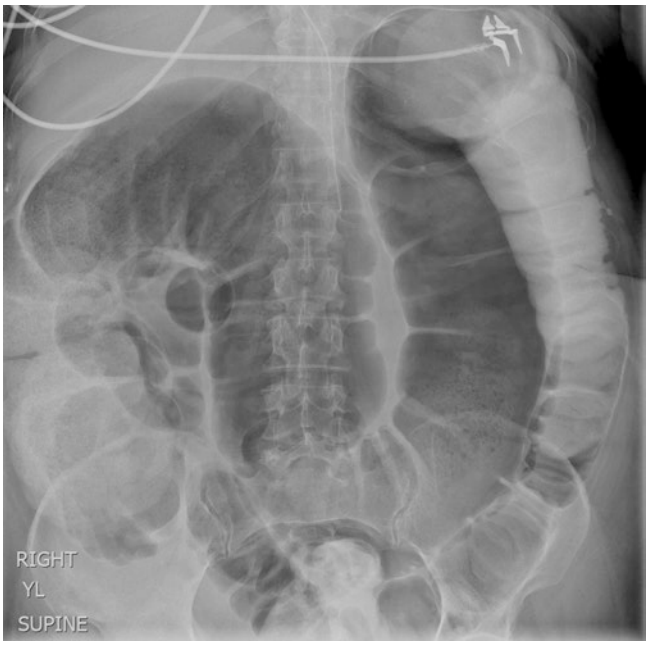

Fig. 39.11 A serial abdominal radiograph of a patient being treated for acute colonic pseudo-obstruction. Notice the dilated right and transverse colon and the relatively decompressed descending colon. Oral contrast has passed through the pseudo-obstructed colon. (Courtesy of Daniel L. Feingold, MD)

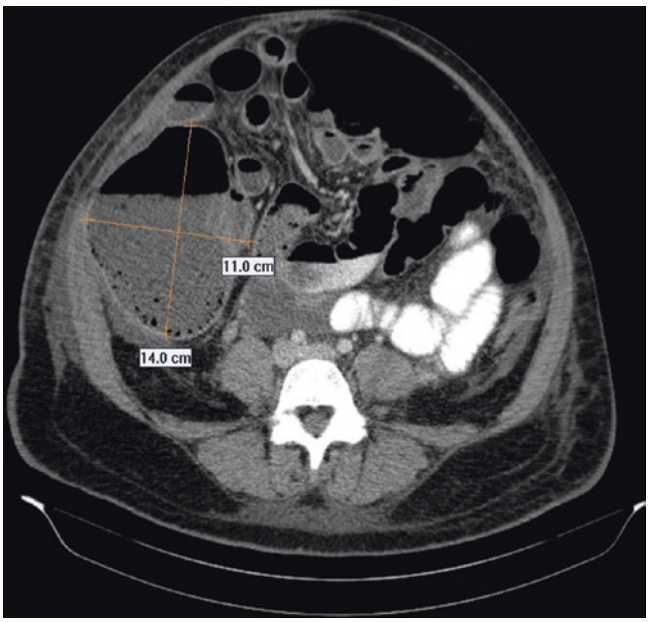

Fig. 39.12 Axial CT scan image measuring the cecal dimensions in the setting of acute colonic pseudo-obstruction. (Courtesy of Daniel L. Feingold, MD)

contrast enema study. Patients presenting with signs and symptoms consistent with ACPO carry a differential diagnosis similar to other etiologies of large bowel obstruction (Table 39.1). Toxic megacolon from an infectious source or from inflammatory bowel disease should also be considered in appropriate circumstances, as this can mimic the presentation and imaging seen in cases of ACPO. Cross-sectional imaging, as with cases of volvulus, can also reveal signs of colon ischemia that would prompt proceeding with surgery.

Medical Therapy

Patients who develop ACPO can progress to critical colonic distension, which increases the transmural pressure, resulting in ischemia from inadequate perfusion and, ultimately, perforation with peritonitis and even death. As with other etiologies of colon obstruction, the most common site of perforation is the cecum due to its increased diameter as compared to the rest of the colon as predicted by the law of Laplace [63]. The likelihood of experiencing these sequelae increases as the cecal diameter distends beyond about 10 cm and as the duration of distension approaches or exceeds about 6 days (Fig. 39.12) [51]. Although larger-diameter cecal dilation is associated with higher risk of perforation, the duration of distension and the acuity of how quickly the colon distends are important factors and contribute to perforation even in cases with less extreme degrees of dilation [64, 65]. The mortality rate associated with ACPO is higher in cases of perforation, ranges from about 10% to as high as 30–40%, and reflects the potential seriousness of the clinical entity as well as the population of patients prone to develop this unique form of large bowel obstruction [59, 60]. Early recognition and appropriate therapy to decompress the colon under the circumstances are important and clearly influence outcomes.

Patients with ACPO with complicating factors like ischemia, perforation, or signs of sepsis require urgent operation as discussed below. Otherwise, the initial management of a patient diagnosed with ACPO includes instituting bowel rest, eliminating or reducing potentially confounding or causative factors (e.g., narcotics and other medications that may influence colonic motility), encouraging ambulation and patient positioning to potentially facilitate colonic activity, correcting metabolic derangements, and decompressing the system with nasogastric and/or rectal tubes. In general, oral laxatives are contraindicated under these circumstances as these can increase intraluminal pressure [65]. This kind of supportive therapy is successful in resolving ACPO in 77–96% of patients [51]. Serial evaluations with physical examination, blood work, and imaging are important in order to determine the response to therapy and whether or not a patient requires escalation in treatment. The management of patients with ACPO usually requires coordinated, multidisciplinary care from medicine, gastroenterology, and surgery services. Patients who clinically worsen or fail to improve within about 48–72 hours of instituting medical therapy or who have cecal diameter of about 12 cm usually proceed with pharmacotherapy.

Pharmacotherapy

Neostigmine is the agent of choice for managing ACPO under these circumstances although it is *not FDA approved* for this indication. Neostigmine methylsulfate is a short-acting, competitive acetylcholinesterase inhibitor that reduces the breakdown of acetylcholine, effectively increasing the concentration of acetylcholine in the synaptic cleft (i.e., it is a parasympathomimetic agent). The efficacy of neostigmine supports, to some degree, the proposed pathogenesis of ACPO reviewed above. Placebo-controlled, double-blinded, randomized trials demonstrate that intravenous neostigmine (typically 2 mg over 3–5 minutes) is effective in 85–94% of cases and are the basis for the off-label use of this drug in patients with ACPO [66]. Neostigmine usually results in clinical decompression within about 10–30 minutes and has a half-life of about 60 minutes. Redosing neostigmine in patients who did not respond adequately to a first dose is successful in 40–100% of cases [67]. Risk factors associated with failure of neostigmine include male gender, younger age, postoperative status, and electrolyte imbalances [62]. After successful decompression, daily polyethylene glycol has been demonstrated to decrease the risk of recurrent ACPO [67].

Given the potential side effects of bradycardia and respiratory distress, neostigmine should be administered in a continuously monitored setting with access to the variety of supportive medications (e.g., atropine) and devices in the event cardiac or respiratory support or resuscitation is needed. Administering glycopyrrolate may prevent side effects like bronchospasm and hypersalivation. Neostigmine is contraindicated in patients with intestinal or urinary tract obstruction or known hypersensitivity and should be used with caution in patients with bradycardia, asthma, renal insufficiency, peptic ulcer disease, or recent myocardial infarction.

It is generally believed that rates of endoscopic and operative interventions for the treatment of patients with ACPO have decreased in recent decades because of the wider recognition of the syndrome as well as the efficacy of medical therapy and of appropriate pharmacotherapy [62]. While neostigmine has traditionally been administered via intravenous bolus delivery, subcutaneous and continuous infusion protocols are also effective and may be associated with fewer side effects. Other agents may be tried in cases of refractory ACPO including oral pyridostigmine, a long-acting acetylcholinesterase inhibitor; methylnaltrexone, a peripherally acting μ-opioid receptor antagonist; and prokinetics like metoclopramide and erythromycin.

Colonic Decompression

Patients who do not respond adequately to supportive measures and fail neostigmine therapy may be treated by colonoscopic decompression with a success rate as high as 95% [61]. While colonoscopy in this setting carries the usual risks of the procedure including perforation, typical patients hospitalized with ACPO have comorbidities and have not had a bowel preparation; they may be at higher than usual risk when undergoing colonoscopy in this setting. As with other etiologies for bowel obstruction, these patients require careful attention to protect their airway while undergoing a procedure under sedation. While there is some evidence supporting endoscopic decompression as superior to pharmacotherapy, given the low cost, overall safety, and efficacy of neostigmine and the cost and risks related to endoscopic decompression, colonoscopy is generally reserved as a second-line treatment [68].

In cases of ACPO, colonoscopy is generally performed using water immersion or minimal CO_2 insufflation rather than ambient air with the goal of evacuating as much colonic gas as possible. The sedation for these cases usually relies on benzodiazepines and other non-narcotics, as narcotics can interfere with colonic motility. The goal of insertion, in general, is to reach the ascending colon rather than the cecum, upon which a long intestinal tube can be deployed to effectively stent the colon allowing for continued postprocedure decompression. Repeated colonoscopy may be required in as many as 40% of patients, especially if a long decompression tube is not utilized. Often symptoms of ACPO resolve within about 48 hours after successful colonoscopic decompression [60]. Case reports detail treating patients with endoscopic or CT-guided percutaneous cecostomy to vent and decompress patients with ACPO, but the utility of these approaches is not well documented [65].

Surgical Therapy

While patients with perforation or concern for ischemia require exploration, patients who do not resolve their ACPO should be considered for exploration in order to decompress the colon prior to developing an emergency indication for operation. The timing and circumstances of proceeding with surgery under these circumstances are variable and should be individualized especially in light of the mortality rate associated with surgery in the setting of ACPO, which is variably reported as about 30% and as high as 60% [65]. In a retrospective review of the National Inpatient Sample, ACPO patients treated with medical therapy, colonoscopic decompression, or surgery experienced higher mortality rates with each escalation in therapy documented as 7.3%, 9.0%, and 12.3%, respectively [62]. In practice, patients without a firm indication for operation may undergo continued medical therapy with repeated attempts of pharmacotherapy and/or endoscopic decompression before ultimately moving to a surgical intervention.

In terms of operative options in the setting of medically refractory ACPO, patients with viable colon without perforation most commonly undergo exploration to confirm there is

no compromised colon and are then decompressed and vented through a colostomy. The role of colectomy under these circumstances is questionable. Meanwhile, patients with ischemic colon and/or perforation require resection of the diseased segment and are commonly left with an end stoma. The extent of the resection under these circumstances depends on the operative findings and clinical course.

Rare Causes of LBO

Intussusception

Intussusception accounts for only 1–3% of mechanical bowel obstructions in the adult population; a demonstrable lesion can be found in 80% of cases [11]. The classic triad of symptoms seen in pediatric intussusceptions (abdominal pain, vomiting, and red currant stools) is rare in adults who tend to present in a non-specific manner [69]. While the most common cause of large bowel intussusception is malignancy (65–87% of cases), benign processes can be implicated and include adenomatous polyps, GISTs, diverticular disease, and villous adenoma of the appendix [11, 70]. CT scan, the most accurate modality to diagnose an intussusception, has a reporting accuracy of 58–100% and can show a characteristic target or sausage-shaped lesion [71]. While colonoscopy can be a useful adjunct to identify a benign lead point such as an adenomatous polyp, concern has been raised that endoscopic reduction of an intussusception could theoretically result in the dissemination of malignant cells if a cancer is present [72]. Given the high incidence of malignancy as the lead point, there should be a low threshold for surgical exploration and an oncological resection of the affected segment.

Hernia

Abdominal wall hernias are a very rare cause of LBO due to the colon's larger caliber and relatively fixed nature. Femoral, inguinal, umbilical, incisional, Spigelian, lumbar, and diaphragmatic hernias can contain large bowel and cause LBO [11]. The management in these cases should follow principles of bowel rest and fluid resuscitation and typically requires surgical exploration.

Infection

While a rare cause of LBO, infectious causes such as actinomycosis can occur where the infection leads to a desmoplastic reaction with multiple abscesses causing extrinsic compression of the colon and LBO. Treatment in these cases can include defunctioning ostomy, directed antimicrobial therapy, and/or surgical resection [3]. LBO can occasionally be seen with abdominal *Mycobacterium tuberculosis* which is typically treated with antibiotic therapy [73]. LBO can also occur secondary to worms arising from schistosomiasis or helminthic infections.

Endometriosis

While endometriosis is a relatively common condition (affecting 8–15% of women), it accounts for less than 1% of cases of bowel obstruction [74]. Intestinal endometriosis can cause luminal stenosis secondary to serosal infiltration, with the rectosigmoid being the most common site of intestinal endometriosis. Most of the literature pertaining to LBO secondary to endometriosis is comprised of case reports that utilize fecal diversion; stent placement and resection have been reported [3, 75].

Other Malignancies

While colorectal cancer accounts for 50–60% of cases of LBO, other malignancies including ovarian, gastric, pancreatic, and bladder can be responsible. With these pathologies, LBO occurs due to intraluminal obstruction, intramural blockage, or extrinsic compression. Management options should be based on clinical presentation and disease extent. A defunctioning ostomy can help relieve the obstruction and may allow for appropriate staging and cancer therapy. Lymphoma accounts for less than 0.5% of colorectal malignancies but can cause LBO. Perforations of large bowel lymphomas are treated by resection with or without anastomosis. Colonic obstruction secondary to lymphoma may be treated with resection, defunctioning ostomy, stenting, or possibly chemoradiation [76].

Lower GI Hemorrhage

40

Mehraneh D. Jafari and Joshua I. S. Bleier

Key Concepts

- LGIB comprises 30–40% of all GI bleeds and is the most common cause of hospitalization due to GI disease in the United States.
- The incidence of LGIB is increasing, especially in octogenarians.
- The most common cause of LGIB is diverticular disease followed by anorectal disease and ischemia.
- A focused H&P (history and physical examination) is most effective in determining the cause of bleeding, and initial resuscitation should be focused on restoring hemodynamic stability with volume and/or blood.
- Characteristics of timing, type of bleeding, volume, and anoscopy can help to rapidly identify appropriate treatment based on potential source and rate of bleeding.
- Appropriate risk stratification can help better predict morbidity and mortality as well as guide appropriate management schemes.
- Upper and lower endoscopy is the preferred initial mode of diagnosis for LGIB. This method best allows for not only potential source identification but offers the potential for therapeutic intervention.
- Radiologic studies can be effective early diagnostic modalities in identifying the source of bleeding. CT angiography has a high sensitivity and specificity and is widely available. Catheter-based angiography can both diagnose and potentially treat bleeding sources if bleeding is brisk enough via transcatheter embolization.
- Nuclear scintigraphy, either via ^{99m}Tc-sulfur colloid or ^{99m}Tc-labeled RBC, can be used to identify bleeding sources that are intermittent or too slow to be identified by CTA or direct angiography.
- Recurrent LGIB is a common problem, and repeated evaluation has additive success rates.
- All attempts at localization should be made in the stable patient prior to consideration of surgical intervention.
- Obscure GI bleeding is defined as bleeding from a source that has not been identified after appropriate endoscopic and radiologic evaluation.
- Most sources of obscure GI bleeding tend to come from the small bowel, and capsule endoscopy is indicated to try and diagnose.
- Double balloon enteroscopy is an advanced modality which may be employed to diagnose and treat bleeding sources in the proximal small bowel.
- Surgery is indicated in patients in whom conservative measures have failed and/or bleeding is causing hemodynamic instability or who have reached significant transfusion thresholds.
- For refractory LGIB that are colonic in origin, but remain unlocalized, a total colectomy with ileostomy should be performed.
- For bleeding from an ongoing or refractory source that is localized, a segmental colectomy may be performed.
- Combining clinical pathways incorporating risk stratification may be helpful in providing a more systematic approach to management of LGIB and improving patient outcomes.

Introduction

Lower gastrointestinal bleeding (LGIB) is defined as a bleeding from a source distal to the ligament of Treitz. Severity and quantification are often difficult to assess, and patient history can vary. In addition to prompt resuscitation, risk stratification should be considered at initial presentation to guide the clinician in appropriate management. The large anatomical range of the "lower GI" distribution can pose as a challenge for clinicians, as it is difficult at times to pinpoint the source of the bleeding, and this is critical for optimal management. The recommended initial localization methods are generally endoscopy and CT angiography. Ultimately, endoscopy and catheter-based angiography can localize and control the bleeding for the majority of patients. In instances of failure, these modalities can help inform appropriate surgical intervention.

Epidemiology

Good-quality epidemiologic studies of lower gastrointestinal bleeding (LGIB) are lacking. LGIB comprises 30–40% of all gastrointestinal bleeds with an estimated incidence of 33–87/100,000 [1, 2]. Gastrointestinal bleeding is the most common cause of hospitalization related to gastrointestinal disease in the United States [3]. The number of LGIB reported is likely underestimated as minor episodes may never present to a hospital or emergency department [4]. Acute LGIB, defined as sudden onset of hematochezia, accounts for 20% of all gastrointestinal bleeding leading to diagnostic evaluation and hospitalization. This consumes a significant amount of medical resources [5, 6]. In the United States, GI hemorrhage leads to 800,000 annual admissions at a cost of $5 billion [3]. Acute colonic bleeding (defined as that occurring from the colon, rectum, and/or anus) has an annual incidence of 36/100,000 [7]. The overall mortality from LGIB is reported as ranging from 1.3 to 3.9% [3, 7, 8]. Importantly, approximately 15% of patients with symptoms of LGIB actually have an upper GI source [9]; early recognition is critical. Fortunately, mortality from uncontrolled LGIB is rare, and most incidence of mortality is related to patient comorbidities [10].

The incidence of LGIB is increasing [3]. There was a 22% increase in the number of LGIB between 2000 and 2009, most likely as a consequence of an aging population and increasing usage of anticoagulants [11]. A recent national audit of the United Kingdom found that the majority of patients are elderly with a median age of 74 and multiple comorbidities [10]. The consensus of the European and American studies is that the incidence of upper GI bleed is decreasing, while the incidence of LGIB is increasing [1–3]. The elderly are at an increased risk of both frequency and mortality from LGIB [1, 3, 5]. In fact, the incidence of LGIB is increased more than 200-fold in patients >80 years old compared to those of 20 years old [12]. This increase can be attributed to a higher incidence of diverticulosis and angiodysplasia with age.

In an era of increasing usage of anticoagulation, this increase in the incidence of bleeding in the elderly with multiple comorbidities is of great concern. In fact, in a large French study, 75% of patients were found to have a predisposing medication contributing to LGIB [13]. Despite this, there has been a decline in morbidity and mortality over the years most likely due to improved access and experience with minimally invasive interventions and improved critical care practices [11].

Etiology

The cause of LGIB can be divided into vascular, anatomical, inflammatory, neoplastic, and small bowel causes (Table 40.1). The most common cause of LGIB is diverticulosis, followed by anorectal disease and ischemia. Less common causes of LGIB include angioectasias, inflammatory bowel disease, and neoplastic processes. Rare causes of LGIB are post-polypectomy bleeding, radiation proctitis, NSAID-induced ulcerations, and Dieulafoy's lesions (Table 40.1) [14–16].

Table 40.1 Etiology of LGIB with associated incidence [14–16]

Etiology	Incidence
Anatomic	
Diverticulosis	30–65%
Anorectal	5–20%
Vascular	
Ischemic colitis	5–20%
Angioectasias	5–10%
Inflammatory	
Inflammatory bowel disease	3–5%
Infectious colitis	2–5%
Neoplastic	3–11%
Others	
Post-polypectomy	2–7%
Radiation proctitis	0–2%
NSAID-induced ulceration	0–2%
Dieulafoy's lesion	0–2%
Small bowel	3–13%
Meckel's diverticulum	
Inflammatory bowel disease	
Angioectasias	
Neoplasms	
NSAID-induced ulcers	
Dieulafoy's lesion	

Diverticulosis is the most common cause of LGIB, accounting for 30–65% of cases, and constitutes the most likely etiology for severe acute hemorrhage [10, 17–21]. Diverticula develop at weak points in the colonic wall caused by penetration of the vasa recta, creating a thin-walled sac where the mucosa is closely apposed to the vessel. It is thus not surprising that this represents a point of vulnerability for vascular erosion. Sigmoid and descending colon diverticulosis is prevalent in 50% of the population with a cumulative incidence of bleeding of 2% at 5 years and 10% at 10 years [22]. The second most common cause of LGIB is anorectal disease (5–20%) [8, 16, 18, 21], of which the most common sources are hemorrhoids and anal fissures [21].

Presentation

Lower GI bleed can have a variety of presentations due to the diversity of its causes. Bleeding may present acutely or in a more chronic manner. LGIB that is acute presents as sudden onset of hematochezia and/or melena and may be associated with hemodynamic instability. Chronic LGIB is associated with longer duration with slow loss of blood resulting in iron deficiency anemia and/or positive fecal occult blood testing. Approximately 15% of patients with hematochezia are ultimately found to have an upper GI bleed. Slower upper GI bleeding sources result in dark, tarry stools, or melena, due to oxidation of heme as it traverses the lower GI tract; thus with a presentation of melena, an upper GI source must be investigated first. However, brisk upper GI bleeds may transit the GI tract much more quickly, too fast to be converted into melena. Therefore, hematochezia associated with hemodynamic instability can be indicative of an upper GI source and typically warrants evaluation with nasogastric lavage and/or endoscopic evaluation [6, 9, 23, 24].

Evaluation

A focused history and physical examination should be performed on any patient who presents acutely in combination with laboratory studies. Assessment of hemodynamic stability is of paramount importance at the time of presentation for both acute and chronic LGIB. Initial presentation can identify patients at higher risk of adverse events and severe bleeding and allow the clinician to triage appropriately [6].

The goal of the history and physical exam is to elicit the source of bleeding. Therefore, history should be focused on color, amount, frequency, and duration of bleeding. Associated abdominal symptoms such as constipation, obstipation, change in bowel habits, or weight loss should be solicited. It is important to have a high suspicion for colorectal malignancy in patients with unintentional weight loss and change in bowel habits. Associated symptoms such as diarrhea and abdominal pain can point to an ischemic, inflammatory, or infectious etiology. Patients should also be asked specifically about upper GI symptoms, vascular surgery, recent endoscopic procedures, history of radiation, and/or inflammatory bowel disease. Family history is especially important to rule out patients at high risk for malignancy. History of liver disease, alcohol consumption, and bleeding disorders (both personal and familial) should be included.

Medication history especially the use of anticoagulants that increase bleeding risk such as nonsteroidal anti-inflammatory drugs (NSAIDs) and antiplatelet therapy should be obtained. Upper GI sources of bleed should be highly suspected in patients with history of portal hypertension and those on anticoagulants [6, 9, 23, 24]. It is important to note the patient's coexisting cardiopulmonary, renal, and hepatic conditions, as these comorbid conditions can uniquely increase the risk of morbidity and mortality and affect management [6, 16, 25].

Initial assessment guides utilization of the potential diagnostic and therapeutic modalities. The initial assessment of a LGIB patient should include vital signs (including postural changes), abdominal exam, and a digital rectal exam. Nasogastric lavage can quickly rule out a gastric source. Anoscopy or anorectal exam is mandatory to rule out a hemorrhoidal source which occurs in <20% of cases [16]. If anoscopy does not reveal obvious stigmata of recent bleeding, further evaluation is needed. Also, it should be mentioned that hemorrhoidal bleeding causing hemodynamic instability is rare, and other sources need to be ruled out in the unstable patient.

Risk Stratification

It is important to risk stratify LGIB patients to improve morbidity and mortality [26]. The shock index (SI), which is determined by dividing the heart rate by systolic blood pressure, can be used to stratify stability. SI >1 is classified as unstable and is predictive of active bleeding. An increasing SI has been associated with mortality and can predict patients with active extraversion on imaging [27, 28]. Once a patient's stability is determined, other risk stratification scores can be used to determine the outcomes of the patient and potential outpatient management of the stable patient.

Risk stratification models for LGIB using predictors are not as well developed as those for upper GI bleeds. These models are not well designed to predict outcomes for outpatient management and are limited in predicting poor outcomes [16, 25, 26, 29–34]. Although the definition of severity can be controversial, clinicians agree that severity is dependent on hemodynamic stability, laboratory findings, and comorbid conditions. Risk factors that are associated with

severe bleeding and poor outcomes are hemodynamic instability, ongoing bleeding, comorbid conditions, age > 60, history of diverticulosis and angioectasia, elevated creatinine, and anemia. In general, risk of bleed and morbidity increases with the increase in number of risk factors [16, 25, 26, 29–34].

Velayos demonstrated that 79% of patients with the presence of the following three risk factors will have recurrent and/or ongoing bleeding: hemodynamic stability longer than 1 hour, hematocrit <35%, and active gross rectal bleeding [31, 32]. The Oakland score is the only risk stratification score specifically designed and externally validated for LGIB. It is comprised of seven variables: age, gender, previous hospital admission with LGIB, digital rectal examination findings, heart rate, systolic blood pressure, and hemoglobin. The score is a summation of risk factors, and any patient with score ≤ 8 can be managed as an outpatient (Table 40.2). However, this scoring system has only been validated in the United Kingdom and may underreport patients who can be safely discharged [27, 35].

Das created an artificial neural network to predict the risk of death, rebleed, and intervention. Essentially, they created a computer-based clinical decision support system which was externally validated with a negative predictive value of 98%. However, clinical use of this non-logistic modeling is difficult to implement due to its requirements for advanced software and data entry [29]. Currently, risk stratification is highly dependent on clinical judgment, and the abovementioned patient risk factors may be used to guide the clinician as to the appropriate treatment and care setting. Table 40.3 discusses the current risk calculators available to guide clinical management [26, 32, 35, 36].

Table 40.2 Oakland scoring system

Predictor	Score value
Age	
40–69	1
>70	2
Male gender	1
Previous LGIB	1
Blood on DRE	1
Heart rate	
70–89	1
90–109	2
≥110	3
Systolic blood pressure	
130–159	2
120–129	3
90–119	4
<90	5
Hemoglobin (g/L)	
130–159	4
110–129	8
90–109	13
70–89	17
<70	22

A score of 8 or less predicts a 95% probability of safe discharge [35]

Management

Due to the diversity of presentation, management of LGIB can be especially challenging. In fact, 80% of LGIB resolve spontaneously [4, 11, 37]. The best way to stratify these patients is to initially assess the severity of the situation. As described above, risk stratification tools using vital signs, patient factors, and laboratory data in combination with clinical judgment can determine whether patient can be evaluated in an outpatient setting. For example, patients with chronic LGIB, anemia, and hemodynamic stability can be assessed in an outpatient setting. Shock index is also a good predictor of active extravasation and can be used to guide management.

Data driving the initial parenteral resuscitative management of hemodynamic unstable patient is mainly derived from management of severe upper GI bleed. These randomized clinical trials do not include LGIB; however, practice may logically follow these guidelines. Based on this data, transfusion of packed red blood cells is used to maintain a hemoglobin of 9 g per deciliter in patients with clinically significant coexisting illness (such as cardiovascular disease) and 7 g per deciliter for everyone else [6, 16, 38, 39]. Essentially, the goal of resuscitation is to normalize the patient's hemodynamics. This includes both blood products and intravenous fluids. The data does not show a difference with regard to colloid versus crystalloid resuscitation. In the upper GI bleed literature, intravenous fluid resuscitation is associated with decreased morbidity and mortality [6, 40, 41].

In our aging population, it is important to assess the patient's anticoagulation status and reverse any coagulopathy which can exacerbate ongoing bleeding. In a stable patient, it is important to communicate with the specialist managing the anticoagulation; the risk and benefit of both reversal and stopping of anticoagulation must be balanced [42, 43]. The American College of Gastroenterology guidelines, based on very low-quality evidence [44–46], dictates that reversal agents be used for an international normalized ratio (INR) >2.5 [6]. INR >1.5 has been a predictor of mortality but not rebleeding [44, 45]. This observed increase in mortality is an effect of INR's association with underlying comorbid disease. Platelet transfusion is generally recommended in patients with platelets <50 x10^9/l [43, 47]. In the setting of massive transfusion, principles of trauma massive transfusion protocols should be observed [47]; but there is no specific literature in GI bleeds to support this recommendation [6].

Table 40.3 Current risk calculators available to guide clinical management

Risk score	Outcome measured	Variables	Score cutoff
Oakland [35]	95% probability of safe discharge	Age	≤8[a]
		Gender	
		History of LGIB	
		Rectal exam	
		Heart rate	
		Systolic blood pressure

[b]Each predictor is given a weight of 1. Rate of severe bleeding based on score 0–5
[c]Calculated score based on variables. Scores placed in quartiles with associated risk factors. Has not been externally validated

The management of target-specific anticoagulants such as rivaroxaban, dabigatran, and apixaban can be very challenging. In a meta-analysis of 43 randomized clinical trials, an odds ratio of 1.45 (95% CI 1.07–1.97) was observed for bleeding risk with these agents [48]. Management is especially challenging as the degree of anticoagulation is not reflected in clotting panels. These agents have half-lives ranging from 5 to 19 hours. Nonspecific agents such as activated prothrombin complex concentrate (aPCC), which is an anti-inhibitor coagulant complex, can be used. No high-level evidence exists in literature with regard to the current available reversal agents [43, 49, 50]. In cases of severe life-threatening bleeding, hematology should be consulted to help manage these oral anticoagulants.

Endoscopic Evaluation

Endoscopy is often the preferred initial mode of diagnosis for LGIB. The major advantage of endoscopic evaluation is its ability to provide source identification and provide for therapeutic intervention [6, 51]. In patients with hemodynamic instability and hematochezia, an upper endoscopy should also be performed in addition to a colonoscopy [6, 16, 51]. The diagnostic yield of colonoscopy ranges from 42 to 90% [9, 23, 27, 52–54] (Table 40.4).

Colonoscopy may be performed on all patients with LGIB with careful evaluation of the mucosa upon insertion and withdrawal. Attempts at irrigation of residual blood and stool should be made, and the terminal ileum should be intubated

Table 40.4 Initial treatment modality

Colonoscopy	
Timing	Within 24 hours
Bowel preparation	Recommended – NGT can be placed to help facilitate
Rule out small bowel source	By intubating terminal ileum
Localization	Place tattoo in case of rebleed
Visualize entire mucosa	Use water-jet irrigation and a large working channel
CT angiography	
High predictive value	0.3 cc–0.5 cc/min of bleedings
	Shock index (SI) >1
	5 U PRBC within 24 h
Obtain 3 phases	Non-contrast, arterial, portal venous phase
Critical finding	Active extravasation
Subtle finding	Site of clot can be visualized on maximum intensity projection images

to rule out a small bowel source. Therefore, colonoscopy with water-jet irrigation and a large working channel should be used to facilitate clearing of food and clot (Figs. 40.1 and 40.2) [6]. Bowel preparation is recommended when feasible, to allow for adequate visualization [6, 16, 23, 24].

The appropriate timing of colonoscopy in LGIB is not well defined [6, 27]. A randomized trial of urgent colonoscopy (<8 hours from presentation) compared to standard of care (next available) demonstrated a significantly improved rate of definitive diagnoses with early colonoscopy (42% vs. 22%, OR 2.6, 95% CI 1.1–6.2). There was no difference in rebleeding, surgery, and/or length of stay [23]. In contrast, Lain randomized 72 patients to colonoscopy within 12 hours or delayed colonoscopy (30–60 hours) and demonstrated no difference in rebleeding, diagnosis, and/or need for therapy [9]. A recent meta-analysis reported improved therapeutic and diagnostic yield and length of stay with early colonoscopy [55]. The American College of Gastroenterology, based on the findings of improved length of stay and diagnostic/therapeutic yields, recommends colonoscopy within 24 hours in high-risk patients. However, it should be stated that this recommendation is not associated with improved clinical outcomes and/or a decrease in the possibility of surgical intervention [6, 16, 27, 53].

Endoscopic Intervention

After localization, the primary strength of endoscopy is the ability to potentially stop bleeding sources. Techniques of endoscopic hemostasis are safe, with reported adverse event rates as low as 0.3–1.3% [15, 37]. If high-risk stigmata of bleeding are visualized during colonoscopy, there are multiple endoscopic interventions that can stop the bleeding. These high-risk stigmata include active bleeding/non-bleeding visible vessel and/or adherent clot [54, 56]. These findings suggest a high rate of bleeding recurrence if no intervention is performed [56, 57]. Interventions include injection, contact and non-contact thermal coagulation, topical sprays/powders, and mechanical therapies such as clips (Figs. 40.3 and 40.4). These therapies can be used as combination therapy and have been deemed safe [58, 59]. It is advised that CO_2 insufflation be used to avoid perforations during long procedure times [27]. Endoscopic intervention is effective; however, data is lacking with regard to optimal technique. Technique is dependent on the clinician's experience and location and type of bleeding.

Endoscopic hemostatic intervention has the highest benefit when treating diverticulosis, angioectasias, and post-polypectomy bleeds [6, 16, 51]. LGIB caused by ischemic colitis, inflammatory bowel disease, and/or colorectal neoplasms are generally not amenable to durable endoscopic hemostasis, but the diagnosis is highly effective in guiding focused surgical and multimodal therapy [16].

Fig. 40.6 Bleeding diverticulum treated with epinephrine injection and endoclipping. Courtesy of Gregory Ginsberg, MD, editing by Mehraneh D. Jafari. https://doi.org/10.1007/000-33r

Endoscopic intervention for diverticular bleeding is indicated when active bleeding is seen or when a non-bleeding visible vessel and/or adherent clot is visualized (Figs. 40.5 and 40.6) [54]. In a pooled analysis of 847 patients, Strate reported 80% successful hemostasis in diverticular bleeds with a reported 8% early rebleeding and 12% late rebleeding rate. No advantage was reported in terms of monotherapy versus combination therapy (e.g., epinephrine injection and clips) [15]. Clips are preferred to cautery in diverticular bleeds, as the inherently thin wall of diverticula may be prone to delayed perforation after thermal treatment. In instances of active bleeding, epinephrine injection should be performed to cause local vasoconstriction and slow down the bleeding, followed by clipping [60]. The clip can be applied to the bleeding vessel and/or applied to close the diverticulum creating tamponade [61–65]. A translucent cap and/or injections can also be used to evert the diverticulum for more precise localization and treatment of diverticular bleed [66]. Left-sided endoscopic banding, similar to that of variceal banding, has also been described as successful [67–69]. India ink tattoo should be placed at the site of intervention to assist localization in cases of rebleeding [6].

Endoscopic treatment in patients with angioectasia (also referred to as angiodysplasia or arteriovenous malformations) is safe and feasible. Angioectasias are more common in the elderly (age > 70) and tend to occur in the right colon. Angioectasias account for 3–15% of patients with LGIB. Risk factors associated with bleeding from angioectasias include multiple comorbidities, the presence of multiple lesions, and use of anticoagulation and/or antiplatelet therapy. Endoscopic evaluation and treatment via thermal therapy is indicated in patients with active bleeding. Argon plasma coagulation (APC) is considered the treatment of choice due to its ease of use, safety profile, and reduction of blood of transfusions [70, 71]. In patients with Heyde syndrome (bleeding angioectasias and aortic stenosis), aortic valve replacement should also be considered [72, 73].

Endoscopic treatment of post-polypectomy bleeding is associated with a 95–100% success rate [74]. Risk factors for post-polypectomy bleeding include polyp size (>2 cm), thick stalk, resection site located in the right colon, and anticoagulation therapy. It occurs in 0.6–9.7% of polypectomy patients [56]. All the abovementioned endoscopic treatment modalities can be used for control of bleeding; however, the best practice is to avoid further tissue damage with energy-based therapies. Therefore, when possible, use of endoscopic clips is preferred [74].

Radiologic Evaluation

CT Angiography

Computed tomography angiography (CTA) can be used as a highly effective early diagnostic modality to localize LGIB (Table 40.4) [75]. A shock index ≥1 can predict extravasation on CTA, and its use may be beneficial to select for those who would most benefit from CTA [28]. A three-phase CTA including non-contrast, arterial, and venous phase imaging should be used for evaluation of LGIB [76–78]. CTA has a reported 85.2% sensitivity and 92.1% specificity of detecting acute GI bleeding [79]. The critical image finding is active extravasation of intravenous contrast into bowel lumen. Fluid distention of the bowel may dilute contrast extravasation and cause false-negative results [80]. Rates of bleeding above 0.25–3 ml/min can be detected with a 79–100% sensitivity and 50–100% specificity when using a portal and arterial phase CTA [78, 79, 81–84]. A negative CTA in a hemodynamic stable patient has been shown to be a good prognostic indicator that no further treatment will be needed [85]. Chen in a review of 62 patients demonstrated that 77.4% did not rebleed with a negative CTA [86].

With the ubiquity of CT scans, CTA can be used as an initial localizing modality to help facilitate localization of GI bleed (Fig. 40.7). A randomized controlled trial compared early colonoscopy to a more conservative algorithm of scintigraphy and angiography followed by colonoscopy only when the other tests were negative. This study showed no difference in outcomes including rebleeding and hospital stay. However, this study was underpowered and did show that colonoscopy definitively diagnosed source of bleeding in 42% of patients compared to 22% in the standard arm [23]. The primary advantage of CTA is its ability to rapidly diagnose and localize bleeding without the need for bowel preparation. Rapid and noninvasive definition of the anatomical source of bleeding informs treatment options and can help target therapeutic interventions. However, contrast nephropathy needs to be considered in patients with renal insufficiency.

Catheter-Based Angiography

Mesenteric angiography is the sole radiographic modality that allows for both localization and therapeutic treatment of the bleeding source (Fig. 40.8). In order for this testing

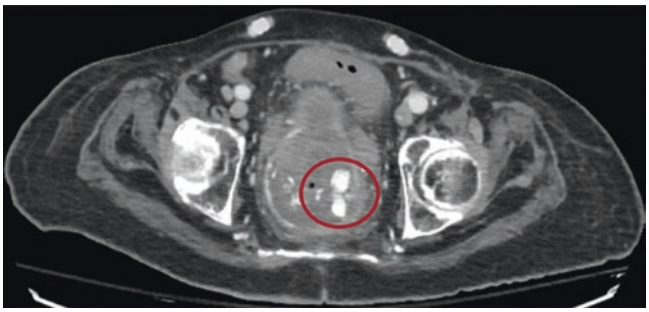

Fig. 40.7 CTA showing contrast extravasation in the upper rectum

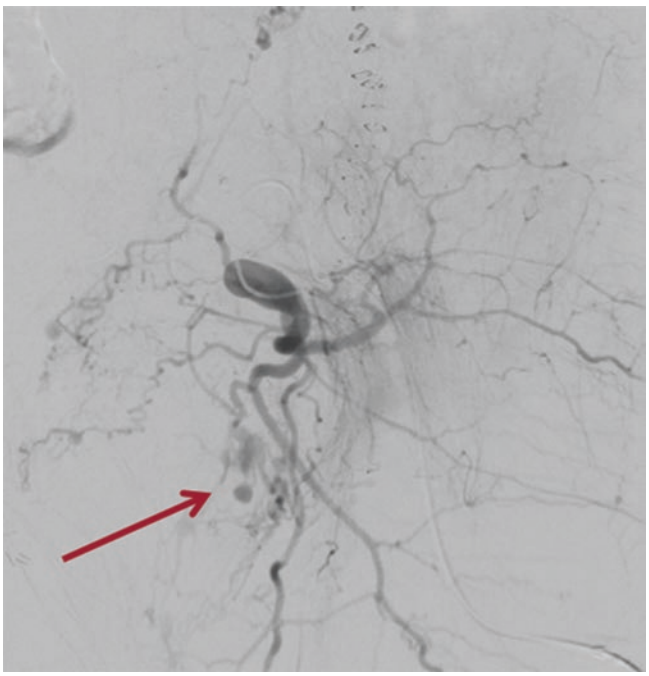

Fig. 40.8 Mesenteric angiography showing contrast extravasation

modality to be successful, the rate of bleeding must be >0.5 ml/minute and continuous [16]. Angiography has a higher success rate at localization in hemodynamically unstable patients who have required >5 units of blood in 24 hours and have a systolic blood pressure of <90 mm Hg [79, 87]. A negative angiogram after a positive CTA is common. Provocative angiography with the use of heparin, nitroglycerin, urokinase, or tissue plasminogen activator can be utilized to increase the likelihood of localization. However, this may lead to uncontrolled bleeding and should only be considered at experienced centers [88, 89]. Super-selective embolization can be achieved in arteries <1 mm in diameter with the use of microcoils, absorbable gelatin sponges, cyanoacrylate glue, or ethylene vinyl or polyvinyl [16]. Angiography has an associated rate of technical success of 73–100% and clinical success of 63–96% and rebleeding rate of 11–50% [16, 90–102]. In the event of unsuccessful control of bleeding, angiography can assist in directing surgical resection of the bleeding source. Self-limited ischemic bowel injury following angiography (abdominal pain, asymptomatic rise in lactic acid) is common. Major ischemic complications are reported in <3% of cases [16, 90–102].

Nuclear Medicine

Nuclear scintigraphy has been a historic gold standard for localization of LGIB, largely due to its extreme sensitivity. ^{99m}Tc-sulfur colloid and ^{99m}Tc-labeled RBC are the two techniques utilized. Technetium-99m-labeled red blood cell scintigraphy has been shown to be superior to that of ^{99m}Tc-sulfur colloid and can detect bleeding rates as slow as 0.04–0.05 ml/minute [103–105]. Despite this, its role in localization is debated due to its major limitations such as its ability to yield a precise anatomical localization and lack of therapeutic capability. In addition, relative patient stability is required, as time is needed to radiolabel the patient's red cells and reinject them. Radiolabeled RBC scintigraphy can detect bleeding for up to 24 hours, at which point most of the label has been lost.

This modality has the advantage of being able to re-scan the patient if the initial scan is negative. Sulfur colloid scanning is an alternative approach in which pre-labeled sulfur colloid is injected. This has the advantage of immediate use, since no autologous radiolabeling is required; however the half-life of the radiolabeled colloid is shorter, and delayed imaging is not possible [105, 106]. Radionuclide scans provide incorrect localization in 10–25% of cases, which can lead to inaccurate surgical treatment [107, 108]. Despite the high sensitivity of radionuclide scans, there is a 55% false-negatives rate using this modality [108]. In a retrospective study, Gunderman suggested that performing scintigraphy before angiography is associated with more selective contrast injection [109]. However, other studies have shown that CTA is the preferred modality for localization of bleed prior to intervention [110] and may obviate the need for the two other studies.

Recurrent LGIB

Early rebleeding, defined as rebleeding before hospital discharge, is reported in 22% of cases and late rebleeding, defined as after hospital discharge, in 16% [9, 23]. Recurrent readmission rates for recurrent LGIB are reported to be as high as 13.7% at 14 days and 19% at 1 year [36, 111]. Patient risk factors include anticoagulation, multiple comorbid conditions, malignancy, non-aspirin antiplatelet agents, dual antiplatelet therapy, age > 65, source of index bleeding (diverticulosis), and initial hemostasis modality [36, 111, 112]. Prevention of recurrent bleeding includes avoidance of NSAIDs and of regular aspirin for primary prevention of cardiovascular events. Repeat endoscopic evaluation and treatment is indicated in patients with recurrent lower GI bleed and has an associated diagnostic yield of 3–60% [16, 113, 114]. If bleeding is unable to be controlled with colonoscopy, and the location is known, angiography and embolization should be considered. In patients with early rebleeds and previous localization, surgical resection can be considered.

Recurrent LGIB without previous localization poses a clinical challenge. Repeat upper and lower endoscopy has diagnostic yields between 40% and 65% [114]. Continued bleeding, without endoscopic localization, should prompt evaluation of small bowel source. Surgical intervention in the absence of a known location, discussed below, is to be avoided.

Small Bowel GIB

Obscure GI bleeding is defined as an unlocalized source of bleeding after endoscopic and imaging evaluations. Most obscure GI bleeding sources tend to be from the small bowel, and therefore it is commonly referred to as "suspected small bowel bleeding." The most common etiologies of small bowel bleeding are inflammatory bowel disease, angioectasia, neoplasms, NSAID-induced ulcers, and Dieulafoy's lesions (mucosal erosion over visible vessel) [113]. Small bowel bleeding should only be considered after second-look endoscopy rules out both upper and lower GI bleeds. During second-look endoscopy, colonoscopy should attempt to evaluate the ileum, and upper endoscopy should attempt to evaluate the distal portion of duodenum and jejunum via push enteroscopy. Small bowel bleeding usually presents as stable occult bleeding. If no source of bleeding is found, other modalities such as video capsule endoscopy or enteroscopy (double or single balloon) should be considered.

Capsule endoscopy (CE) is a modality in which a video-recording capsule is swallowed. It transmits video of its tran-

sit throughout the small bowel wirelessly, allowing diagnostic evaluation of the mucosa. It is associated with a diagnostic yield of 38–83% and allows for noninvasive evaluation of the entire small bowel in 70–90% of patients [115]. CE can lead to a change in management in 37–87% of patients [116, 117]; it is associated with high positive (94–97%) and negative predictive (83–100%) values [117, 118]. CE is associated with positive findings in patients with hemoglobin <10 g/dl, >6 months' duration of bleeding, more than one episode of bleeding, overt bleeding, and CE performed within 2 weeks of bleeding episode [119–122]. The major drawbacks of CE are the inability to render therapeutic intervention and difficulty in precise localization of the lesion. Viazis demonstrated that a repeat CE can be diagnostic in occult bleeding with hemoglobin drop of >4 g/dl [123]. Multiple retrospective and prospective studies have shown CE to be superior in evaluation of small bowel bleed when compared to enteroscopy [114, 124].

Enteroscopy

Double balloon enteroscopy (DBE) can be used to evaluate a distance of approximately 240–360 cm of the bowel distal to the pylorus. It is advantageous in comparison to CE due to its diagnostic and therapeutic capabilities [121, 125, 126]. It is associated with a diagnostic yield of 60–80% and therapeutic intervention yields of 40–73% [121, 127–129]. DBE is limited by its invasive nature, prolonged intubation times, and need for properly trained and multiple personnel. Overall complication rates including perforation and pancreatitis are reported at 1.2% [130]. Single balloon enteroscopy (SBE) is similar to that of DBE except this device has no balloon at the end of the enteroscope. SBE is equivalent to DBE for the evaluation of a small bowel bleeding source [131, 132]. Use of CE prior to DBE is encouraged to minimize the performance of an invasive procedure in patients with low probability of small bowel findings [133–135]. However, in patients with high suspicion for small bowel bleed, CE may be falsely negative, and therefore enteroscopy may need to be performed to rule out a small bowel etiology [136].

Surgery

In instances where radiological and endoscopic attempts fail at localization and/or treatment of LGIB, surgical consultation should be obtained. Surgical consultation should also be considered in patients who are hemodynamically unstable so that the surgeons can be part of the decision-making process. Surgical resection is required in only 7–25% of patients to stop LGIB [21, 137]. Localization and diagnosis is critical in the evaluation for surgical intervention. Bleeding associated with inflammatory bowel disease and malignancy may markedly change the operative strategy and approach. For cases of colonic and/or small bowel malignancy in which patients have ongoing hemorrhage, oncological resection when possible should be attempted. In cases of rectal cancer, consideration for imminent start of radiation therapy to stop bleeding should be considered as part of the treatment paradigm.

Non-localized LGIB

In the case of a LGIB where a small bowel source has been ruled out (e.g., only colonic blood is seen, anoscopy is negative, and terminal ileal intubation is negative, for blood), subtotal colectomy should be considered. The planned approach for totally non-localized LGIB when surgery cannot be avoided should be diagnostic laparoscopy and/or exploratory laparotomy in which the bowel is run in its entirety to rule out any palpable lesions. Intraoperative colonoscopy and enteroscopy are options if no lesion is found.

Intraoperative enteroscopy involves the evaluation of the small bowel during laparotomy or laparoscopy. It can be performed transorally, transrectally, and/or through an enterotomy. It has a reported diagnostic yield of 50–88% with rebleeding rates of 60% [138–142]. If no source is identified despite colonoscopy and/or enteroscopy and colonic origin is suspected, a blind subtotal colectomy can be considered. Consideration can be given, in the relatively stable patient, to performance of a temporary loop ileostomy. This may afford the opportunity to better distinguish between a small and large bowel source. Rebleeding rates after blind subtotal colectomy are approximately 4% [143–148].

Segmental resection is the most appropriate option when the source has been confidently identified, due to improved bowel function when compared to subtotal colectomy [145, 149]. Segmental colectomy has been associated with bleeding rates of up to 4–14% [143–145, 150]. Subtotal colectomy should be performed in patients when the source of colonic bleeding is uncertain. The role of stoma in subtotal colectomy will be dependent on the hemodynamics of the patients.

Conclusion

Lower GI bleeding is common and potentially morbid; however, it is rarely a surgical disease. Current endoscopic and radiologic modalities and techniques have allowed for diagnosis and management of the majority of these bleeds. Risk stratification strategies may help guide therapy. While surgeons should commonly be involved in the management of these patients as part of the multidisciplinary team, surgical resection is only occasionally warranted. Surgery for non-localized bleeding should be avoided whenever possible.

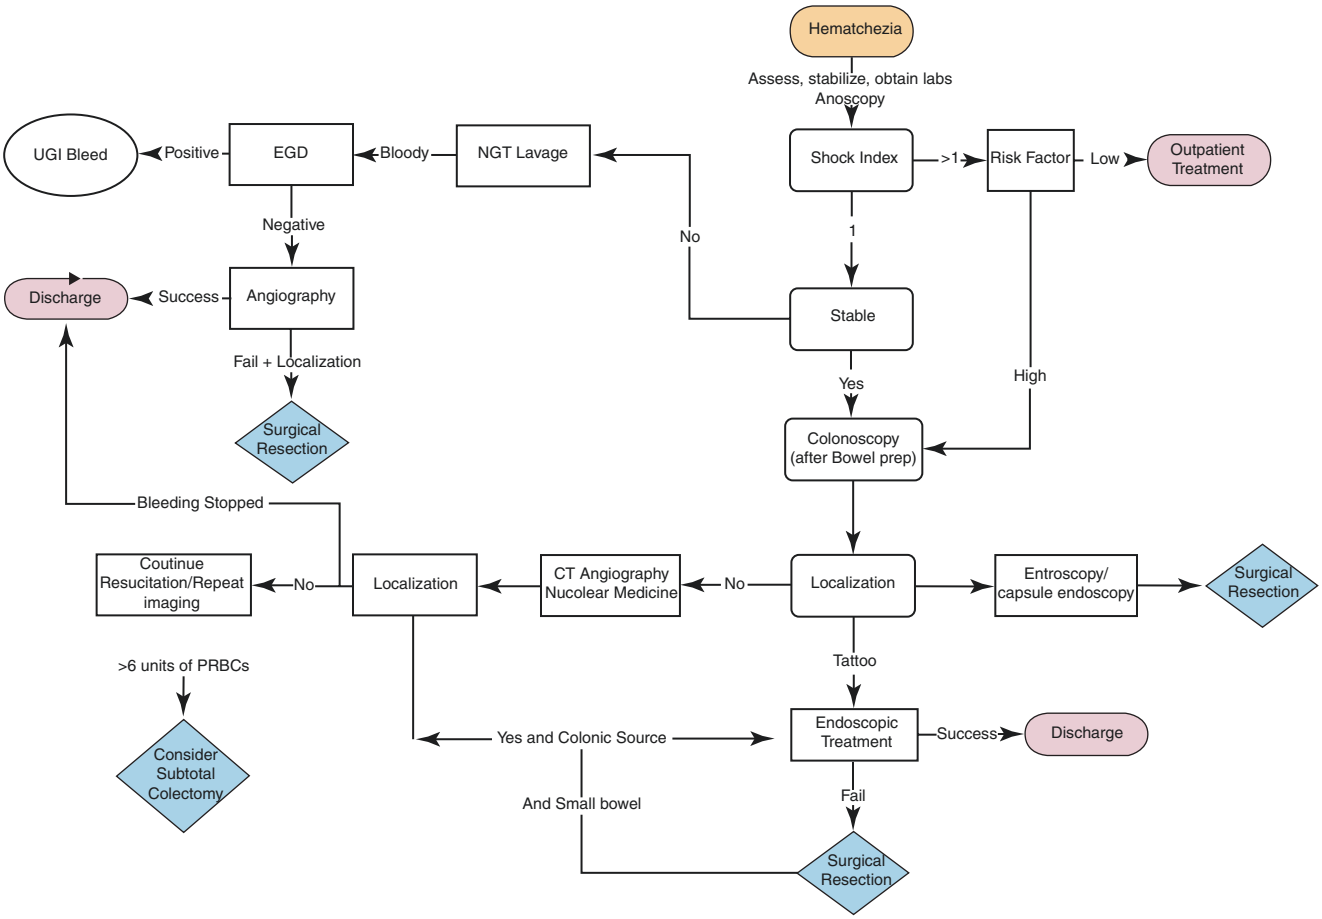

Fig. 40.9 Algorithm for the treatment of lower GI bleeding

The algorithm in Fig. 40.9 shows the treatment schema for lower GI bleeding.

Endometriosis

41

Heidi Chua and Michael J. Snyder

Key Concepts

- Endometriosis is a common cause of young women undergoing pelvic surgery.
- Endometriosis causes pelvic pain, infertility, and dyschezia.
- Laparoscopy and pathologic identification of endometriosis are the gold standard for diagnosis.
- Symptomatic Stage 4 endometriosis requires surgery.
- A multidisciplinary approach with gynecologists and urologists for advanced endometriosis is optimal.

Introduction

Endometriosis is simply a disease characterized by the presence of viable endometrial-like glands and stroma outside the uterine cavity. For the millions of women afflicted with endometriosis, however, there is nothing simple about the evaluation and management of this painful, chronic, and inflammatory disease. While it is one of the most common conditions requiring surgery for women during their reproductive years, diagnostic delays remain a significant barrier to patients seeking appropriate and timely care with a delay in diagnosis from the onset of symptoms of 7–12 years [1, 2]. Endometriosis is often associated with disabling pelvic pain, intractable infertility, and gastrointestinal instability around the time of menses. The degree of symptomatology is variable and may not be indicative of the extent of pathology encountered at surgery. Small lesions may cause severe pain and infertility, while larger lesions may be asymptomatic and be found only incidentally during surgery for other diagnoses. Laparoscopy is the gold standard for diagnosis, but many patients are found during laparotomy for other conditions, such as appendicitis or ruptured ovarian cysts (endometrioma of the ovary). Colon and rectal surgeons often become involved in the management of patients with intestinal endometriosis. This involvement often occurs as a result of a combined procedure with a gynecologist or in management of an endometrioma masquerading as a neoplastic or inflammatory lesion. Treatment for endometriosis is usually multimodal and may require surgery in those patients with infertility, pelvic pain, obstruction, or a poor response to hormonal suppression. While advances in diagnostic tests and therapy have been made, endometriosis remains a frustrating and incompletely understood disease for both the patient and her physicians.

Epidemiology

The true prevalence of endometriosis is unknown. There is no noninvasive screening test for endometriosis, and its diagnosis depends on the visual or pathologic identification of implants during laparoscopy or laparotomy. Various authors have estimated that up to 15% of all women of reproductive age representing an estimated 200 million women worldwide are afflicted with the disease [3–5]. Endometriosis is more common in women suffering from infertility (25–50%) and chronic pelvic pain (71–87%) [4–6]. A study by Houston et al. is the only population-based study of endometriosis [7]. After reviewing the medical records for Caucasian women in Rochester, Minnesota, during the 1970s, they estimated that 6.2% of premenopausal women have endometriosis. The cost of endometriosis to the individual and society is significant with an estimated $69.4 billion per year in health expenditures [4]. The health costs are similar to diseases such as diabetes, rheumatoid arthritis, and inflammatory bowel disease with direct costs over $12,000 per year [8]. For women

in the prime working years, 50% of women with endometriosis lost nearly 18 days a year in productivity [9].

While endometriosis is primarily a disease of the reproductive years, the widespread use of exogenous estrogens and increasing obesity in our society have made it more prevalent in postmenopausal women. Conversely, there is a decrease in the incidence of the disease when women use oral contraceptives or experience multiple pregnancies [10]. These observations, coupled with the fact that the incidence of endometriosis increases over time after a woman's last childbirth, suggest that uninterrupted menstrual cycles predispose susceptible individuals to the development of endometrial implants [11]. Spontaneous regression can occur, but in primate studies, with females who suffer from a similar disease, endometriosis is a progressive disorder [12]. There is no racial predilection for endometriosis other than in Japanese women who have doubled the incidence of the disease than do Caucasian women [13].

Diagnostic delays are a critical barrier to women with endometriosis. The inability to receive timely and appropriate care frequently causes physical and emotional damage, severely impacts quality of life, may lead to addiction, and is often accompanied by a diminished relationship with physicians. As previously mentioned, the delay in definitive diagnosis is on average 7–12 years. The reason for this is multifactorial. Laparoscopy is invasive and costly and has its own risks. Despite recommendations for medical treatment before definitive diagnosis is confirmed, few practitioners have changed their practice [14]. Gynecologists believe that the absence of a valid noninvasive diagnostic test contributes to the significant delay in diagnosis in many patients [15].

Stigma around menstrual issues and pelvic pain also play a role in the delay. One study revealed that women do not make an appointment for a little over 2 years from the onset of symptoms before seeking help [2]. In addition, chronic pain is not specific to endometriosis, and the process of ruling out the myriad of other disorders contributes to the delay in diagnosis and treatment. Women with endometriosis make approximately seven appointments with their primary care physician before being referred to a specialist, and three quarters experience a misdiagnosis. Despite the prevalence of endometriosis, one survey of primary care physicians found that half could not name three of the main symptoms of endometriosis and two-thirds did not feel competent in the diagnostic evaluation and follow-up [16].

Etiology

The precise etiology that completely explains the cause and pathogenesis of endometriosis is unknown. The two most popular theories as to its etiology are coelomic metaplasia and the implantation of viable endometrial cells from retrograde menstruation through the fallopian tubes. Coelomic metaplasia, postulated by Meyers, suggests that under the correct hormonal milieu, the coelomic epithelium will undergo metaplastic changes and transform into endometrial tissue [17]. He bases his theory on studies demonstrating that the peritoneum and uterine endometrium both originate from embryonic coelomic epithelium. While this theory offers a good explanation for endometriosis in men and nonmenstruating women, it does not adequately address the anatomical distribution and clinical pattern of endometriosis. The vast majority of endometriosis occurs in the pelvis, but the peritoneum at risk with this theory is evenly distributed throughout the abdominal cavity. In addition, metaplasia should worsen with age and endometriosis clearly does not.

Retrograde menstruation, first proposed by Sampson in 1921, remains the most plausible explanation for the distribution of endometrial implants [18]. This theory postulates that endometriosis arises from retrograde menstruation through the fallopian tubes and into the peritoneal cavity. Viable endometrial tissue has been demonstrated in menstrual effluent, and endometriosis has been induced both in primates, with artificially produced retrograde menstruation, [19] and in women volunteers who permitted injection of menstrual tissue into their peritoneum [20]. This theory, however, is probably only part of the answer.

While retrograde menstruation is very common, occurring in virtually all women, endometriosis affects only a small minority. Clearly other factors must be involved to permit the implantation and growth of endometrial tissue. Several studies indicate a possible genetic aspect to endometriosis. Simpson et al. demonstrated that the disease appears to occur more commonly within families. He found a 7% relative risk for blood relatives of affected individuals as opposed to a 1% relative risk for non-blood controls [21]. Additionally, the clinical manifestations of the disease were more severe among the related group. It appears that the inheritance pattern is polygenic or a combination of genetic and environmental factors. This conclusion is consistent with the clinical associations with delayed childbearing and uninterrupted cyclic menstruation.

Dmowski et al. have theorized that the genetic factor may involve the immune system [22]. They demonstrated depressed cellular immunity in monkeys with spontaneous endometriosis. Other investigators have confirmed alterations in both cellular and humoral immunity in humans [23, 24]. The most striking change observed in cellular immunity is the high concentration of activated macrophages and decreased functional capacity of natural killer cells. The most significant abnormality in humoral immunity is the presence of autoantibodies against different cellular components. These changes have been observed in both the perito-

neal cavity and the systemic circulation, suggesting that endometriosis may be a systemic disease. It is still unclear whether these changes represent manifestations of the disease or a subsequent reaction to it. This research, however, suggests that mild subclinical immunosuppression may subsequently lead to endometriosis many years later.

Endometriosis has such a diversity of symptoms, severity, and lesion appearance which many believe that endometriosis represents a group of disorders. Superficial peritoneal disease, ovarian endometriomas, deeply infiltrating lesions into the rectum and rectovaginal septum, and extra pelvic endometriosis all behave clinically different and respond differently to medical management [25]. Except for the dyspareunia found in infiltrative lesions in the rectovaginal septum, lesion size and number correlates poorly with severity of symptoms and degree of patient disability (Figs. 41.1, 41.2, and 41.3) [26].

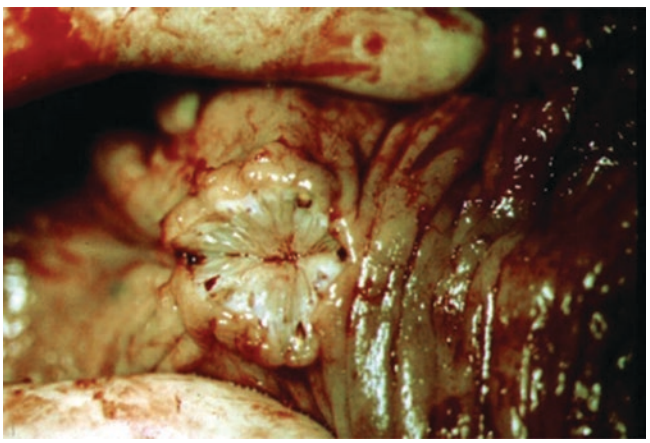

Fig. 41.1 Polypoid endometrial implant of the colon causing mucosal abnormalities

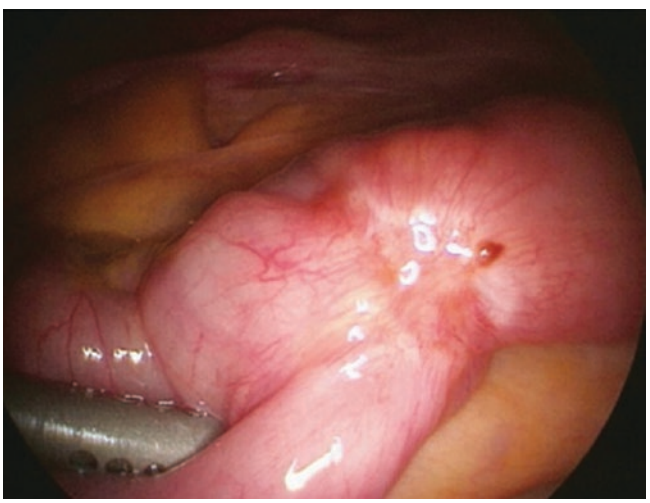

Fig. 41.2 Laparoscopic view of an endometrial implant on the small intestine

Clinical Manifestations

Clinical manifestations of endometriosis are based on the organs involved, but most patients complain of pelvic pain, pelvic mass, and infertility. Patients may describe the pelvic pain as pain with defecation or dyspareunia (especially with deep penetration). Women with abnormal menstrual cycles, family history of endometriosis, or congenital or traumatic defects in the reproductive tracts presenting with pain should be evaluated for endometriosis. Because endometriotic cysts can occur in wounds after cesarean sections or episiotomies, these lesions can cause pain and swelling during the perimenstrual cycle. Other unusual locations of involvement include the bladder, lungs, or brain [27].

Traditionally thought to affect women in their mid-reproductive years, endometriosis can affect adolescents and those postmenopausal. Teens who present with pelvic pain, worsening dysmenorrhea, rectal pain, and dyspareunia should be evaluated for endometriosis. And with the increasing use of hormone replacement in the postmenopausal women, symptoms for endometriosis may recur in those who had disease earlier in life. In other cases, the diagnosis of endometriosis is made during surgery either for gynecology-related or other concerns.

Pelvic pain in patients with endometriosis maybe described as deep, constant, or a dull ache in the pelvis. It usually occurs during the menstrual cycle but may occur before or close to the onset of the menstrual cycle. Some will not have pain, while others will have significant pain with minimal lesions. The pain may occur during sexual activity, with bowel movements, in cases of GI involvement, or during pelvic examinations. With colonic involvement of endometriosis, patients may complain of pain with defecation or with rectal filling. With larger and deeper lesions involving the GI tract, symptoms of obstruction, perforation, and bleeding can occur.

With bladder involvement, pain during micturition and cyclic hematuria have been described, and cystoscopy will aid in its evaluation. If suspected, cystoscopy should be performed during the menstrual cycle. With ureteral involvement, ureteral obstruction can lead to renal dysfunction if left undiagnosed and rarely is bilateral.

Another unusual location for endometriosis is in the lungs (thoracic endometriosis syndrome) or diaphragm where pneumothoraxes have been described. With erosions into the lung parenchyma, perimenstrual hemoptysis, dyspnea, and chest pain can occur. Brain lesions can cause perimenstrual headaches and seizures and will need a high index of suspicion for diagnosis and treatment.

Pain during pelvic examination with a pelvic mass may be indicative of endometriosis, particularly if pain is elicited upon palpation of the uterosacral ligaments during rectovaginal exam. The mass may be an endometrioma or secondary

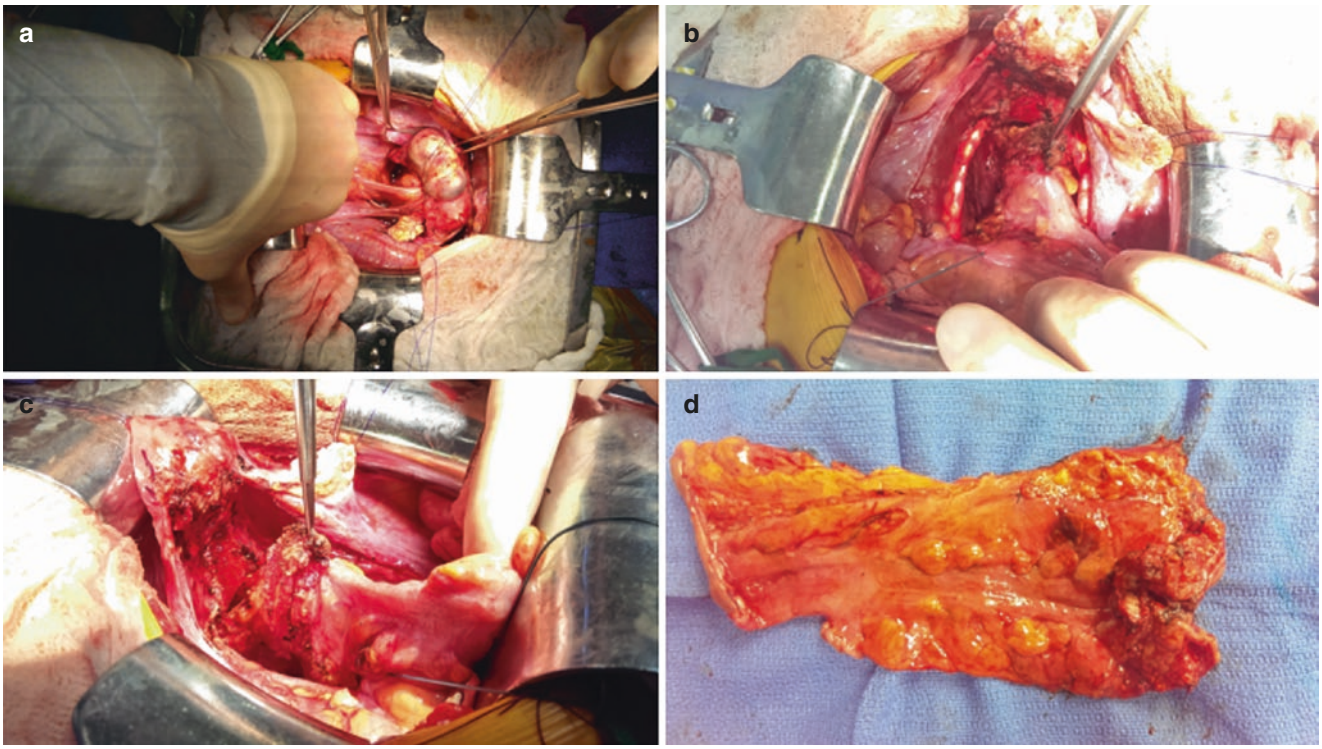

Fig. 41.3 (**a**) Demonstrates the view of the endometrial implants obliterating the pouch of Douglas and an associated large endometrioma on the left ovary at the start of the procedure; (**b**) the large nodule of endometriosis has been dissected from the ureters and posterior vagina (note the lighted ureteral catheters that facilitate the dissection); (**c**) demonstrates visualization of the normal fat within the rectovaginal plane after fully dissecting cul-de-sac of Douglas and mobilizing the lesion rostrally out of the pelvis to allow resection; (**d**) demonstrates sectioning of the specimen to show the typical appearance of an endometrioma after hormonal therapy which induces diminished vascularity of the lesion

to adhesions from the endometriotic tissue. The endometrioma is a fluid-filled endometriotic cyst which is most commonly found in the ovaries. The endometrioma may be single and can grow to a large size without symptoms. In other cases, the mass is secondary to adhesions between pelvic structures binding them together. Radiologically, bilateral endometriomas may fuse the ovaries at the midline; this sign is called "kissing ovaries" and is pathognomonic for endometriosis.

Infertility is the most common presenting complaint in patients who suffer from endometriosis. The exact prevalence is unknown, but reports as high as 30% of women with endometriosis are infertile. The mechanism of infertility in patients with endometriosis is quite variable. Referral to the appropriate fertility specialist will aid in the evaluation and management of patients with infertility – whether the cause is related to endometriosis or others.

Possible mechanisms of infertility in endometriosis [27]:

"Extensive" endometriosis

1. Tuboovarian adhesions preventing ovum pickup
2. Adhesions surrounding ovary of blocked fallopian tube
3. Destruction of ovarian tissue

"Mild" endometriosis

1. Abnormal menstrual cycle
   (a) Anovulation
   (b) Abnormal LH surge
   (c) LUFS – luteinized unruptured follicle syndrome
   (d) Luteal phase inadequacy
2. Hyperprolactinemia
3. Immune dysfunction
4. Altered peritoneal fluid
   (a) Prostaglandins
   (b) Macrophages
5. Spontaneous abortion

In 2013, the Endometriosis: History, Diagnosis and Outcomes (ENDO) group reported on risk factors associated with endometriosis. In their prospective matched, exposure cohort design, 495 women aged 18–44 years were compared to age-matched population cohort of 131 women. The diagnosis of endometriosis was done at laparoscopy or by pelvic magnetic resonance imaging. They found an incidence of endometriosis at 40% of the operative cohort (per criteria from the American Society for Reproductive Medicine)

compared to 11% in the population cohort. History of infertility increased the odds of endometriosis in both groups – operative (adjusted odds ratio (AOR) 2.43; 95% CI, 1.57–3.76) and population (AOR 7.91; 95% CI 1.69–37.2). Dysmenorrhea (AOR 2.46; 95% CI, 1.28–4.72) and pelvic pain (AOR 3.67; 95% 2.44–5.50) increased the diagnosis in the operative group only. Gravidity (AOR 0.49, 95% CI 0.32–0.75), parity (AOR 0.42; 95% CI 0.28–0.64), and body mass index (BMI) (AOR 0.95; 95% CI 0.93–0.98) decreased the odds of the diagnosis in the operative group [28].

A study by Hemmings indicated a higher rate of endometriosis in educated women. A total of 2777 subjects who underwent diagnostic laparoscopy, tubal ligation, or hysterectomy were included; 890 subjects were classified with endometriosis, whereas 1881 served as controls. Their study showed a higher rate of endometriosis in women with higher education. They reported no significant association between BMI, smoking, and alcohol use with endometriosis. They did find an inverse relation with gravidity and endometriosis [29].

Diagnosis

Since endometriosis can affect the entire pelvis and the signs and symptoms sometimes nonspecific, diagnosis can present as a challenge to the clinician. A high index of suspicion is key to helping these patients. No serum markers are currently available for the diagnosis, but CA −125 has been used. Recent interest in biomarkers have yielded a few options for early "screening" for endometriosis, but further research is needed for validation (Table 41.1) [30].

Table 41.1 Biomarkers for early "screening" for endometriosis

Biomarker		Test characteristic for prediction
CA-125 + prolactin		Sensitivity 77%, specificity 88%
Glycoproteins	Follistatin	Sensitivity 92%, specificity 96%
	Zn-alpha-2-glycoprotein	Sensitivity 69.4%, specificity 100%
	Glycodelin	Sensitivity 78.4%, specificity 82.1%
Cytokines	Serum IL −6	Sensitivity 100%, specificity 100%
	Serum IL-8	Sensitivity 90%, specificity 92%
	TNF-alpha	Sensitivity 95%, specificity 86.2%
	Serum CRP	Sensitivity 85%, specificity 93.7%
miRNA		Sensitivity 93.22%, specificity 96%
ICAM-1 (intercellular cell adhesion molecule)		Sensitivity 58.3%, specificity 60.0%
Circulating cell free DNA		Sensitivity 70%, specificity 87%
Autoantibodies		Sensitivity 83%, specificity 79%

Several imaging modalities are available for the evaluation of endometriosis. These include physical exam, transvaginal ultrasound (TVUS), MRI, rectal ultrasound, and endoscopy. On pelvic exam, the finding of an irregular and/or painful nodule will lead one to suspect endometriosis. Thickening and/or the presence of an irregular hypoechoic cystic or non-cystic mass within the rectovaginal septum or anterior-lateral to the rectum on TVUS would also be concerning for endometriosis. With MRI, irregular thickness or spiculated nodules in the rectovaginal septum with hypointense signal on T1- and T2-weighted images would be concerning for endometriosis. The use of rectal ultrasound and endoscopy for diagnosis for endometriosis would be of benefit in deep infiltrating endometriosis with direct involvement of the rectal wall. Deep infiltrating endometriosis is a form of endometriosis where ectopic endometrial tissue invades >5 mm deep to the peritoneum. It is often found in the posterior cul-de-sac of Douglas, uterosacral ligaments, and rectosigmoid colon [31]. The sensitivity, specificity, and accuracy of transvaginal ultrasound for identification of the direct rectal involvement were 26.7%, 85.7%, and 52.7% and with MRI 73.3%, 92.9%, and 82% respectively. With endorectal ultrasound, the sensitivity, specificity, and accuracy are 86.7%, 85.7%, and 86.2% [32]. Lastly, laparoscopy with direct visualization of the pelvis is currently the gold standard for diagnosis of endometriosis. Laparoscopy is described later in the chapter.

Rectal involvement, with partial or complete obliteration of the pouch of Douglas, brings another concern to the management of patients with endometriosis. Not only can it cause significant pain, it also adds to the operative management. Appropriate assessment preoperatively allows for the multidisciplinary approach to surgery. When the posterior aspect of the cervix or uterus does not "slide" freely again into the rectum or sigmoid, it is called the "negative sliding sign" and is concerning for obliteration of the pouch of Douglas. Reid and Condous reported a sensitivity of 83.3% and specificity of 97.1% in predicting the pouch of Douglas obliteration when using the sliding sign [33].

The use of US for evaluation of cul-de-sac obliteration was also confirmed by Arion and her group who compared point-of-care TVUS with manual pelvic exam. They compared TVUS to manual pelvic exam (specifically the finding of a palpable mass) for the prediction of the pouch of Douglas obliteration. They reported a preoperative negative sliding sign had a sensitivity of 73.2% (95% confidence interval, 57.1–85.8%) and specificity of 93.9% (95% confidence interval, 89.9–

96.6%) in predicting the pouch of Douglas obliteration versus a sensitivity of 24.4% (95% confidence interval, 12.4–40.3%) and specificity of 93.4% (95% confidence interval, 89.4–96.3%) on palpation of a nodule on pelvic exam. They also reported on longer operating times and more difficult surgery in the setting of the pouch of Douglas obliteration [34].

Leonardi et al. argue that deep infiltrating endometriosis warrants more in-depth evaluation as management may require a multidisciplinary approach. They proposed the use of the advanced, expert-guided transvaginal sonography or ETVS. Transvaginal sonography allows for assessment of the uterus and ovaries, while he argues that ETVS assess for deep infiltrating endometriosis, cul-de-sac obliteration, ovarian mobility, and site-specific tenderness [35].

The role of colonoscopy in the diagnostic workup of endometriosis is to rule out other causes of abdominal discomfort. In a prospective observational study performed by Milone et al., endoscopic findings suggestive of endometriosis were detected in only 4% of their study population. Endoscopy failed to diagnose endometriosis in over 92% of the patients. It did, however, diagnose endometriosis if there was mucosal involvement [36]. Therefore, the role of colonoscopy in the diagnostic workup of endometriosis is to identify other causes of abdominal pain. In cases where there is mucosal involvement of endometriosis, the clinical features can mimic other diseases, namely, inflammatory bowel disease, solitary rectal ulcer, or cancer to name a few. Even with biopsies, the diagnosis for endometriosis can be difficult. A high index of suspicion with appropriate histologic testing in pathology would be helpful. Wei et al. presented a series of 15 patients with gastrointestinal endometriosis. The most common presenting complaints were pelvic pain, rectal bleeding, rectal urgency, abdominal mass, and bowel obstruction. The most common endoscopic finding is a polypoid mass with the most common preoperative diagnosis as colorectal carcinoma. Since endometriosis affects the serosa or muscularis propria more commonly, the mucosa may exhibit nonspecific inflammatory changes or ulcerations on biopsy specimens which could mimic inflammatory bowel disease. Fibromuscular hyperplasia within the lamina propria as seen in solitary rectal ulcers can also be seen with mucosal involvement of endometriosis. Immunohistochemical stains are important to differentiate these disease entities and direct management. The panel of CK7, ER, CK20, and CDX 2 are commonly used. Ectopic endometrial glands express CK7 and ER, while the stroma expresses CD 10 and ER. Rectal glands express CK20 and CDX 2 [37]. In limited tissue samples, CD7 and ER are adequate.

Endometrial glands can also exhibit metaplasia. In the 15 cases presented by Jiang et al., the most common metaplastic change was the ciliated (tubal) hyperplasia, which is a helpful clinical differentiator since intestinal glands do not have cilia. Other metaplastic changes are squamous, eosinophilic, hobnail, and mucinous metaplasia [38]. This raises the concern for malignancy which will be discussed later in the chapter.

While physical exam and imaging are important in the initial evaluation of pelvic pain, laparoscopy continues to be the gold standard for diagnosis of endometriosis. Surgical resection of all lesions is essential to provide maximal clinical benefit to patients who suffer from endometriosis. Therefore, identification of all lesions during laparoscopy is important. Early-stage disease and atypical lesions are difficult to identify during laparoscopy. The study by Ma et al. was designed to identify whether narrowband imaging will improve laparoscopic identification of superficial and early-stage endometriosis. Fifty-three patients underwent standard white laparoscopy followed by narrowband imaging to assess for additional areas of concern. They found only three additional areas of concern with narrow band imaging (NBI) if the white light survey was negative, but none of the lesions were positive for endometriosis. They concluded that the additional predictive value of NBI was 86% if the white light survey was positive but 0% if the white light survey was negative [39]. This is in contrast to the pilot study by Barrueto et al. who described the technique in 2008, where 14 of the 20 patients had lesions identified by NBI that were not identified by the standard white light laparoscopy [40].

While laparoscopy continues to be the gold standard for identification of endometriosis, the addition of NBI may improve identification of additional lesions in the early stages.

On laparoscopy, the lesions can be superficial patches ranging in colors from red, brown, black, white, clear, yellow, or blue. Classically, blue-tinted implants are called powder burn lesions and are highly suspicious for endometriosis. Alternatively, endometriosis implants can be subtle and appear as fibrotic areas of peritoneum or convalescence of small vessels on the pelvic side wall. Fibrosis can accompany the lesions or, if large enough, can form nodules. Ovarian endometriomas are filled with a brown fluid and are called "chocolate cysts." The lesions can involve the ovaries, the anterior and posterior cul-de-sac, broad ligaments, fallopian tubes, uterosacral ligaments, uterus, round ligament, sigmoid colon, and appendix. Other less common areas of involvement are the vagina, cervix, rectovaginal septum, cecum, ileum, inguinal canal, perineal wounds, bladder, and ureter. It is therefore crucial during surgery to evaluate all these areas to assess the full extent of involvement and tailor surgery based on the findings and symptoms.

Classification of Endometriosis

The most widely used classification for endometriosis is the revised American Society for Reproductive Medicine (r-ASRM) classification (Fig. 41.4) [41]. It is a scoring

Patient's Name _____ Date _____

Stage I (Minimal) - 1–5
Stage II (Mild) - 6–15
Stage III (Moderate) - 16–40
Stage IV (Severe) - > 40
Total _____

Laparoscopy _____ Laparotomy _____ Photography _____
Recommended Treatment _____
_____
Prognosis _____

PERITONEUM	ENDOMETRIOSIS	< 1cm	1–3cm	> 3cm
	Superficial	1	2	4

system for lesions in the peritoneum, ovaries, fallopian tubes, and cul-de-sac. The size and depth of lesions, adhesions on the ovaries and fallopian tubes, and severity of cul-de-sac obliterations are assigned points. The summation of all the points allows classification of endometriosis to four grades of severity: Stage I (minimal endometriosis, 1–5 points), Stage II (mild endometriosis, 6–15 points), Stage III (moderate endometriosis, 16–39 points), and Stage IV (severe endometriosis, 40 points). This has led to the use of the ENZIAN classification for deep infiltrating endometriosis (DIE). With the ENZIAN classification for DIE, the pelvis is divided into three compartments, namely, A, B, and C, with a second group designated as F ("far") for lesions in the bladder, ureter, or bowel. A, B, and C groups are subjected to a metric level system for depth of infiltration (Fig. 41.5).

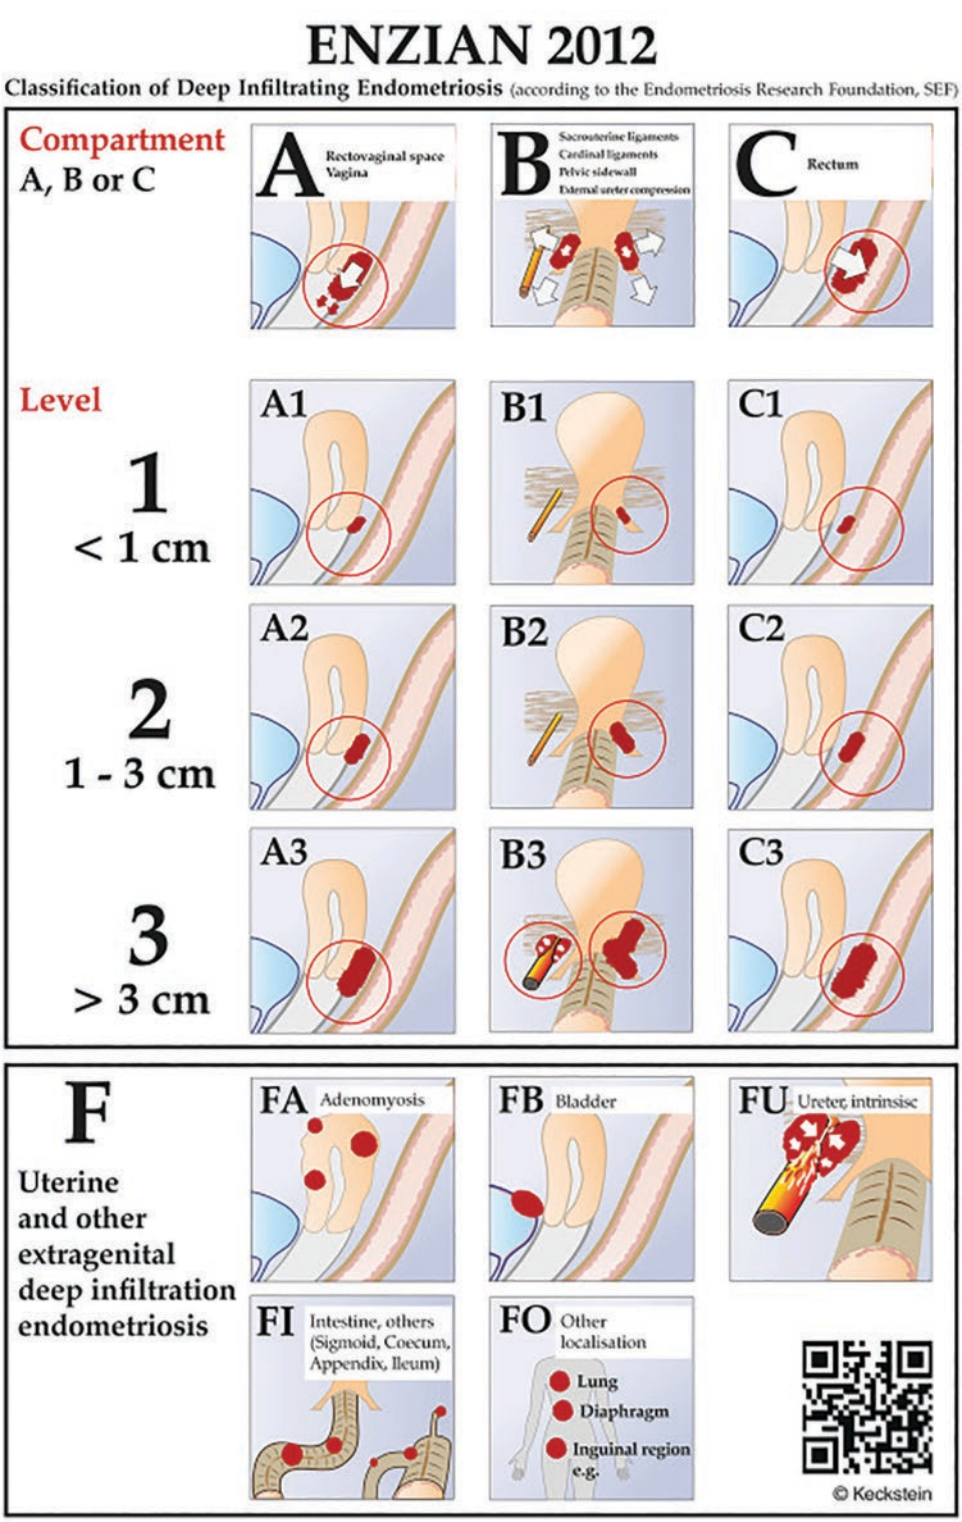

Fig. 41.5 ENZIAN classification (Reused with permission from Ref. [25]. Copyright © Oxford University Press)

In April 2014, a consensus meeting [42] was held to discuss the development of a classification system that included the r-ASRM and the ENZIAN system – both of which are based on lesion appearance and locations but not ovarian function or fertility outcome. They proposed the addition of the endometriosis fertility index staging system which predicts fertility outcomes in patients following surgical staging of endometriosis when appropriate

ENDOMETRIOSIS FERTILITY INDEX (EFI) SURGERY FORM

LEAST FUNCTION (LF) SCORE AT CONCLUSION OF SURGERY

Score		Description
4	=	Normal
3	=	Mild Dysfunction
2	=	Moderate Dysfunction
1	=	Severe Dysfunction
0	=	Absent or Nonfunctional

To calculate the LF score, add together the lowest score for the left side and the lowest score for the right side. If an ovary is absent on one side, the LF score is obtained by doubling the lowest score on the side with the ovary.

	Left		Right		
Fallopian Tube					
Fimbria					
Ovary					
Lowest Score		+		=	
	Left		Right		LF Score

ENDOMETRIOSIS FERTILITY INDEX (EFI)

Historical Factors			Surgical Factors		
Factor	Description	Points	Factor	Description	Points
Age			LF Score		
	If age is ≤ 35 years	2		If LF Score = 7 to 8 (high score)	3
	If age is 36 to 39 years	1		If LF Score = 4 to 6 (moderate score)	2
	If age is ≥ 40 years	0		If LF Score = 1 to 3 (low score)	0
Years Infertile			AFS Endometriosis Score		
	If years infertile is ≤ 3	2		If AFS Endometriosis Lesion Score is < 16	1
	If years infertile is > 3	0		If AFS Endometriosis Lesion Score is ≥ 16	0
Prior Pregnancy			AFS Total Score		
	If there is a history of a prior pregnancy	1		If AFS total score is < 71	1
	If there is no history of prior pregnancy	0		If AFS total score is ≥ 71	0
Total Historical Factors

(Fig. 41.6). The group acknowledges that the classification systems do not predict pelvic pain, response to medications, disease recurrence, and quality of life measures. Further research into a more comprehensive classification system is needed.

Endometriosis and Cancer

Endometriosis is a benign disease but has been shown to increase the risk of certain types of ovarian cancer, namely, clear-cell ovarian cancer (CCOC) and endometrioid ovarian cancer (EOC). The World Health Organization has classified ovarian cancer into two major groups. Type I tumors are the clear-cell, endometrioid, low-grade serous, and mucinous carcinomas and seromucinous and malignant Brenner tumors. Type II tumors are the high-grade serous carcinoma, carcinosarcoma, and undifferentiated carcinoma. Both CCOC and EOC are considered Type I tumors. Barreta et al. reviewed 50 women with CCOC and EOC treated in their institution and found histologic confirmation of endometriosis in 80% of their study population. Forty-two percent were nulliparous and 42% were premenopausal. The tumor marker CA 125 was elevated in both International Federation of Gynecology and Obstetrics Stages 1–2 disease (mean 614.7 Ui/ml) and Stages 3–4 disease (mean 2361.2 Ui/ml). Patients with endometriosis-associated CCOC presented at an earlier stage. Endometrioid ovarian carcinoma and early-stage CCOC were shown to have good prognosis, while late-stage CCOC had sooner recurrences and shorter overall survival (OS) [43].

Saavalainen et al. reported on the relative risk of ovarian cancer based on the type of endometriosis in their population-based study in 2018. The subtypes of endometriosis were divided into ovarian, peritoneal, and deep infiltrating. Gynecological cancers were obtained from the Finnish Cancer Registry. They reported a standardized incidence ratio of 1.76 (95% CI 1.47–2.08) for ovarian cancer in patients with endometriosis, specifically, the risk of ovarian cancer with endometrioid (3.12 [95% CI 2.15–4.38]), clear cell (5.17 [95% CI 3.20–7.89]), and serous (1.37 [95% CI1.02–1.80]) histology. Of the various subtypes, the ovarian endometriosis subtype was shown to have an increased standardized incidence ratio of ovarian cancer: EOC (4.72 [95% CI 2.75–7.56]) and CCOC (10.1 [95% CI 5.50–16.9]). The peritoneal endometriosis subtype was associated with an increased risk for the endometrioid ovarian cancer (2.03 [1.05–3.54]). They did not see any association with the deep infiltrating endometriosis and ovarian cancer. There was no increase in the risk for endometrial, vaginal, or vulvar cancer in the study group, while a decreased standardized incidence ratio was noted in squamous cell cervical cancer and noninvasive neoplasms of the cervix [44].

Treatment

Medical Management

Medical management of endometriosis includes both pain control and cessation of growth of the endometriotic lesions. Understanding the pathophysiology of endometriosis is important in deciding the appropriate medical management for the disease (Table 41.2) [45].

Nonsteroidal anti-inflammatory, oral contraceptive pills, gonadotropin-releasing hormone agonist, and aromatase inhibitors are commonly used (Table 41.3).

Medical management is usually the first line of treatment for endometriosis and can be delivered either orally, by injection, or using an implantable device. For example, in advanced endometriosis cases, preoperative GNRH agonist injections can decrease the disease burden and allow for more localized resection. It does have limitations as they suppress ovulation and have limited use for patients who desire fertility. Oral contraceptive medications also have venous thromboembo-

Table 41.2 Pathophysiology of endometriosis

lism concerns and carry increased risk in older women, women with migraine with aura, and other chronic medical conditions (lupus, hypertension, liver disease).

Surgical Management

Surgery in most cases is for diagnosis and treatment of endometriosis. Currently, the laparoscopic approach is the preferred method. A thorough evaluation of the abdomen and pelvis to document areas of involvement and biopsy for histology would be necessary both to treat the disease and for future management. Biopsy showing endometrial glands and stroma with inflammation and fibrosis provide definitive diagnosis.

Endometriosis can present in a variety of scenarios: peritoneal endometriosis (superficial endometriosis), endometriomas (endometriotic cysts), and deep infiltrative endometriosis (invasion of anatomical structures and organs created 5 mm beyond the peritoneum). The endometrial tissue could involve the uterosacral ligaments, the rectosigmoid colon, the vagina, and the bladder; therefore, surgical management depends on the location and size the endometrial tissue. Superficial lesions can be excised or ablated/fulgurated with different energy devices such as cautery, the harmonic scalpel, or laser as deemed appropriate. Smaller but deeper lesions can be managed by shaving or disc excision with larger lesions requiring segmental resections. Location-specific considerations will be discussed here.

Ovarian endometriomas occur in 17–44% of endometriosis cases [46]. Oophorectomy is performed in the older patient and if the cyst is potentially malignant. Cystectomy is preferred in the younger patient to preserve ovarian function, but disease recurrence should be discussed with the patient. In the appropriate setting, cystectomy can still be performed in large, multiloculated cysts. Unilateral oophorectomy can be considered in unilateral involvement, but recurrence in the contralateral ovary can be as high as 24.75% in the first 5 years as reported by Hidari [47].

Involvement of a hollow viscus such as the colon and rectum presents other dilemmas. Shaving is described as nodule excision without opening the colon or rectum, while disc excision requires excision of the bowel wall. Lesions <3 cm, unifocal, and involve <60% of the circumference of the bowel wall are amendable to disc excision [48]. More extensive involvement of the bowel wall may require a segmental resection (i.e., low anterior resection with diverting stoma). In cases where rectosigmoid mucosa or submucosal involvement is identified, more than 40% of the bowel circumferences will be involved with endometriosis [48, 49].

As with any surgery, postoperative complications such as rectovaginal fistulas, pelvic abscess, anastomotic leaks, and strictures are a concern. But incomplete excision of the lesions could lead to decrease success in treating symptoms and lack of improvement in fertility. Major complications (those requiring immediate intervention such as surgery) are reported in the range of 2.9–8.4% for deep infiltrating endometriosis without bowel resection and 7.4–25% in patients with DIE and bowel resection [50–53].

In addition to increased complications with bowel resection, there is also a difference in sexual function in patients with bowel resection as reported by Lermann [54]. They compared 89 patients without bowel resection, 87 patients with bowel resection, and 100 control (no history of endometriosis) patients. Preoperatively, the study groups had poorer scores in the German version of the Massachusetts General Hospital Sexual Functioning Questionnaire (KFSP). The KFSP is based on five questions on a six-point scale (1, more than before; 2, normal;3, minimally less than before; 4, less than before; 5, considerably less than before; 6, nonexistent), with questions documenting the level of sexual interest and their ability to reach sexual arousal, experience orgasm, lubrication, and sexual satisfaction. Lermann and colleagues reported poorer KFSP scores in the study groups when compared to the control group. After surgery, the group without bowel resection had improved scores in all categories and was comparable to the control group. The bowel resection group, on the other hand, did not show any improvements in their scores; in fact, they had poorer scores when compared to the control group. Possible explanation for the lower scores could be worse disease, which required more extensive resections (Fig. 41.7).

Colorectal anastomotic stenosis is a known complication after bowel resection. The study by Bertocchi showed endoscopic dilation is a valid option for management of anastomotic stenosis after resection for endometriosis and should be considered. The use of a protective ileostomy is a modifiable factor related to anastomotic stenosis. Patients with deep infiltrating endometriosis may benefit from a combined multidisciplinary approach with colorectal and gynecologic surgeons [55–58].

Recurrence After Surgery

Disease recurrence can happen despite aggressive surgical management. Both patient- and surgery-associated factors have been described. The recurrence rate has been reported

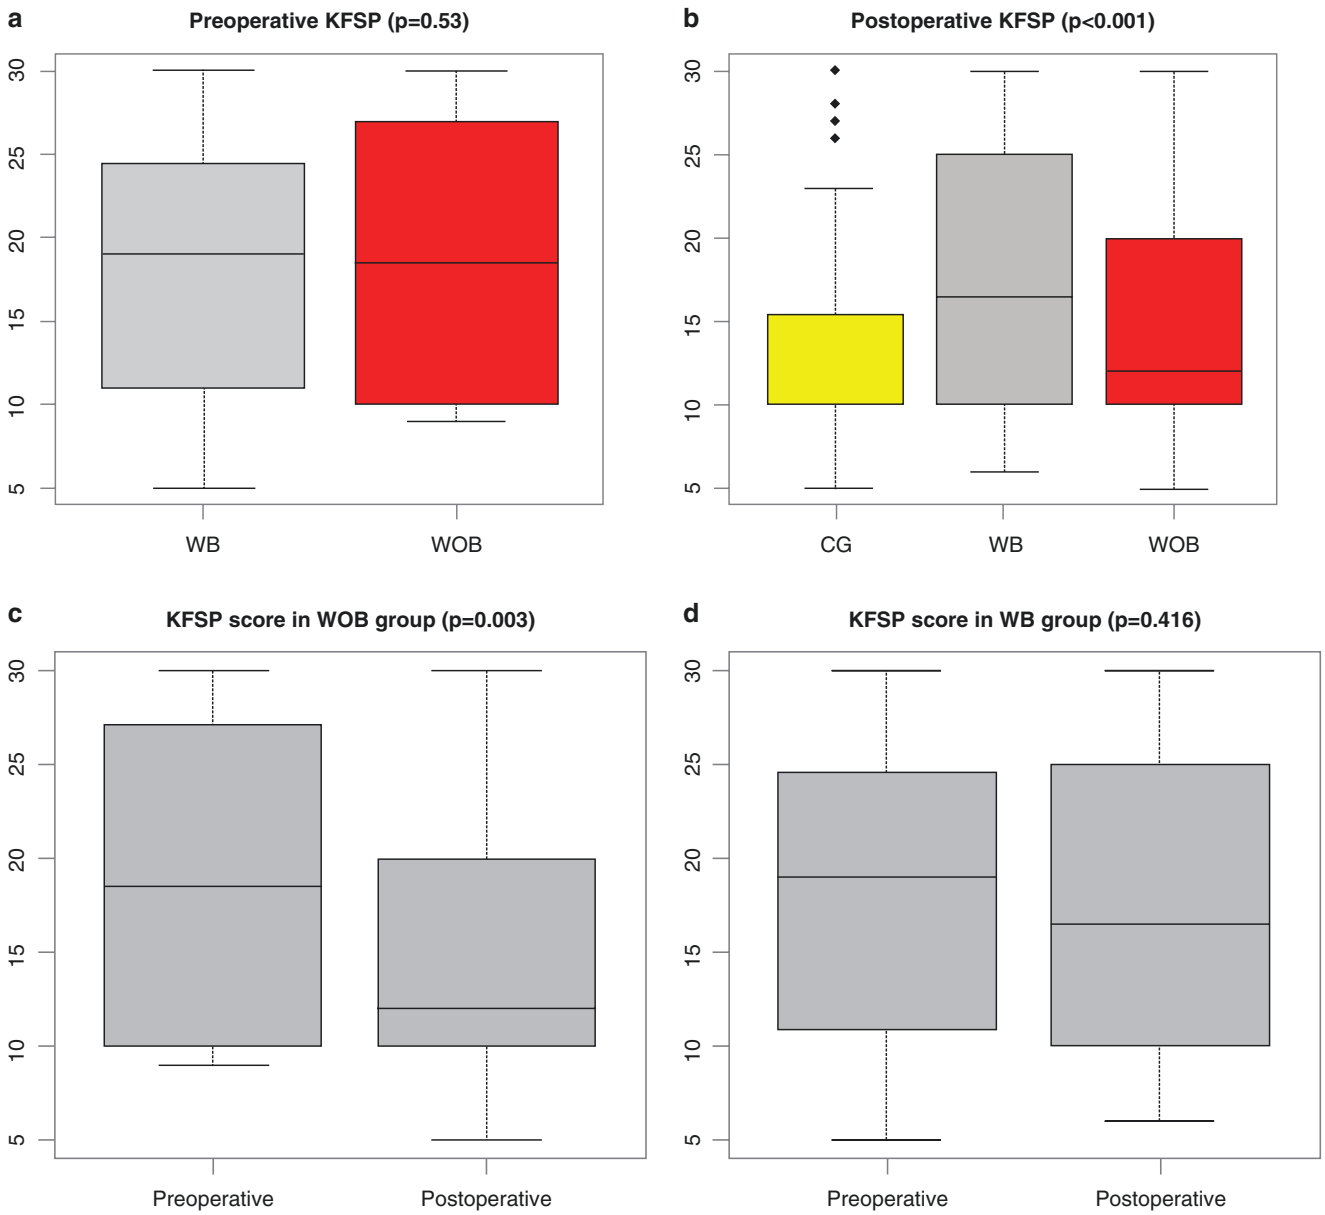

Fig. 41.7 Preoperative and postoperative KFSP scores. (Reused with permission from Ref. [54]. Copyright © Elsevier)

to be between 6% and 67% depending on the criteria used. Current definition of recurrence includes relapse of pain, absence of improvement in infertility, or revisualization of the lesions on US or surgery. Vignali reported recurrence rates at 3 and 5 years of 20.5 and 43.5% for pain and 9% and 28% for clinical recurrence. The success of the initial surgery is a prognostic factor for recurrence in patients undergoing resection for endometriosis [59]. Other risk factors are shown in Table 41.4 [60]. Most agree that disease recurrence after surgery should be managed medically first.

Conclusion

The diagnosis and management of intestinal endometriosis have evolved tremendously over the last 40 years with the widespread availability of laparoscopy and a clear understanding of the necessity to remove all endometrial implants in symptomatic patients. With the advent of stapling devices that facilitate low pelvic anastomoses, the intestinal surgeon should be able to resect the endometrial implants and restore bowel continuity in virtually all patients with minimal morbidity and preserved fertility, when desired. Further improvements in outcomes will probably not occur until a better understanding of the precise etiology and growth of the endometrial implant is elucidated.

Benign Colorectal Disease Trauma of the Colon and Rectum

42

Reza Askari, Ali Salim, and Matthew Martin

Key Concepts

- Most colonic injuries are associated with penetrating trauma.
- Colonic injuries can often be treated by primary repair or resection with anastomosis.
- Extraperitoneal rectal injuries are usually treated with colostomy; washout and presacral drainage are not generally indicated.

Introduction and Historical Perspective

Over the past several decades, the management of colon trauma has changed dramatically. These changes have led to a significant improvement in colon-related mortality. Mortality rates have fallen from approximately 60% during World War I to <10% in the more recent conflicts in Iraq and Afghanistan. A recent multicenter study of modern civilian colon trauma found a colon-related mortality of only 1.3% [1]. Similarly, low morbidity and mortality rates have been reported from several combat operations in Iraq and Afghanistan [2, 3]. Many factors have led to the overall decline in mortality rates. These include quicker transport times, as well as improvements in resuscitation strategies, antibiotic use, and surgical techniques. However, morbidity rates of abdominal sepsis from colon-related injuries remain anywhere from 16 to 33% in various military and civilian studies [4–10].

Prior to World War I, mortality rates from bowel injury approached 100% as management of injuries was largely nonoperative. In fact, laparotomy was largely condemned as a treatment option [11]. By World War II, advances in causality transport and prehospital care led to abandonment of nonoperative management in favor of laparotomy and primary repair of the injured colon [12, 13]. This led to a decrease in the overall battlefield mortality but was still associated with a considerable risk of repair failure, sepsis, and death.

The next shift in the management of colorectal trauma management occurred following the publication of Ogilvie's classic analysis of the management of colon wounds from the North African campaign of 1942 [14]. Ogilvie strongly advocated either fecal diversion of all colonic injuries or repair/resection with proximal diversion. This approach led to a drastic decrease in mortality rates compared to World War I [14, 15]. In fact, the US surgeon general adopted proximal diversion as a formal policy directive for the treatment of all colonic injuries [15, 16]. During the Korean and Vietnam war era, the management of colonic injuries became more anatomically based. Selected right-sided injuries underwent resection and primary anastomosis versus routine colostomy formation for left-sided injuries [17].

For rectal injuries, the principles of wide local washout in addition to proximal diversion were adopted during World War II [17, 18]. This led to a significant decrease in mortality from pelvic sepsis. This approach was further modified during the Korean and Vietnam wars with the addition of distal rectal washout and presacral drain placement. This led to the "4 Ds" of rectal trauma: direct repair, divert, drain, and distal washout.

The more recent combat conflicts in Iraq and Afghanistan over the past decade have led to several published series [2, 3, 19]. The overall trend now is that the majority of colonic injures are being managed with primary repair or resection and anastomosis. Despite this paradigm shift, approximately one-third of patients still underwent diversion in the management of colon-related injuries. An important factor in recent decades is the introduction of the principles of damage control surgery. This has allowed a delay in decision-making as

it relates to anastomosis versus proximal diversion in the unstable patient. Combat damage control data assessing primary repair versus anastomosis have demonstrated comparable and acceptable morbidity rates [19, 20].

Colon Trauma

Epidemiology

Most injuries to the colon are due to penetrating abdominal trauma, with gunshot injuries the most common cause followed by stabbing and impalement. After the small bowel, the colon is the most commonly injured organ in penetrating abdominal trauma [21]. Blunt colonic injuries are less common and account for <10% of injuries found at laparotomy. Lap belt use, particularly without the concomitant use of the shoulder harness, increases the risk of visceral injury. Most colonic injuries secondary to blunt trauma result in superficial injuries from small hematomas or serosal tears. However, a third will have full-thickness colon perforation [22]. Mesenteric tears and ischemic necrosis of the colon should be suspected in injuries secondary to rapid deceleration. In rare cases, colonic injuries can present in a delayed presentation secondary to a colonic wall hematoma or contusion. Blast injuries such as explosions are more likely to lead to injuries to hollow viscera than solid organs, with the colon being the most susceptible. Sometimes, these injuries can present without external signs of abdominal trauma [23].

The American Association for the Surgery of Trauma has now published a grading scale for colonic injuries (Table 42.1) [23]. This is useful in predicating possible complications and evaluation of different therapeutic interventions.

Diagnosis

In penetrating abdominal trauma to the anterior abdominal wall, prompt abdominal exploration accurately identifies the majority of colonic injuries. The highest level of suspicion should be for gunshot wounds to the trunk that have passed from anterior to posterior or crossed the midline from side to side. Perineal or trans-pelvic gunshot wounds should be assumed to have a rectal injury until proven otherwise. For those undergoing a trial of nonoperative management, serial abdominal examinations and computed tomography (CT) scan evaluation with IV contrast are useful both for visualizing injuries and for reconstructing the projectile tract and assessing the structures at risk [24].

Wounds to the flank and back can lead to colonic injuries despite the absence of initial peritoneal irritation or hemodynamic instability. CT scan with triple contrast is useful for delineating such injuries, with 90% sensitivity and 96% specificity [25]. However, it is unclear whether a "triple-contrast" CT scan provides any more sensitivity or specificity versus standard CT with IV contrast only. In most cases, we have found that standard CT is adequate and avoids the inherent delays of administering oral and rectal contrast.

Diagnosis of colonic injury following blunt trauma can be difficult. This is particularly challenging in patients who are unevaluable secondary to drug or alcohol intoxication or the presence of concomitant brain or spinal cord trauma. CT scan remains the diagnostic modality of choice looking for the presence of free air, unexplained free peritoneal fluid, or thickened colonic wall. The presence of free intraperitoneal air mandates exploration for perforated hollow viscus. Free intraperitoneal fluid in the absence of solid organ injury should significantly raise the index of suspicion for bowel injury and mandate either surgical exploration or close serial examinations and possible repeat imaging. Diagnostic peritoneal lavage and laparoscopy have little utility in the contemporary evaluation of patients with suspected colonic injury. Laparoscopy could be useful in stable patients with back, flank, or pelvic wounds. Some of the key aspects of the initial evaluation of colorectal trauma are summarized in Table 42.2.

Table 42.1 Time from injury to surgical management in American wars

Grade	Injury description
I	A. Contusion or hematoma without devascularization B. Partial-thickness laceration
II	Laceration ≤50% of circumference
III	Laceration >50% of circumference
IV	Transection of the colon
V	Transection of the colon with segmental tissue loss

Management

Preoperative Consideration

Once the decision has been made for operative intervention for a suspected colorectal injury, the basic principles of emergency surgery and Advanced Trauma Life Support (ATLS) apply. Attention should be paid to hypothermia prevention and management with active warming devices. The possibility of ongoing bleeding should be anticipated. Emergency-release blood products should be standing by, and type and cross should be performed as soon as possible. A Foley catheter should be placed barring any signs of urethral injury. Antibiotics should be administered as soon as there is evidence of the injury or a decision for laparotomy has been made. The optimal goal is to administer antibiotics 30–60 minutes prior to skin incision. Re-dosing of antibiotics should be performed if the surgery is prolonged or in

Table 42.2 Key elements of the initial trauma evaluation for colorectal trauma

History	Physical examination	Diagnostic and imaging studies
Abdominal pain or complaints	Overall impression ("sick" or "not sick")	Chest x-ray – free air, elevated or blurred diaphragm
Allergies and medications	Vital signs	FAST exam – free fluid in the abdomen or pelvis
Prior abdominal surgery: particularly any prior bowel surgery, hernia repairs, mesh implantation, and aortoiliac surgery	Focused abdominal exam: tenderness, distension, rebound, guarding, bruising, "seat-belt sign." Identify all prior incisions and any hernias	CT scan of the abdomen/pelvic: diagnostic study of choice in most patients. No oral contrast required for initial study. Consider follow-up CT with oral contrast or "triple contrast" for equivocal initial study or concerning clinical picture
Major comorbidities: vasculopathy, congestive heart failure, high-dose steroid use, immunosuppressants	Location of all open penetrating wounds	"Triple-contrast" CT scan: may be useful for penetrating flank or back wounds with suspicion for retroperitoneal colonic injury, but usually standard CT is adequate
Injury mechanism (from high to low risk): Penetrating, missile Penetrating, stab Blunt, high velocity Blunt, low velocity	Logroll and full back/flank exam	Abdominal x-rays: not useful as routine study in blunt trauma. Can be very useful in gunshot wounds for identifying location of fragments and estimating trajectories. Place radiolucent markers on all external wounds
	Pelvic and perineal exam	Diagnostic peritoneal lavage: mainly of historical interest but can be used with equivocal CT findings (i.e., free fluid with no solid organ injury) in patients with unreliable exam
	Digital rectal exam (DRE)	Anoscopy, rigid proctoscopy: penetrating perineal trauma, open pelvic fracture, positive DRE, any other suspicion for rectal injury

Reused with permission from Complexities in Colorectal Surgery (p. 520, Table 34.1) by Steelee SR, Maykel JA, Champagne BJ, Orangio GR, editors. New York; 2014. Copyright © 2014 by Springer Nature

cases where blood loss and transfusion are approaching one whole blood volume. Antibiotics need to only be continued for 24 hours, and there is no benefit of continuing them any longer, even in the face of large-volume contamination [26]. The only exception to this would be the patient with a delayed presentation of a colonic injury, where there is now sepsis and an established intraabdominal infection.

Timing of Injury and Operative Decisions

Most traumatic colorectal injuries will present within the first few hours, and a short delay (2–8 hours) should not impact management decisions. However, occasionally there may be a significant delay to either diagnosis or intervention in a patient with a major colorectal injury. This can result in severe morbidity or mortality. These scenarios may occur in settings where there is a failure to recognize peritoneal signs or imaging findings at initial presentation, the presence of factors that compromise the abdominal exam (i.e., head injury or intoxication), or the masking of peritoneal signs by medications (i.e., steroids) or other patient factors. Generally, delays of more than 8–12 hours in the setting of fecal contamination will alter both the anatomy and the patient physiology, potentially altering surgical decision-making.

As a general principle, in the setting of fecal contamination and peritonitis as a result of delay to operation, there should be a much more liberal use of proximal diversion as opposed to primary anastomosis. However, this decision should be individualized based on the patient's age and comorbidities, the physiologic status during surgery, the location and severity of injury, and the local anatomic factors. Factors that can alter the operative approach in these cases include:

1. Hemodynamic instability secondary to septic shock from fecal contamination
2. Staple line compromise secondary to bowel wall induration and edema
3. Presence of significant bowel distension
4. Mesenteric thickening and shortening that can limit colostomy creation

Operative Management: When to Repair, Resect, or Divert

Several factors go into the decision to repair, resect, or divert. Classically, the teaching has been to categorize injuries as either destructive (>50% of bowel circumference or devascularized) or nondestructive. The recommendation for destructive injuries is to resect the injured area, whereas primary repair is recommended for nondestructive wounds. However, several other factors must be considered. These are outlined

in Table 42.3. Important factors include not only the size of the injury but the numbers and locations.

Injuries secondary to high-velocity gunshot wounds require that the wound edges be debrided back to healthy tissue before closure. It is important to remember that missile injuries can cause extensive tissue damage or even direct thermal injury (Fig. 42.1), which will often lead to breakdown of the closure if the edges have not been adequately debrided. Another important factor is the status of the mesentery, as this will determine the adequacy of the blood supply to the area. The classic "bucket-handle" deformity is a large tear in the mesentery without injury to the colon wall, which may occur in blunt trauma from rapid deceleration. The bowel will often appear uninjured but should be resected due to the large area of devascularization and the potential for delayed perforation or anastomotic leak (Fig. 42.2).

Table 42.3 Factors to guide primary repair versus resection for colon surgery

Primary repair	Resection
Small size (nondestructive)	Destructive (>50% circumference or devascularized)
Single injuries or multiple with adequate spacing	Multiple injuries with short spacing
Clean margins (after debridement of edges)	Inflamed or necrotic edges
Minimal or no mesenteric injury	Large mesenteric hematoma or laceration
Tension-free closure	Cannot be closed without tension
Healthy surrounding bowel	Major edema, inflammation, bowel wall hematoma
No major pathology present	Major pathology present (cancer, diverticulitis, etc.)
Closure leaves widely patent lumen	Closure would narrow lumen (>25%)
Low-velocity wound	High-velocity wound
At risk for short gut syndrome with resection	Adequate bowel length after resection
No adjacent pancreatic injury or leak	Pancreatic injury/leak adjacent to injury

Fig. 42.1 Missile wound to the bowel with small perforation but significant thermal injury to the surrounding bowel wall. This injury should be completely debrided and then repaired or resected. (Reprinted [adapted] from Complexities in Colorectal Surgery (p. 524, Fig. 34.3) by Steele SR, Maykel JA, Champagne BJ, Orangio GR, editors. New York; 2014. Copyright © 2014 Springer Nature)

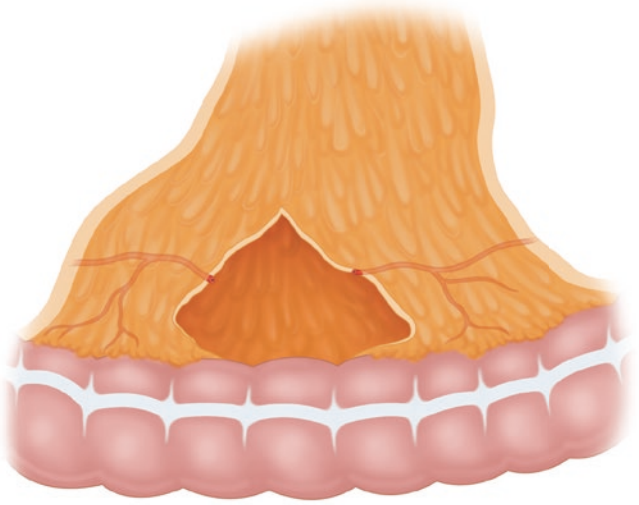

Fig. 42.2 Large tear of the mesenteric border of the bowel ("bucket-handle" deformity) from blunt deceleration forces. This usually requires resection of the now devascularized bowel segment to avoid subsequent ischemic complications

While each individual colon and rectal injury type and location may have an associated "textbook" answer for the most appropriate operation to perform, this often does not consider the wide variety of presentations, number of injuries, presence of associated injuries, and patient physiology.

Evidence and Practice Guidelines

In 1979, Stone [26] performed the first reported trial of patients randomized to exteriorization or colostomy versus primary repair for small colonic injuries (n = 268). This study demonstrated a tenfold reduction in the incidence of complications with primary repair and a significantly increased hospital stay and cost associated with colostomy. Several years later, studies by Chappuis [27], Sasaki [28], and Gonzalez [29] together randomized more than 300 patients to primary repair or colostomy. These studies showed that primary repair or anastomosis was safe and effective; in fact, they reported fewer complications in the repair group as compared to those who underwent proximal diversion (Table 42.4).

Table 42.4 Mortality rate of penetrating colorectal trauma in American wars

	Primary repair		Colonic diversion	
Study	No. of patients	Rate of abdominal septic complications (%)	No. of patients	Rate of abdominal septic complications (%)
Chappuis et al. [27]	28	14.3	28	17.9
Sasaki et al. [28]	43	2.3	28	28.6
Gonzalez et al. [29]	89	18	87	21
Total	100	13.1	143	21.7

A further randomized study by Kamwendo [30] in 2002 confirmed the safety of primary repair. This study was important in that it included patients with delayed presentation, contamination, associated injuries, and shock. In fact, similar to the outcomes of prior studies, it showed that primary repair/anastomosis was superior to colostomy even in the high-risk patients with contamination. In a sense, the colon trauma literature largely mirrors the diverticulitis literature, with better outcomes consistently reported with resection and primary anastomosis versus resection and colostomy or proximal colostomy alone.

Multiple other prospective observational trials have also added valuable evidence upon which to base recommendations [4, 7, 31–34]. The majority of these support the use of primary repair or anastomosis without diversion for all types of colonic injury. This has led to the abandonment of the dogma that right- and left-sided injuries should be treated differently and that left-sided injuries mandated a colostomy.

The American Association for the Surgery of Trauma (AAST) conducted a multicenter randomized prospective trial of diversion vs. resection and anastomosis for destructive colonic injuries that was published in 2001 [1]. In this study, there were 297 patients; 66% were managed with primary anastomosis and 33% by diversion. Colon-related mortality was 1.3%, all in the diversion group. Anastomotic leak rate was 6.6% with zero mortality. Risk factors for abdominal complications were severe fecal contamination, transfusion of more than four units of blood within the first 24 hours, and inappropriate antibiotic selection. If all three factors were present, the rate of abdominal complications reached 60%. The authors concluded that resection with anastomosis is the treatment of choice in all destructive colonic injuries regardless of severity of injury.

However, the low incidence of severe (destructive, high-velocity, etc.) colonic injuries in this trial does limit the conclusion about the potential benefit of fecal diversion in select high-risk cases. These findings have also been misinterpreted by some as indicating that colostomy should be performed in patients with certain risk factors (severe contamination, transfusion requirement, etc.). In actuality, these factors increased the risk for abdominal complications regardless of whether ostomy or primary anastomosis was performed and should not be used as independent criteria for performing a colostomy.

The evolution of damage control laparotomy (DCL) for devastating abdominal trauma has led to a significant reduction in morbidity and mortality. Abbreviated laparotomy and resuscitation in the intensive care unit help to avoid, or more rapidly correct, the lethal triad of coagulopathy, acidosis, and hypothermia [35]. The management of colonic injuries in these situations has evolved as well. Early in the DCL era, colostomy was considered the treatment of choice. However, several studies supported selected repair or resection and delayed anastomosis after DCL, citing the potential ability to inspect the suture or staple line at subsequent operations [36–38]. Others voiced more caution in this patient population, particularly if there was a persistent need for vasopressors [39]. In 2009, Weinberg's retrospective review showed DCL patients that had resection with anastomosis had higher rates of complications compared to colostomy [40]. In 2011, Ott reported an enteric leak rate of 27% for patient who had a DCL, with higher leak rates associated with transfusion requirements and left-sided colonic injuries [41].

More recently, however, several studies have refuted the higher rates of complications for delayed anastomosis in patients that undergo DCL [42]. A recent multicenter retrospective cohort study performed across three Level I centers by Tatebe in 2017 indicated that DCL was not associated with increased enteric leaks, fistula, SSI, or intraperitoneal abscess despite nearly two-third having delayed repair. However, the study was underpowered, and a prospective trial was still recommended [43].

The Eastern Association for the Surgery of Trauma published its initial guidelines for the management of penetrating colonic injuries in 1998 [44]. More recently, in 2018, a meta-analysis was performed, and the guidelines were updated. The most recent guidelines recommend repair or repair and anastomosis in low-risk patients (no signs of shock, hemorrhage, severe contamination, or delay to surgical intervention). In high-risk civilian trauma patients (delay >12 hours, shock, associated injury, transfusion >6 units of blood, contamination, or left-sided colonic injuries), including those who undergo DCL, the society *conditionally* recommends that colon repair or resection and anastomosis be performed rather than mandatory colostomy except in patients with the most severe injuries [45].

Technical Considerations

In managing traumatic injuries, the surgeon is often faced with the need to make decisions rapidly with imperfect and incomplete information, often in suboptimal and chaotic settings. The patient should be widely prepped and draped, including the lateral abdominal wall in case a colostomy or ileostomy is needed. For the unstable or actively bleeding patient, a generous midline incision should be made at the start to allow rapid access to all quadrants of the abdomen. For the stable patient, a smaller laparotomy incision can be considered and may be extended based on the injuries that are identified. If a large amount of hemoperitoneum is discovered on entering the abdominal cavity, even in the "stable" patient, then all attempts at a "minilaparotomy" should be abandoned, and the incision should be extended from the xiphoid to several centimeters above the pubic symphysis.

During the initial exploration for penetrating trauma, it is important to optimize the operative exposure and visualization. This can often be obtained by taking a few minutes to set up a self-retaining retractor of choice. Gross spillage should be controlled with quick suturing or stapling as soon as exsanguinating hemorrhage is stopped. This does not have to be a definitive resection or repair. In penetrating trauma, paracolic and retroperitoneal hematomas should be fully explored. Primary repair can be safely accomplished utilizing a number of methods. There is little difference between single- and double-layered suture techniques, with attention to careful suture placement and complete defect closure more important than how many layers are performed. Perforations that are within a few centimeters of each other are best treated by removing the intervening bridge of tissue and performing a single repair (Fig. 42.3) or resecting the involved segment. There is little difference between stapled and sutured anastomosis in terms of leak rates, anastomotic complications, or function. There is no need for colonic lavage even with left-sided anastomosis. In general, ileocolostomy is associated with fewer leaks than colocolostomy.

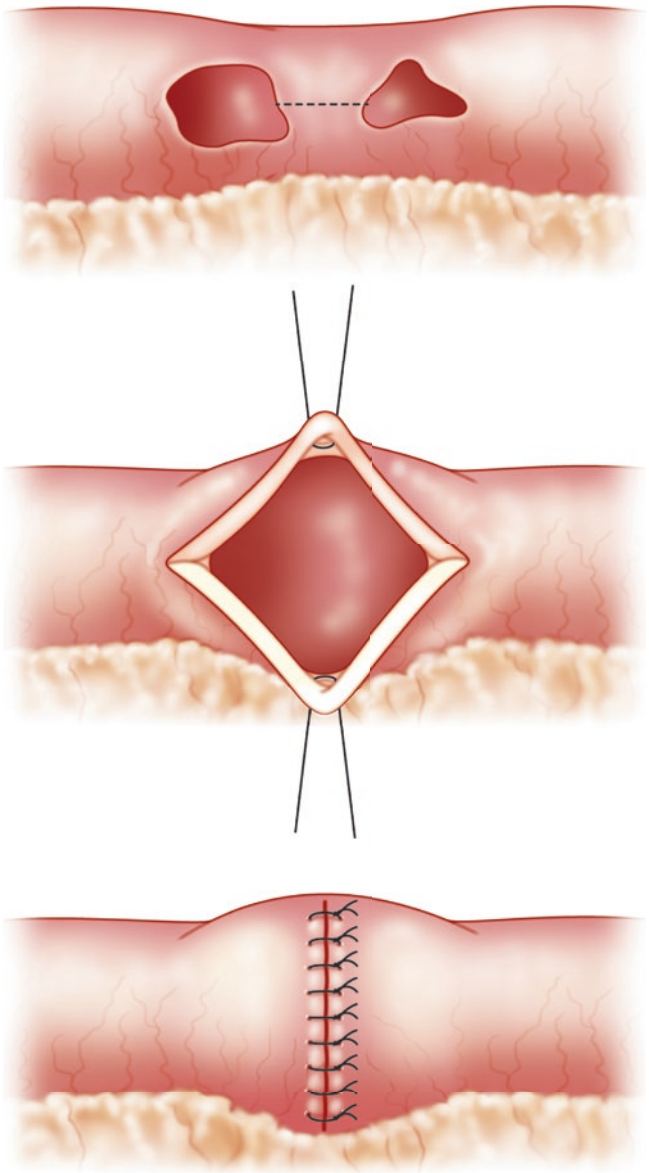

Fig. 42.3 The intervening bridge of tissue between two closed perforations can be removed, and the resulting single defect can be closed transversely

Should DCL be necessary, the colon can be left in discontinuity at the initial exploration. The key concept of DCL is to perform an abbreviated laparotomy that addressed only active bleeding and control of gastrointestinal contamination. The classic indications for DCL are alteration in patient physiology marked by acidosis, hypothermia, and coagulopathy. Detailed exploration and reconstruction are deferred to a later time. Other indications include the presence of multiple complex injuries that will require prolonged surgical reconstruction and the presence of questionably viable bowel that will need a second-look operation. The abdomen is temporarily closed, and resuscitation is continued in the intensive care unit. Once restoration of normothermia and correction of acidosis and coagulopathy are accomplished, the patient is returned to the operating room for further treatment. Every attempt should be made to close the abdomen early, as earlier closure has been shown to decrease complication rates. There is also no optimal or standard time interval between operations that should be utilized. This decision should be based on the patient's injuries and response to resuscitation, and not a predetermined time interval. We strongly recommend avoiding intervals longer than 48 hours in the presence of stapled-off bowel, as this inevitably leads to proximal dilation, edema, and increased fluid requirements.

In most cases, there are multiple intraoperative decisions that need to be made quickly which will have a significant impact on both short-term and long-term outcomes. Table 42.5 provides a summary of these key decisions with

Table 42.5 Key intraoperative management issues and decision in colorectal trauma

Key decision	Factors to consider	Technical issues/pearls
Primary repair or resection?	Size of injury Shape of injury (linear, round/stellate) Single or multiple Tissue quality Mesentery status (rents, hematomas, devascularized segment)	Debride injury or burned tissue Connect close injuries rather than leaving "bridges" Evacuate large mesenteric hematomas Close mesenteric tears Resect segment with "bucket-handle" mesenteric defect
Damage control?	Patient stability Transfusion requirement Acid/base getting better or worse? Multiple injuries? Another reason for a "second look" (i.e., borderline bowel visibility)	Make decision early in case Proceed if patient improving; terminate if getting worse Vacuum-assisted temporary closure works best Usually no need for other drains
Anastomosis or ostomy?	Patient baseline status (age, comorbidities, meds) Physiologic status Quality of the tissues Other injuries and proximity to anastomosis Body habitus, ability to properly site an ostomy	Consider difficulty and risk of ostomy takedown Be wary of anastomosis with an associated pancreatic injury! Obesity increases difficulty and complications with ostomy
Anastomosis: hand-sewn or stapled?	Operative time Other injuries to address Personal experience and comfort Tissue quality, edema Anatomic area and bowel alignment Available equipment	No difference in leak or complication rates in most series Hand-sewn potentially more secure with suboptimal tissue quality, bowel wall edema Laparoscopic staplers great for pelvis, hard to reach areas, or sharp angles
Ostomy: loop, end, or others?	High-risk anastomosis that needs protection? Need access to distal bowel segment? Body habitus Mesentery – shortened, edematous	Loop may reach the skin easier with obesity or shortened mesentery May not get complete fecal diversion with a loop Remember the "end-loop" option (see text) Use an ostomy bar if any tension or obese patient Wrap ostomy in Seprafilm® for easier takedown
Leave a drain?	No indication for routine drainage of bowel anastomosis Widely drain any other adjacent injuries (pancreas, bladder, etc.) Other reasons: associated abscess cavity, control ascites in cirrhotic patient	Avoid direct contact of drain with anastomosis Larger sump drains usually not beneficial Make exit site remote from incision and any ostomy
Place a feeding tube?	Degree of bowel injuries and surgery Estimated need for prolonged NPO status Estimated inability to take oral nutrition Need for feeding access as well as gastric decompression? Pancreatic or duodenal injury?	Generally avoid making additional holes in the bowel in the trauma setting Stamm gastrostomy relatively safe and secure Higher complications with jejunostomy tubes with little benefit Consider intraoperative placement of nasojejunal tube

the associated factors and technical pearls that should be considered. This table is by no means all-inclusive but does highlight many of the common decisions.

Rectal Trauma

Epidemiology

Rectal injuries, while infrequent, are associated with a higher risk of missed or delayed diagnosis, as well as a significant risk of morbidity and mortality. These injuries are most often seen in the setting of penetrating trauma in the civilian population. Gunshot wounds account for greater than 80% of these injuries [3]. Accidental or intentional impalement, iatrogenic endoscopic and urologic injuries, and rectal foreign bodies account for the rest. In the military setting, rectal traumatic injuries occur at a higher rate and are typically more destructive, as they are often due to higher-velocity missile or blast mechanism [46].

Diagnosis

A high degree of suspicion is required to avoid the significant morbidity and mortality that can occur with a missed or delayed diagnosis. While the overall incidence of these injuries is low, certain injury patterns or mechanisms should

raise suspicion and prompt particular attention to the anorectal evaluation. Any penetrating trauma to the buttock, groin, proximal thighs, perineum, or sacra area should raise concern for an associated anorectal injury. Additionally, any trans-pelvic gunshot wound should be assumed to have a rectal injury until proven otherwise. Also, any injuries to any of the other closely associated organs or structures such as the bladder, uterus, vagina, or iliac vessels should prompt an evaluation for concomitant rectal injuries. In blunt trauma, an isolated anorectal injury is rare and is almost always associated with other major pelvic/perineal injuries and a high-velocity mechanism. Any pelvic fractures, particularly an "open-book" fracture, or those with major posterior pelvic/sacral disruption, can cause rectal injury from bone fragments or shearing forces (Fig. 42.4). Additional scenarios that are risks for blunt rectal trauma include straddle-type injuries and any fall with perineal impalement.

The presence of gross blood on digital rectal examination is highly suggestive of rectal injury and should mandate further evaluation. However, this exam finding lacks adequate sensitivity or specificity and should not be considered a definitive test to rule in or rule out a rectal injury. Sigmoidoscopy, either rigid or flexible, should be performed and has an expected diagnostic accuracy of 80–95% [47]. Care must be taken not to worsen a potential defect during the exam by aggressive scope advancement or insufflation [48]. A careful endoscopic exam with full 360-degree circumferential inspection must be performed, as often the signs of injury can be subtle. Visualization of a full-thickness defect of the rectal wall is relatively uncommon, and frequently the only endoscopic finding is a small hematoma at the site of injury.

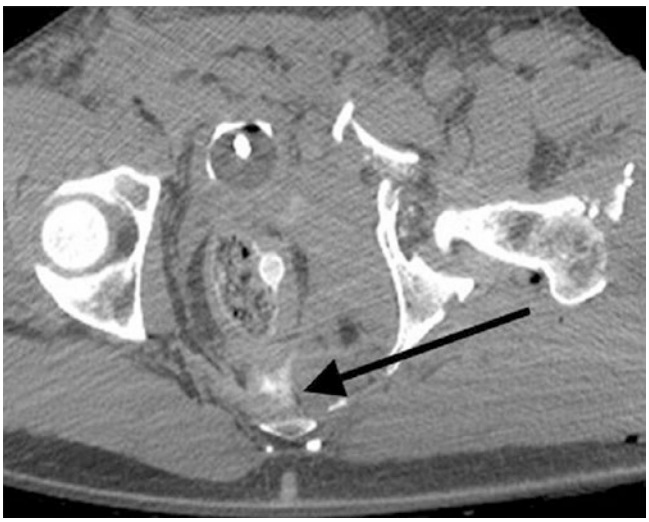

Fig. 42.4 Computed tomography showing rectal injury with contrast extravasation from a severe pelvic fracture

Table 42.6 AAST organ injury grading scale for injury to the rectum

Grade	Type of injury	Description of injury
I	Hematoma	Contusion or hematoma without devascularization
	Laceration	
II	Laceration	Laceration <50% of circumference
	Laceration	
III	Laceration	Laceration ≥50% of circumference
IV	Laceration	Full-thickness laceration with extension into the perineum
V	Vascular	Devascularized segment

Reused with permission from Fundamentals of Anorectal Surgery (Chap. 29, Table 28.1) by Beck DE, et al. (eds). 2019. Copyright © 2019 by Springer Nature

Computed tomography (CT) is now the most common radiologic adjunct in the trauma setting. It is often ordered with only IV contrast. However, should a rectal injury be suspected, the use of triple-contrast CT imaging (IV, oral, and rectal) can improve its diagnostic accuracy [49, 50]. The American Association for the Surgery of Trauma (AAST) has defined injuries to the rectum based on the degree of injury thickness and extent of circumference involved (Table 42.6) [51]. Similar to colonic injuries, rectal injuries are classified as either "destructive" or nondestructive." Any injury involving greater than 50% of the circumference of the bowel wall or with associated mesenteric injury that compromises the perfusion of the segment of bowel is considered "destructive."

Anatomic Considerations

The anatomy of the rectum is unique. The proximal anterior and lateral portions of the upper two-third of the rectum are covered with peritoneum, while the posterior surface is extraperitoneal. The distal third of the rectum lies completely extraperitoneal. This portion of the rectum is surrounded by a thick connective tissue and fat layer which contains the neurovascular supply. Since the dissection required to expose the extraperitoneal rectum is much more extensive and difficult compared to the intraperitoneal portion, the optimal operative strategy in rectal injuries differs vastly between intraperitoneal and extraperitoneal injuries.

It is also important to have a clear understanding of the anatomic locations and relationships of other key pelvic structures and organs in the operative exposure and repair of a rectal injury. These structures include the bladder anteriorly, the sacrum and sacral venous plexus posteriorly, and the iliac vessel and ureters posterolaterally. In males, the prostate and seminal vesicles and, in females, the uterus and vagina will also be found anteriorly.

Management of Intraperitoneal Rectal Injuries

These injuries have historically been managed like that of a distal left colon, with near-universal use of a diverting colostomy even for relatively small isolated injuries. However, there is little reason to treat these injuries any differently than injury to other portions of the colon, and a diverting ostomy should no longer be considered mandatory or "standard of care." The use of primary repair without diversion is a safe option in most nondestructive injuries in hemodynamically stable patients. A larger, more destructive injury to the intraperitoneal rectum should be managed with segmental resection of the injured portion. Following segmental resection, a decision for anastomosis versus ostomy must be made.

Using the same risk scaling approach described earlier in the chapter, we recommend an ostomy without anastomosis or an anastomosis with a protective proximal stoma in high-risk and select moderate-risk patients. Low-risk patients and select moderate-risk patients can safely undergo primary anastomosis as described previously for colonic injuries. Another important factor to consider is the location of the resection that is required. In general, if the resection has to be carried out down to the mid or lower third of the rectum, we recommend an anastomosis with a protective loop ileostomy. Subsequent elective return to the operating room and ileostomy reversal can be done as early as 4–6 weeks after the initial surgery. This can almost always be performed as a local procedure without the need for a repeat laparotomy.

Management of Extraperitoneal Rectum

Classically the teaching for the management of extraperitoneal rectal injuries has involved the "4 Ds": diversion, direct repair, distal washout, and drain placement. In reality, very few patients require all four (or even three) of these interventions, and the mainstay of care for most rectal extraperitoneal rectal injuries should be primary repair (if easily accessible) and proximal diversion. The most important of Ds will be proximal diversion as primary repair of an extraperitoneal rectal injury can be challenging due to its location, presence of bleeding, and proximate anatomic structures. Whether an end or loop colostomy is performed depends on the extent of the injury, associated injuries, body habitus, and operative approach. Creation of a loop colostomy as opposed to an end colostomy has been shown to provide appropriate fecal diversion and avoids the added risk of complicated takedown procedures [52, 53]. As with the loop ileostomy, a loop colostomy can frequently be reversed via a local procedure without the need for repeat laparotomy.

It is recommended that direct repair of extraperitoneal injuries be performed only when they are easily accessible without significant dissection or if the injury is encountered during the exposure of an associated injury [54]. While injuries to the proximal extraperitoneal rectum can be carried out via abdominal mobilization, a very distal injury will be best approached from inside the rectum.

Another option that can be considered is to resect the damaged segment, perform a primary anastomosis, and protect it with a diverting loop ileostomy [55]. While there may be some debate as to whether a loop ileostomy provides adequate diversion for a distal anastomoses, a modification of it to create a stapled end-loop ileostomy (or colostomy), with the distal stapled end buried in the subcutaneous tissue for future identification can be considered (Fig. 42.5) [56, 57]. This modification will provide complete fecal diversion and obviate the need for a future laparotomy when it comes to time for reversal.

When it comes to the other 2 Ds, distal washout and drain placement need only to be used infrequently. When there is a large volume of retained stool in the rectal vault and the injury has been controlled or excluded, then a distal washout can be performed. Similarly, presacral drainage has lost significant support over the years, and in fact it is not necessary in the vast majority of the cases. A prospective trial in 1998 randomized patients with extraperitoneal rectal injury to presacral drain placement versus no drain and found that there was no benefit of presacral drains in reducing infectious complications [58]. Some still advocate for the use of a presacral drain for those injuries that are inaccessible and cannot be repaired or that have a heavy degree of presacral contamination. This should be done in conjunction with a diverting ostomy [59, 60]. Figure 42.6 shows the location of a properly placed presacral drain. This can be placed by making a curved transverse incision posterior to the anus and bluntly dissecting the presacral space to the level of the injury.

Similarly, distal washout of the rectum has not shown to have any benefit in the routine management of penetrating civilian rectal trauma. Those supporting distal rectal washout claim that removal of remaining stool in the defunctionalized rectal vault will decrease the risk of sepsis. Others argue that forceful irrigation of liquid into the rectal vault will only increase the amount of local spillage and can push fecal material into otherwise unaffected tissue planes. Overall, the authors of this chapter do not routinely employ distal rectal washout in the setting of rectal trauma.

Guidelines

The Eastern Association for the Surgery of Trauma (EAST) has released practice guidelines for the management of nondestructive extraperitoneal rectal injuries. They *conditionally* recommend *for* proximal diversion and *against* presacral drainage and distal rectal washout. Keep in mind that these

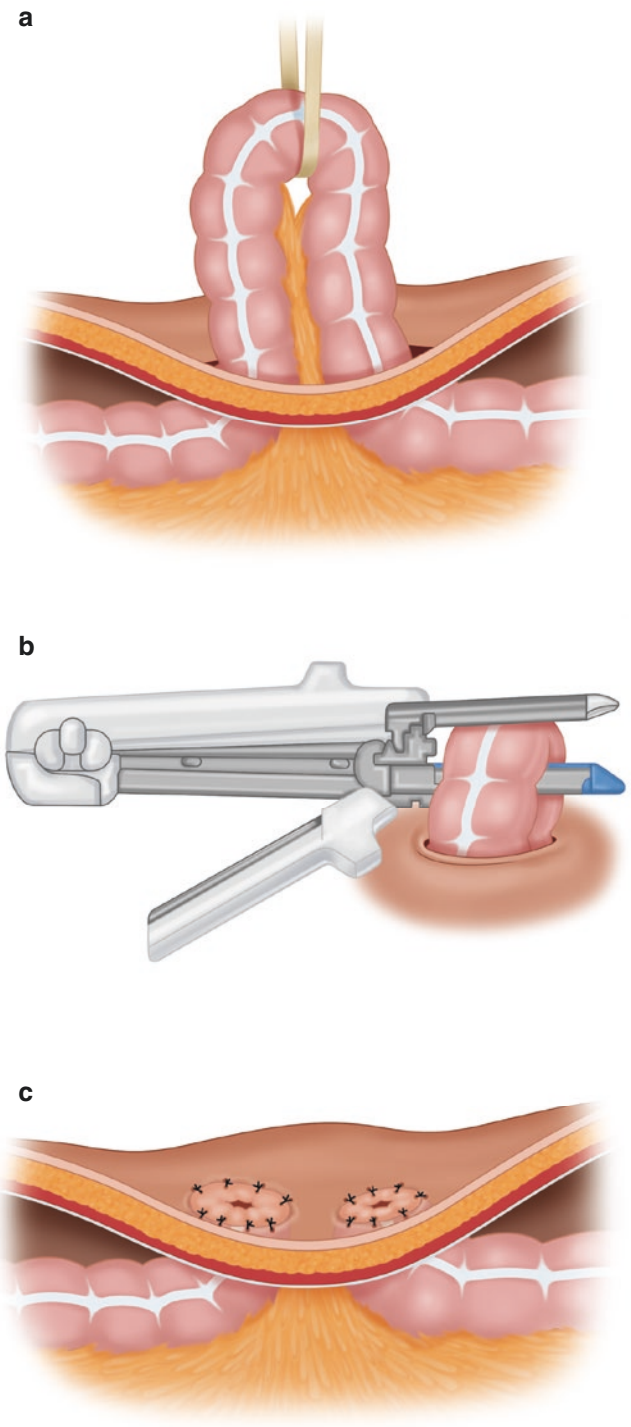

Fig. 42.5 Technique for end-loop ostomy (colon or ileum). (**a**) Loop of the bowel is delivered, (**b**) the bowel is divided at the site of the planned ostomy, and (**c**) proximal end is matured, and the distal stapled end is secured in the subcutaneous position for easy future access and restoration of continuity

recommendations are based on evidence graded as "very low" by the committee [61]. However, this represents the best currently available evidence and synthesis of the disparate literature on this topic.

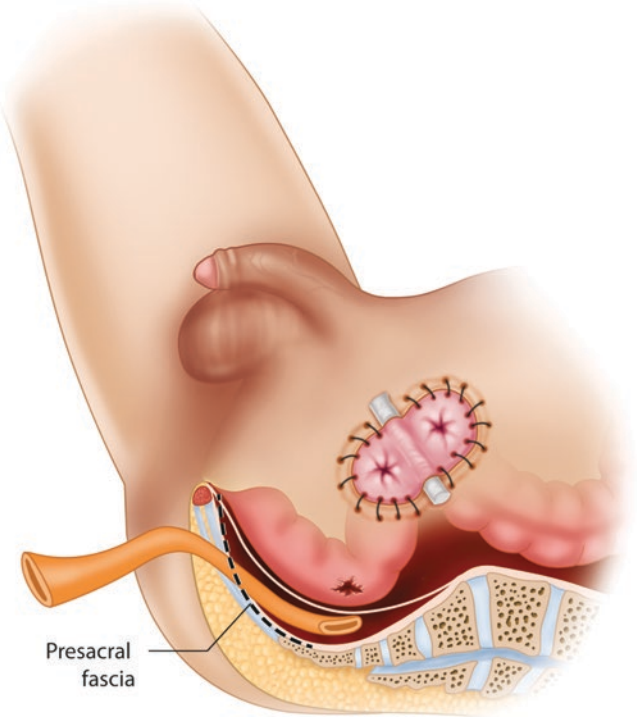

Fig. 42.6 Placement of drains in the presacral space, anterior to Waldeyer's fascia, up to the level of colorectal injury. (Reprinted (adapted) from Fundamentals of Anorectal Surgery (Chap. 29, Fig. 28.2) by Beck DE, et al. (eds). 2019. Copyright © 2019 Springer Nature)

The American Association for the Surgery of Trauma [62] published a recent large multicenter study of traumatic rectal injuries in 2017. This analysis of 758 rectal injuries is the largest in the literature and provides additional support for the current trends outlined above. For intraperitoneal rectal injuries, those managed with a diverting colostomy had twice the complication rate (22% vs. 10%) compared to those managed with primary repair or primary anastomosis without diversion. For the extraperitoneal rectal injuries, the majority were managed with proximal diversion with or without direct repair of the injury. On multivariate analysis, the use of distal rectal washout and presacral drainage were independent risk factors for increased abdominal complications (odds ratios of 3.4 and 2.6, respectively) [62].

We recommend that if the injury is limited and easily accessible with minimal dissection with either transanal or abdominal exposure, then primary repair with or without loop colostomy diversion should be performed. Destructive or inaccessible injuries should be diverted with loop colostomy. Distal rectal washout and presacral drainage are not routinely recommended but can be considered in highly select indications.

Anal Trauma

Epidemiology

While non-obstetric trauma to the anus or sphincter is rare, the onset of the recent wars in Iraq and Afghanistan has led to an increase in perianal and pelvic wounds due to ground-level improvised explosive devices (IEDs). These injuries are often seen in conjunction with other massive destructive injures to the perineum, extremities, and trunk. In the civilian trauma setting, the majority of anal trauma is seen with penetrating injuries to the perineum and straddle or impalement injuries or in association with complex open pelvic fractures.

Diagnosis

The diagnosis of anal injuries is usually readily apparent on history and physical exam during the secondary survey. If the patient is awake and able to respond appropriately, then a history of perineal trauma can usually be elicited as well as any current complaints of anal or perianal pain or pressure. The perineum and anus should be evaluated thoroughly; the majority of clinically significant injuries are readily diagnosed by visual inspection. The perineum should be carefully inspected and palpated. The sphincter tone and voluntary function should be assessed with a digital rectal examination. Females should undergo a vaginal exam as well.

If an injury is suspected or identified, a careful examination in the operating room should be done to assess for involvement of the anal sphincters. Gentle anoscopy/proctoscopy should be performed both to evaluate the anal canal and look for associated rectal injury. Particular care should be taken in patients with obesity as even major injuries can be remained hidden until the buttocks and any redundant tissue is adequately retracted to expose the perianal area. It is also critical to obtain a detailed history (as possible) from the patient regarding any prior trauma, preexisting anal/perineal problems, and existing problems with fecal continence. These factors may have significant impact on the evaluation and subsequent management decisions.

Management

Minor injuries to the anal canal can be treated with either local wound care alone or a transanal debridement back to healthy tissue and primary suture repair. Care must be taken to preserve the anal sphincter mechanism to the extent possible and to avoid narrowing of the anal orifice or canal. Simple lacerations to the anal canal involving the sphincter muscles can be repaired primarily with absorbable suture. In all anal injuries, it is critical to clearly identify and document the exact size of the wound, the location relative to the anal verge and dentate line, and the presence and extent of injury to any related structures such as the urethra, penis or scrotum, vagina, bladder, pelvic nerves, bony pelvis/sacrum, and spine/spinal cord.

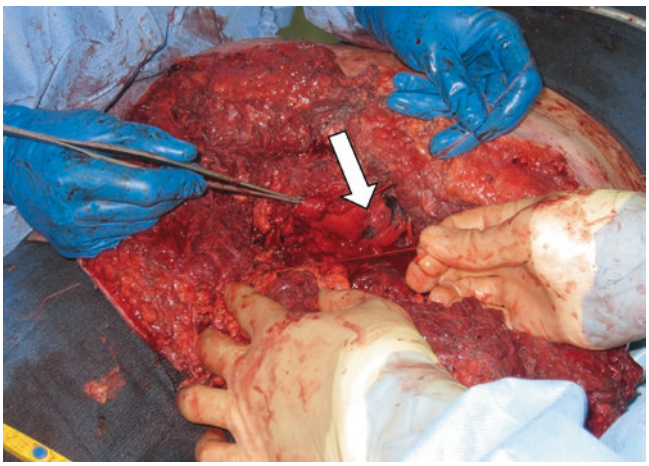

Fig. 42.7 Massive perineal blast wound with destruction of the sphincter complex and exposed distal rectum (arrow). These patients warrant immediate operative intervention to prevent exsanguination, perform debridement, and in this case perform diverting colostomy. (Reprinted (adapted) from Fundamentals of Anorectal Surgery (Chap. 29, Fig. 28.4) by Beck DE, et al. (eds). 2019. Copyright © 2019 Springer Nature)

Massive injures to the perineum can result in significant loss of tissue and complex wounds (Fig. 42.7). Nonviable tissue should be debrided to healthy tissue, but excessive debridement should be avoided at the first operation in order to minimize the loss of sphincter muscle and maximize future options for wound closure. The cut ends of the sphincter muscles should be tagged with sutures for future repair if not repaired at the initial operation. A colostomy is usually indicated in complex perineal wounds involving the anal sphincters and should be performed as early as possible. Although relatively uncommon, large destructive wounds (as seen with military blast injuries) with injury to both the anus and extraperitoneal rectum may require a proctectomy to control contamination and pelvic sepsis.

A vacuum-assisted wound closure device can be used on the perineum while serial debridement is ongoing (Fig. 42.8). It is imperative to investigate the genitourinary tract as many patients will have combined injuries. Older studies have shown good functional outcomes with delayed sphincter repair [63]. Anorectal manometry has been shown to predict functional outcome and should be performed prior to colostomy reversal. Due to the complex nature of these injuries and the local anatomy, we recommend early involvement of a multidisciplinary team including a colorectal surgeon to

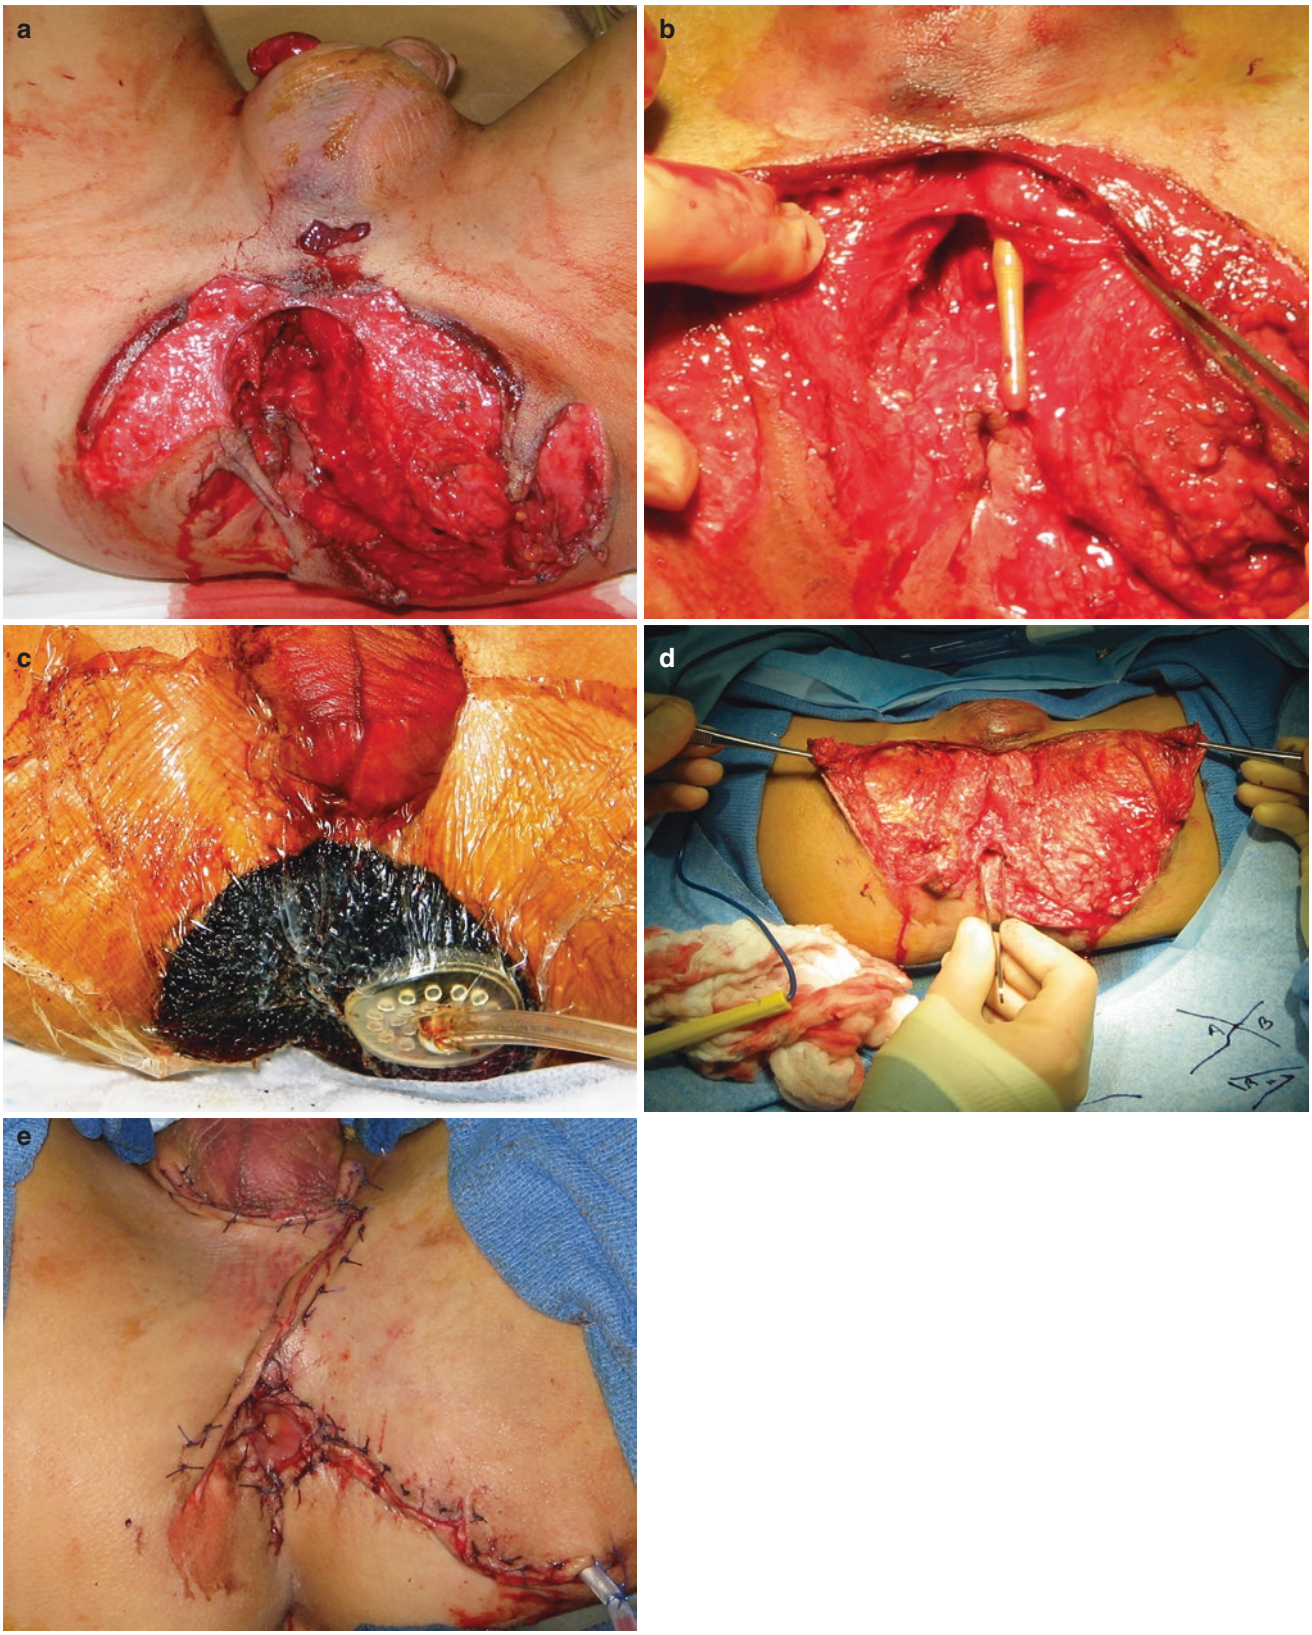

Fig. 42.8 (**a**–**e**). Destructive perineal and anal injury. (**a**) Mortar fragment entered the right hemiscrotum and exited the perineum, causing a massive injury. (**b**) Urethral transection was repaired through the perineum. (**c**) Serial debridements and wound vacuum-assisted closure changes created a healthy wound bed. (**d**) Flaps were constructed to facilitate closure. (**e**) After sphincteroplasty, the final wound closure. Colostomy was closed 6 weeks later and patient had excellent continence

assist with planning and subsequent management. The use of pelvic floor physical therapy with sphincter exercises and biofeedback can improve tone and squeeze mechanics, with improvement of continence in the setting of minor traumatic sphincter injuries [63, 64]. Those individuals with poorly or non-functioning sphincter complexes (or preexisting incontinence) are usually best served with a permanent colostomy.

Inflammatory Bowel Disease: Pathobiology

43

Benjamin D. Shogan and Pokala Ravi Kiran

Key Concepts

- The pathophysiology of IBD is incompletely understood but thought to be multifactorial and a complex interaction between genetic, environmental, microbial, and immune factors.
- While hundreds of susceptibility genetic loci have been identified to increase the risk of disease, all identified loci individually contribute only a small percentage of the expected heritability in IBD.
- The significantly increasing incidence of IBD in developing urban countries worldwide lends strong evidence that environmental factors may play the dominate role in its pathogenesis.
- The composition of the gut microbiota is significantly different in patients with IBD and has increased colonization of *Fusobacterium* and members of the Proteobacteria phylum and decreased colonization of Firmicutes and Bacteroidetes. Yet, no single organism has been identified to be solely responsible for the development of IBD.

Introduction

Inflammatory bowel disease (IBD) is a disorder characterized by chronic relapsing intestinal inflammation. The incidence of both Crohn's disease and ulcerative colitis has gradually increased since the Second World War, especially in northern Europe and North America, where the highest incidence rates have been reported. Other areas with traditionally low disease prevalence, such as Asia and Africa, have reported increasing numbers in more recent years.

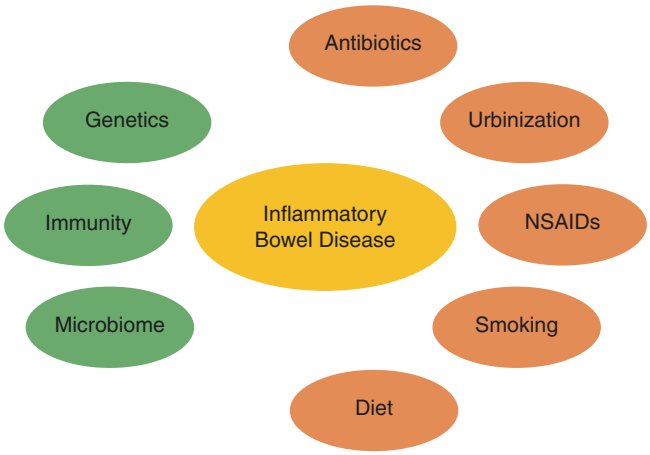

Fig. 43.1 The pathophysiology of IBD consists of host factors (green) and environmental factors (orange)

These shifts in the risk of developing IBD within a relatively short time period provide evidence for the importance of exposure to environmental factors in disease pathogenesis. The greater risk for CD in Ashkenazi Jews regardless of geographic location or time period suggests ethnic differences in the genetic predisposition to IBD.

Various theories have been espoused as to the underlying cause of IBD. A complex interaction between genetic, environmental, and microbial factors, which promote the associated immune responses in susceptible individuals, appears responsible for the pathogenesis (Fig. 43.1). Advances in genetics and immunology have allowed the identification and delineation of contributory mechanisms in IBD.

These factors variably influence the development of IBD as well as its manifestations. While Crohn's disease and ulcerative colitis behave differently, they have some similarities and differences in phenotypic manifestations. This is congruent with the underlying genetic and immunologic mechanisms involved, which also demonstrate similarities and differences in their characteristics. Environmental factors

such as urbanization, diet, and smoking, as well as medications such as NSAIDs, may also have an impact. In this chapter, we will review the current evidence on the pathobiology of IBD including both host and environmental factors.

Host Factors

Genetics

Population-based studies suggest that genetic factors contribute to IBD. There is an eight- to tenfold greater risk of IBD among relatives of UC and CD [1]. 15% of patients with Crohn's have an affected family member with IBD, and twin studies for CD have shown 50% concordance in monozygotic twins compared to <10% in dizygotics. In contrast, the concordance rate in monozygotic twins is 10–15% in UC. Thus, non-genetic factors may have a more important role in UC than in CD. Similarly, family studies suggest that a child has a 26-fold increased risk for developing CD when another sibling already has the condition while the risk is increased 9 times in the case of UC [2].

Most cases of genetic susceptibility are polygenic, but there is a spectrum of rare genetic disorders that can contribute to early-onset IBD. Monogenic defects have been found to alter intestinal immune homeostasis through many mechanisms. While a variety of genetic factors have been identified in IBD, there remains an important role for microbial and environmental factors. Epigenetic factors can further mediate interactions between environment and genome and could affect the development and progression of IBD. Epigenomics is an emerging field, and future studies could provide new insight into the pathogenesis of IBD.

Conventional IBD is a group of polygenic disorders in which hundred(s) of susceptibility loci contribute to the overall risk of disease. While genetic components are important factors involved in disease pathogenesis, identified genetic factors account for only a small proportion of the disease variance: 13.1% for CD and 8.2% for UC. More than 50% of IBD susceptibility loci have also been associated with other inflammatory and autoimmune diseases.

Monogenic defects are rare but can lead to early-onset (younger than 5 years) and very early-onset (younger than 2 years) CD and cause severe disease manifestations. These defects lead to disruption of the epithelial barrier and the epithelial response, as well as reduced clearance of bacteria by neutrophil granulocytes and other phagocytes. Other single-gene defects induce hyperinflammation or autoinflammation, or disrupted T- and B-cell selection and activation, due to defects in IL-10 signaling or dysfunctional regulatory T-cell activity. Defects in IL-10 or one of the subunits of its receptors cause extensive inflammation of the colon and perianal region. Next-generation sequencing (NGS) through whole exome sequencing (WES) has allowed the identification of single variants in very early-onset IBD.

Progress in genetic testing and DNA sequencing has allowed many genome-wide association studies, which have identified new single-nucleotide polymorphisms (SNPs). Nucleotide-binding oligomerization domain-containing protein 2 (NOD2) was the first susceptibility gene for CD that was discovered in 2001. This gene codes for a protein that acts as an intracellular receptor for bacterial products in monocytes and transduces signals leading to NFkB activation. The activation of NOD2 with muramyl dipeptide induces autophagy in dendritic cells. Dendritic cells from CD patients with NOD2 gene defects are deficient in autophagy induction and also show reduced localization of bacteria in autophagolysosomes. Two other autophagy-related genes, *IRGM* and *ATG16L1*, may have an important role in immune responses in IBD. Genetic variants that have been found to confer an increased risk of CD indicate the importance of innate immunity, autophagy, and phagocytosis in its pathogenesis. Other genes, like *IL23R* and *PTPN2*, are also associated with autoimmune disease, suggesting another aspect of Crohn's disease pathogenesis.

Epigenetics refers to mitotically heritable changes in gene expression via changes in structure and function of chromatin without alterations in DNA sequence. DNA methylation, histone modification, RNA interference, and the positioning of nucleosomes are some epigenetic mechanisms and are important in the interaction between environment and genome. Hypermethylation of gene promoters is associated with IBD patients; differences in DNA methylation status between normal and inflamed tissues from CD and UC patients have been identified.

MicroRNAs (miRNAs) are endogenous small non-coding single-stranded RNA molecules acting as post-transcriptional regulators of gene expression. MiRNAs have an important role in the development, regulation, and differentiation of the innate and adaptive immune system and are strongly implicated in the pathogenesis of many common diseases, including IBD. A lot of miRNAs have been discovered, but little is known of their function. In the intestinal tract, miRNAs are involved in tissue homeostasis, intestinal cell differentiation, and the maintenance of intestinal barrier function. CD and UC patients have unique miRNA expression profiles in their target organs as well as peripheral blood. Thus, identification of distinct miRNA expression profiles may provide an early method to determine a patient's disease course and a target of future treatments.

Immunity

The mucosal immune system is essential for establishing and controlling intestinal inflammation and injury. The role of

immunity in the causation and development of IBD is still evolving. The normal intestinal milieu consists of a complex interplay of genetic, microbial, and environmental factors that lead to mucosal immune and nonimmune responses. At rest and even in non-diseased states, there exists controlled mucosal inflammation regulated by a delicate balance of cytokines Th1, Th17, Th2, Th3, Th9, and Treg cells. In IBD, there is an imbalance whereby the adaptive immune system responds to self-antigens, leading to chronic inflammation and damage. Defects in innate immune functions of the epithelial barrier, pathogen recognition, and autophagy as well as adaptive immune dysfunction, particularly in T-cell activation, differentiation, and function, have all been implicated.

The first layer of defense against pathogens in the intestinal mucosa is the epithelium that faces the luminal surface. Paneth cells, which produce antimicrobial peptides, are located in this layer. Next is the lamina propria, where macrophages and dendritic cells are located and are responsible for the innate immune response. Dendritic cells have cytoplasmic extensions interdigitated among the epithelial cells to sample the luminal contents and then present antigens to T cells in the lamina propria and underlying lymphoid follicles. T and B cells and Peyer's patches form the adaptive immune system.

In the normal physiological state, gut-associated lymphoid tissue (GALT) constituted by Peyer's patches, lymphoid follicles, and mesenteric lymph nodes provides local intestinal immunity. Since there are a disproportionate number of microorganisms in the normal gut, a delicate balance of the innate and adaptive immunity is critical to avoiding an immune response, and a loss of this balance may be responsible for IBD. Alterations in autophagy, which is a cellular process related to the degradation of intracellular pathogens, antigen processing, regulation of cell signaling, and T-cell homeostasis that results in reduced clearance of pathogens, may contribute to the onset of inflammatory disorders in susceptible subjects [3, 4]. There is some evidence that problems with tolerance to self-antigens in the intestinal mucosa may lead to IBD [5, 6].

Macrophages and dendritic cells identify the molecular patterns of microorganisms by using pattern recognition receptors (PRR), such as toll-like receptors (TLR) and nucleotide-binding oligomerization domains (NOD). NOD2 is an intracellular microbial sensor that acts as a potent activator and regulator of inflammation. Mutations in the caspase recruitment domain-containing protein 15 (CARD-15) gene encoding the NOD2 protein have been identified in CD. Deficiency in NOD2 impacts the immune response in the lamina propria leading to chronic inflammation.

An internal imbalance in the cytokines in the intestinal mucosa has also been described in IBD. Such an imbalance may impact the intensity and duration of the inflammatory response in susceptible individuals. Various cytokines such as interferon-gamma (IFN-γ), tumor necrosis factor-alpha (TNF-α), and transforming growth factor-beta (TGF-β) are implicated. UC is often described as Th2-mediated disease and CD as a Th1 condition, but the underlying mechanisms may be interrelated and more complex. Recent data suggest that IL-17 and IL-22, cytokines that initiate and amplify the local inflammatory signs and promote the activation of counter-regulatory mechanisms targeting intestinal epithelium cells, are related to the induction of colitis.

IL-2, released by macrophages and dendritic cells in the intestinal mucosa, activates signal transducer and activator of transcription (STAT) 4 in memory T lymphocytes, stimulating the production of IFN-γ. IFN-γ triggers the production of inflammatory cytokines in cells of the innate immune system, contributing to the increase of the inflammation present in colitis. IL-9 that regulates intestinal epithelial cells has also been implicated. The role of the other cytokines in IBD is as follows: IL-1 activates T cells to produce IL-8 and IL-6; IL-6 helps differentiate Th17 and Treg cells; IL-12 promotes the differentiation of Th1 cells; IL-23 stimulates the production of IL-17 and TNF-α and IL-6, while TNF-α acts on Th2 surface receptors promoting the proliferation of macrophages and inhibits Treg cells.

Intestinal Microbiome

Over the last decade, the importance of the intestinal microbiome in health and disease has become very apparent. The introduction of 16S rRNA next-generation sequencing has allowed researchers the ability to investigate how perturbations of microbes may lead to disease. Not surprising, there has been an abundance of research investigating the role of intestinal bacteria on the development of IBD.

It has been well shown that the composition of the gut microbiota in IBD patients significantly differs from healthy controls. As a whole, the microbiota of IBD patients shows less diversity and richness [7]. Increased abundance of certain pathogens is also found in patients with IBD. For example, *Fusobacterium* and members of the Proteobacteria phylum (Enterobacteriaceae, *Escherichia coli*) are commonly found to be increased in IBD patients compared to controls [8–10]. Conversely, patients with IBD have been consistently found to have decreased members of the Firmicutes (e.g., *Faecalibacterium prausnitzii*, *Ruminococcus*, *Oscillibacter*) and Bacteroidetes phyla [7, 11].

In addition to microbial composition, metagenomics has been used to provide insight into the functional characteristics of the microbiome. Interestingly, the dysbiosis seen in IBD patients is not seen in unaffected twins and relatives, suggesting that these changes are related to the disease state or environment effects, rather than underlying genetics [12, 13].

Table 43.1 Microorganisms associated with the development of IBD

Bacteria	Viruses	Fungus
Enterobacteriaceae	Caudovirales	*Saccharomyces cerevisiae*
Mycobacterium avium	*Synechococcus* phage S	*Candida albicans*
Escherichia coli	*Retroviridae* family	
Faecalibacterium prausnitzii		
Ruminococcus spp.		
Oscillibacter spp.		
Bacteroidetes		

Although cultivation of single organisms has been associated with active IBD, there is limited evidence that implicates individual organisms as the sole driver of IBD (Table 43.1). For example, *Mycobacterium avium* can induce granulomatous enteritis in animals and has been investigated as an inducer of Crohn's disease [14]. However, a clear link between *Mycobacterium avium* inducing granulomas and IBD in human patients remains unproven [15]. Colombel found that adherent-invasive *E. coli* strains colonized ileal lesions in patients with Crohn's disease. These strains demonstrated a cytolytic effect in cell culture by production of alpha-hemolysin and were hypothesized to promote Crohn's disease by increasing intestinal permeability. Yet, the fact that these strains were found in 33% of healthy controls demonstrates that they alone are not sufficient to cause disease [16].

Global metabolic changes associated with bacterial compositional alterations likely play a role in the development of IBD. Metagenomics has shown an increased prevalence of certain virulence factors in IBD patients, such as endotoxins and hemolysins [17]. Morgan analyzed both the compositional and functional differences in 231 patients with IBD compared to healthy controls [18]. They reported that while only 2% of the bacterial composition was different (at the genus level), 12% of the metabolic pathways were different between IBD patients and controls. Patients with IBD had increased virulence and secretion pathways as well as major oxidative stress pathways. Other studies have demonstrated significant decreases in microbial metabolism such as short-chain fatty acids and amino acid production [19].

The role of viruses and fungi in the pathogenesis of IBD has been receiving increasing attention. Similar to bacteria, certain patterns have emerged in patients with IBD compared to healthy controls. A comprehensive analysis of the virome in IBD patients has been performed [20]. The authors demonstrated significant expansions of certain virions including Caudovirales bacteriophages. Others have found associations of *Synechococcus* phage S and the *Retroviridae* family of viruses in IBD patients [21]. Interestingly, some studies have shown these virome changes are independent of IBD-associated bacterial composition changes. In a similar fashion, Sokol characterized the fungal microbiota in 235 patients with IBD [22]. They found increased abundance of multiple fungal species including *S. cerevisiae* and *C. albicans*. Additionally, they reported that *Basidiomycota* abundance was associated with IBD flares.

While these microbiota changes have consistently been demonstrated in patients with IBD, whether they are driving the disease or are a consequence of inflammation remains uncertain. For example, inflammation decreases the oxygen tension of the intestinal mucosa, preventing the growth of aerotolerant taxa [23]. Alternatively, the changing oxygen level can promote anaerobic microorganisms and dysbiosis [24]. Further studies are needed to understand the interplay between dysbiosis and inflammation and determine which may be driving the pathogenesis of IBD.

Antibiotics

Antimicrobial agents have a strong influence on the composition and diversity of gut microbiome. Multiple studies have demonstrated that within the first few days following antibiotic administration, there are a profound and immediate decrease in diversity and significant shift of the bacterial community structure [25]. While the microbiome begins to reconstitute to its initial state after antibiotics are stopped, in some cases the microbiome remains altered [26].

Given this large influence of antibiotics on the microbiome, researchers have investigated if antibiotic exposure is a risk factor for the development of IBD. In a Canadian case-control study, 294 children diagnosed with IBD were compared to 2377 controls [27]. The authors found that patients who were diagnosed with otitis media (a proxy for antibiotic use) were 2.8-fold more likely to have IBD (95% CI 1.5–5.2; $p = 0.001$) compared to controls. In a similar study, antibiotic prescriptions were significantly associated with both the development of ulcerative colitis and Crohn's disease [28]. In a recent meta-analysis, 8 case-control and 3 cohort studies including 7208 patients with IBD were analyzed. Antibiotic exposure was significantly associated with Crohn's disease (OR 1.74, 95% CI 1.35–2.23), but not with ulcerative colitis (OR 1.08, 95% CI 0.91–1.27). While all antibiotics, except for penicillin, were associated with Crohn's disease, metronidazole and fluoroquinolones were most significantly associated with IBD overall. Taken together, the evidence strongly supports antibiotics to be a risk factor for the development of IBD, further implicating the microbiome as a major driver of IBD.

Environmental Factors

Urbanization

Since its discovery in the late 1800s, IBD has long been thought to be a disease of Caucasian people of European descent; IBD continues to be most prevalent in wealthy Western countries, with a prevalence of ~0.5% in North America and Europe [29, 30]. Because of new diagnoses and the low mortality rate in IBD patients, the prevalence of IBD in these countries is increasing [31]. While IBD was rare in developing nations during the twentieth century, the emergence and increasing incidence of IBD in developing countries in Asia, Africa, South America, and the Middle East is now well documented (Fig. 43.2) [32]. For example, in Brazil the incidence of ulcerative colitis increased to 4.5 cases per 100,000 people in 2005 from 1.0 per 100,000 between 1986 and 1990 [33]. Similarly, in the 1960s–1980s, IBD was barely recognized in Hong Kong, while now the incidence ranges from 1.3 to 2.1 per 100,000 patients [34].

Industrialization and urbanization in developing countries is associated with a multitude of factors including changes in lifestyle, diet, smoking habits, pollution, and healthcare delivery. In fact, Benchimol found that growing up in a rural environment was significantly protective of later development of IBD (IRR 0.58, 95% CI 0.43–0.73). Thus, the emergence and increasing incidence of IBD in these developing countries worldwide provides strong evidence that environmental factors play a large role in pathogenesis. While it is not possible to isolate all environmental changes associated with urbanization, herein we will review the influence of certain lifestyle changes on the development of IBD.

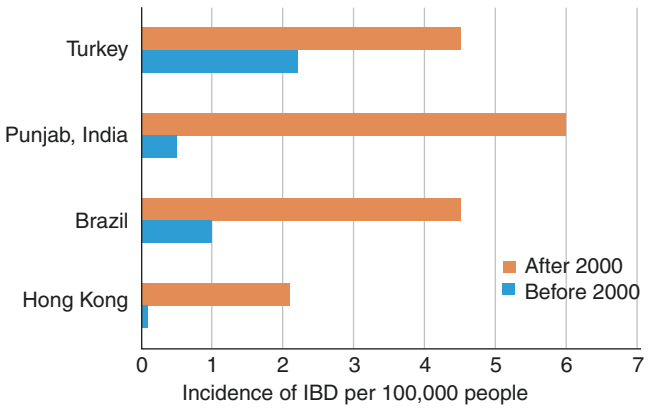

Fig. 43.2 The incidence of IBD is significantly increased over the last two decades in developing countries

Smoking

The divergent findings of smoking as a risk factor for Crohn's disease, yet potentially protective for ulcerative colitis, have been appreciated since the early 1980s. Both passive and active smoking is associated with a twofold increased risk of development of Crohn's disease (OR 1.76; 95% CI 1.4–2.2) [35]. Additionally, smoking portends a significantly increased risk of fistula formation, strictures, and need for surgery [36]. On the other hand, it is well accepted that smoking is protective against ulcerative colitis. In a meta-analysis of 13 articles investigating the association of smoking on IBD, the authors reported that current smokers have a significantly lower incidence of ulcerative colitis compared to controls (OR 0.58; 95% CI 0.45–0.75) [35].

How smoking promotes IBD is unclear. Smoking changes the microvasculature, which can contribute to inflammation via decreased perfusion and recruitment of immune cells. This can increase oxidative stress which subsequently affects gut barrier function, mucus production, and microbiome changes [37, 38]. How these molecular changes promote Crohn's disease but protect against ulcerative colitis is uncertain. Ananthakrishnan studied nicotine metabolism in 634 patients with Crohn's disease and 401 with ulcerative colitis. They found that certain genetic polymorphisms in nicotine-metabolizing enzymes, such as CYP2A6, and GSTP1, were associated with the development of Crohn's diseases and protection against ulcerative colitis [39]. Thus, a genetic predisposition may exist as to the effects of smoking on the pathophysiology of IBD.

NSAIDs

Nonsteroidal anti-inflammatory drugs (NSAIDs) have long been associated with the development or exacerbation of IBD, although the literature shows conflicting results. Long recently retrospectively studied 791 patients from a prospectively collected database with IBD patients that were in remission [40]. They reported that Crohn's disease patients with NSAID use more than five times per month had a greater risk of active disease (RR 1.65; 95% CI 1.12–2.44), while no effect was seen in patients with ulcerative colitis (RR 1.25; 95% CI 0.81–1.92). Ananthakrishnan reported that NSAID use at least 15 times per month increased the risk of development of both Crohn's disease and ulcerative colitis [41].

Low-dose NSAID does not appear to promote IBD. In 426 Crohn's disease patients and 203 ulcerative colitis patients, low-dose NSAID (<200 mg/day and used less than daily) was not associated with an increase in disease activity. High-dose NSAID use was associated with a higher numeri-

cal disease activity score in Crohn's patients, but was not associated with an increase in disease flares in Crohn's or ulcerative colitis patients. Takeuchi studied the effect of NSAIDs in patients with quiescent IBD. Patients were given either acetaminophen, naproxen, diclofenac, or indomethacin for 4 weeks and then assessed for recurrence [42]. The authors reported a 17–28% recurrence rate in both Crohn's disease and ulcerative colitis patients within 9 days of administration of NSAIDs, but no recurrence was seen with acetaminophen.

Given these mixed results, a recent systematic review and meta-analysis of publications between 1983 and 2016 examined the association between acetaminophen and NSAIDs on the risk of disease exacerbation [43]. Pooled analysis of 18 publications found that NSAID use was not associated with exacerbation of Crohn's disease (OR, 1.42, 95% CI, 0.65–3.09) or ulcerative colitis (OR, 1.52, 95% CI, 0.87–2.63). Similar findings were observed with acetaminophen.

Multiple mechanisms have been suggested as to how NSAIDs can promote IBD. NSAIDs inhibit cyclooxygenase (such as COX-1 and COX-2) and prevent accumulation of prostaglandins. Cyclooxygenases and prostaglandins play a critical role in epithelial wound healing, mucosal defense, and immune modulation within the colon [44–46]. For instance, using a model of dextran sulfate sodium (DSS)-induced colitis, inhibition of COX-1 and COX-2 resulted in significantly decreased amounts of mucosal prostaglandins and exacerbation of DSS colitis [47]. Of the many pathways impacted by COX inhibition, increased mucosal permeability has most often been suggested as the main pathogenic factor. Animal models of IL-10-deficient mice (a common animal model for colitis) given 4 weeks of NSAID treatment had a 75% reduction of PGE_2 and developed colitis, with infiltration of the lamina propria by macrophages and CD4+ T-cells [48]. Collectively, while the literature is mixed, there is a biological basis to support the notion that NSAIDs influence the pathobiology of IBD.

Diet

A recent Cochrane review concluded that the effects of dietary interventions on Crohn's disease and ulcerative colitis are uncertain [49]. However, observational studies have shown associations between dietary patterns and the risk of being newly diagnosed with Crohn's disease and ulcerative colitis, as well as the exacerbation of symptoms. Greater consumption of meat and animal products has been associated with the onset of Crohn's disease and ulcerative colitis, whereas greater consumption of fruits and vegetables had a lower incidence. Some hypotheses used to explain the impact on diet on IBD suggest a direct alteration of the microbiome. Dietary antigens may also influence the immune response of the gut. Alternatively, diet may directly affect the mucosal barrier or indirectly affect immune function by influencing the composition of gut enzymes, bile acids, and hormones. Some diet-based therapies have been shown to impact IBD, particularly in CD. Studies are underway to further elucidate the role of diet on the pathogenesis of IBD.

Pouchitis Pathobiology

Pouchitis is a common complication in patients who undergo restorative proctocolectomy with ileal pouch-anal anastomosis (IPAA). The incidence of pouchitis depends upon the indication for surgery; pouchitis occurs in approximately 50% of patients with ulcerative colitis but rarely if ever it occurs in patients with familial adenomatous polyposis [50–52]. While the pathogenesis of pouchitis remains unclear, the finding that the incidence is dependent upon the primary diagnosis strongly suggests an underlying genetic component. Carter found that patients who carried the +2018 single-nucleotide polymorphism in interleukin-1 were at a significantly higher risk for the development of pouchitis (relative risk 3.1; 95% CI 1.2–7.8) [53].

Similarly, Sehgal investigated the association of NOD2 mutations to the development of pouchitis [54]. They reported that mutations in NOD2 were significantly higher in patients with severe pouchitis compared to either asymptomatic IPAA patients or patients with IPAA complications such as abscess or fistula. Genetic changes have also been linked to immune alterations in patients with pouchitis. Increased expression of toll-like receptors 2 and 4 is seen in patients with pouchitis [55]. Additionally, aberrant expression of defensing-1 and increased expression of defensing-5 is expressed in IPAA patients when compared to normal ileum [56, 57].

The reservoir function of an IPAA promotes fecal stasis, leading to adaptation and metaplasia of the mucosa from small bowel to colon-like mucosa [58]. Similarly, the pouch bacteria move closer to a colonic-like microbiome after pouch creation [59]. Because fecal stasis promotes bacterial overgrowth, the influence of microbiome changes on pouchitis has been investigated. McLaughlin investigated the colonizing bacterial community of the pouch in patients with ulcerative colitis and familial adenomatous polyposis [60]. Interestingly, they found a significant decrease in Bacteroidetes and significant increases in Proteobacteria in patients with ulcerative colitis compared to polyposis patients. Additionally, bacterial diversity, which is a marker of bacterial health, was significantly increased in polyposis patients, compared to ulcerative colitis patients.

Functional characteristics of the host in relation to microbiome changes have also been studied in IPAA patients. Investigators have found that the most strongly microbe-associated transcriptomic pattern is enrichment with activation of the interleukin-12 pathway and complement cascade

genes. Collectively, the investigations to date suggest that pouchitis is a multifactorial disease resulting from immune and microbial changes in a genetically susceptible host.

IBD Diagnosis and Evaluation

44

Mantaj S. Brar and Helen MacRae

Key Concepts

- Crohn's disease may present in a wide variety of ways depending on site of disease and phenotype.
- Multiple scoring and grading systems are in use to assess disease-related activity.
- Extraintestinal manifestations are common and may be the presenting sign of diagnosis in ~ 1/4 of patients with IBD.
- Pathologists are commonly unable to distinguish between UC and CD on endoscopic biopsies.

Inflammatory Bowel Disease Epidemiology

Inflammatory bowel disease (IBD) was arguably first described by Matthew Baillie in 1793 [1]. It is a chronic idiopathic condition with genetic predilection and environmental triggers [2–4]. The highest prevalence of IBD is in North America and Europe (~0.3–0.7%) [5, 6]. While the incidence in these populations has stabilized, that of newly industrialized countries has been increasing over the last 30 years [5, 6]. Immigration from low-prevalence areas to Europe and North America has been associated with increased incidence of IBD, both in immigrants and in their children, highlighting the importance of environmental triggers in the pathogenesis of IBD [7, 8].

Clinical Presentation of IBD

Given the varied disease distribution and severity, IBD can present in a myriad of ways and must be in the differential diagnosis of a variety of clinical scenarios. Patients can present with a change in bowel frequency (either increased or decreased); crampy abdominal pain, with or without blood in the stool; tenesmus; urgency; incontinence; food intolerance(s); anorexia; and/or weight loss. Symptoms can be subtle and may be related primarily to extraintestinal manifestations of their disease. Some patients present in a very delayed fashion and have internalized their chronic bowel symptoms, while others present with acute severe colitis as the first manifestation of their disease. When evaluating a patient with gastrointestinal symptoms, a careful history must be taken to evaluate the chronicity of symptoms, family history of IBD, as well as risk factors for infectious colitis or enteritis, such as recent travel, sick contacts, and recent antibiotic use. In addition, a thorough past medical history and medication history are important, especially with respect to NSAID exposure, previous radiation therapy, or immunosuppression. Lastly, a thorough review of systems may elucidate extraintestinal manifestations of IBD. Taken together, these components of the history will assist in narrowing the differential diagnosis and aid in selection of the appropriate diagnostic tests.

IBD Phenotypes

Due to the lack of known etiologic causes and "gold standard" diagnostic tests, IBD phenotypes are based on the distribution of inflammation, macroscopic appearance of the bowel, and histologic findings. Although two classic phenotypes of Crohn's disease (CD) and ulcerative colitis (UC) are often presented, this dichotomization of the vast spectrum of disease may prove with time and greater understanding of the underlying etiology of IBD, to represent an oversimplification of IBD subtypes. However, appropriate patient selection for surgical intervention is predicated on establishing the IBD phenotype of the patient.

Crohn's Disease

First described in 1932, Crohn's disease was initially described as a chronic inflammatory condition of the terminal ileum leading to the development of strictures and fistulas [9]. Although the terminal ileum is the most common site of involvement, Crohn's disease can involve any part of the GI tract from the mouth to the anus and may have areas of involved bowel interspersed with spared areas (skip lesions). In addition, inflammation in Crohn's disease may involve all layers of the bowel wall with possible progression to fistula development, stricture formation, or perforation. Macroscopically, in addition to bowel wall thickening, Crohn's disease can be accompanied by *creeping fat*, or mesenteric adipose tissue extending beyond the mesenteric border around the inflamed intestine. Although traditionally thought to be a consequence of the inflammation of the bowel wall, there are emerging hypotheses that the mesentery is an active mediator of local inflammatory changes and may contribute to stricture formation and postoperative recurrence [10, 11].

Ulcerative Colitis

In contrast to Crohn's disease, the hallmark of ulcerative colitis is mucosal inflammation that involves the distal rectum and extends proximally in a continuous manner to involve the colon while sparing the small intestine, upper GI tract, and anus (see Table 44.1). However, there are specific scenarios where patients with UC may not have this distribution of disease. For example, patients with inflammation extending to the cecum may also have inflammation for a short distance of the terminal ileum ("backwash ileitis"); a patch of non-contiguous cecal inflammation (i.e., cecal patch) is occasionally observed in UC patients with more distal disease. Patients who receive topical enema therapy or have a partial response to medical therapy may be observed to have relative rectal sparing and/or discontinuous inflammation [12–14]. However, it remains controversial whether complete rectal sparing (without treatment) represents a subtype of UC rather than CD, in the absence of other features of CD [14, 15]. Patients who present with severe acute ulcerative colitis or fulminant colitis may have inflammation that extends beyond the mucosa or through the colon wall which may lead to perforation. These patients also have "skip" lesions or relative sparing of portions of the colon as the disease develops. The presence of these findings should prompt further evaluation, and a review by an experienced pathologist of available histology to ensure diagnosis of UC rather than CD is favored, as the surgical options following colectomy rely on appropriate phenotypic diagnosis.

Table 44.1 Features distinguishing Crohn's disease from ulcerative colitis

	Crohn's disease	Ulcerative colitis
Distribution Ileal involvement Perianal disease	Any part of the GI tract Often Common	Distal rectum and extending proximally to involve the colon Limited to backwash ileitis Rare – in the setting of cryptoglandular disease
Bowel wall involvement	Full thickness	Mucosal inflammation; unless fulminant colitis
Creeping fat	Present	Not present
Skip lesions	Often	Rare – but may be the consequence of treatment response
Fistulas	Possible	Rare
Deep ulceration/ fissures	Common	Only in fulminant colitis
Strictures	Common	Rare

IBD-Unclassified (IBD-U) and Indeterminate Colitis

In approximately 10% of adult-onset IBD and up to 30% of pediatric-onset IBD, a clear diagnosis between UC and CD cannot be established despite clinical, endoscopic, imaging, and histological evaluation [16–19]. Prior to colectomy, these patients should be labelled as IBD-unclassified (IBD-U). Following colectomy and pathological review of the specimen, the term indeterminate colitis (IC) is employed if no classic phenotypic diagnosis can be made [18, 20]. Although this label represents a heterogenous group of patients, they generally have a milder disease course and require less medical therapy than those diagnosed with UC [16]. Approximately a quarter of patients labelled with IBD-U will ultimately be reclassified in the first 5 years following diagnosis, with 2/3 of them being diagnosed with UC [16].

PSC-IBD

Primary sclerosing cholangitis (PSC) is a chronic liver disease characterized by bile duct inflammation and often progresses to stricture formation within the bile ducts. While ~3/4 of PSC patients will also be diagnosed with IBD (predominately UC), approximately 2–4% of IBD patients will develop PSC [21, 22]. Despite the strong association with IBD, the exact mechanisms of interplay between IBD and PSC remain poorly understood, with little genetic correlation between the two entities and conflicting evidence on the role of intestinal microbiota [21–24]. In addition to conventional UC (or less often CD) associated with PSC, there appears to be a distinct phenotype among IBD patients with PSC (PSC-

IBD). PSC-IBD has been characterized as pancolitis with rectal sparing, right- greater than left-sided inflammation, higher rates of backwash ileitis, milder symptoms despite endoscopic activity, and a higher medical treatment response rate [22, 23, 25]. Importantly, patients with PSC and colonic IBD also have an increased risk of developing IBD-associated mucosal dysplasia and colorectal cancer [22]. Although it has been previously observed that PSC progression is independent of IBD activity, recent reports suggest that timing of colectomy is associated with the risk of liver transplant for PSC, and ileoanal pouch reconstruction may be associated with poor graft survival after liver transplantation for PSC – suggesting a possible link between gut and liver inflammation [22, 26–29].

Extraintestinal Manifestations

Involvement of other organ systems occurs in 1/3 to 1/2 of all IBD patients during their disease course, and importantly, 1/4 of patients with extraintestinal manifestations (EIMs) present with extraintestinal symptoms prior to their IBD diagnosis [30, 31]. The pathogenesis of EIMs is poorly understood and may be related to genetic risk (associations with HLA subtypes have been described) and dysregulated adaptive immunity [30]. The most common EIM is joint involvement, which occurs in up to 40% of IBD patients, while cutaneous, biliary, and ocular are also common sites of EIMs [30–32]. While some EIMs follow the course of intestinal inflammatory burden, others do not, and there is some uncertainty about the relationship in others (see Table 44.2) [30–32]. During the assessment of a patient with suspected IBD, a review of the common EIM symptoms/diagnosis is necessary and may aid in the diagnosis. In addition, decisions regarding medical and surgical therapy may rely on an accurate EIM diagnosis, especially PSC in light of the increased risk of malignancy.

Table 44.2 Common extraintestinal manifestations of IBD, stratified by organ system and relationship to intestinal inflammation [30–32]

Organ system	Associated with intestinal activity	Unclear association with intestinal activity	No association with intestinal activity
Mucocutaneous	Oral aphthous ulcers (10%) Erythema nodosum (10–15%)	Pyoderma gangrenosum (1–5%)	
Joints		Peripheral arthropathy (5–20%)	Ankylosing spondylitis (5–20%)
Ophthalmologic	Episcleritis (2–3%)	Uveitis (2–6%)	
Biliary		PSC (5–8%)	

In addition to EIMs, there are several common manifestations of IBD activity and treatment that may warrant evaluation and treatment, such as anemia, osteopenia, cholelithiasis, nephrolithiasis, tubulointerstitial nephritis, and venous thromboembolism [31].

Diagnostic Evaluation of Suspected IBD

After thorough history, assessment of vital signs, and physical examination of the abdomen, skin examination, inspection of the orbits, and perineal examination with digital rectal exam, a number of preliminary investigations are relevant to the workup of suspected IBD.

Laboratory Investigations and Stool Tests

Laboratory investigations include a complete blood count, electrolyte, creatinine, liver enzyme, bilirubin, and iron studies. In addition, inflammatory markers such as C-reactive protein (CRP) should be drawn given their correlation with disease severity (in CD more than in UC); however, it must be noted that elevations in CRP are not specific enough to rule out infectious or other causes of colitis and CRP may be normal in up to 30% of patients with active CD [33–36]. Erythrocyte sedimentation rate, despite extensive use, has limited clinical utility in establishing a diagnosis of IBD [37]. In the first presentation of diarrhea, stool cultures and examination for ova and parasites are necessary, as well as *C. difficile* toxin assay if there has been any recent hospitalization or antibiotic use. If there is a history of anal receptive intercourse, consider anal swabs for STIs and nucleic acid amplification testing for *Chlamydia* [38]. The use of serological markers pANCA and ASCA individually have limited diagnostic utility for IBD given their low sensitivity; however, the combination of +pANCA and -ASCA serology has been demonstrated to have a sensitivity and specificity of 70% and 93%, respectively, for differentiating UC from CD once the diagnosis of IBD has been established [39, 40].

The measurement of fecal calprotectin is often employed to evaluate the burden of inflammation in IBD patients and may aid in the initial evaluation of patients with suspected IBD. Fecal calprotectin is a neutrophil cytosolic protein which is released during cellular degranulation in response to intestinal inflammation, and can be elevated in IBD, infectious colitis, cancer, and diverticulitis, and in response to NSAID or proton pump inhibitors [41]. There are variable cutoffs for elevated fecal calprotectin reported in the literature, and normal values vary by age (higher in children and the elderly), limiting the generalizability of reported diagnostic utility [33, 42]. Several meta-analyses have demonstrated a pooled sensitivity of 93–95% and specificity of

90–96%; the high negative predictive value suggests that patients may be able to avoid invasive testing in the setting of a fecal calprotectin level <50 mcg/g [33, 42].

Diagnostic Imaging

Diagnostic imaging studies are commonly employed in the diagnosis and staging of IBD. Abdominal X-rays have limited clinical utility in the evaluation of IBD except perhaps in acute severe colitis where the findings of a toxic megacolon or perforation would mandate urgent colectomy. In the absence of severe colitis, the utility of imaging studies for the evaluation of UC (other than to rule out small bowel CD) is limited. In contrast, given the varied distribution of disease and possible involvement of endoscopically difficult-to-reach jejunum and proximal ileum, as well as the higher risks of complicated disease in CD, imaging is a key component of evaluation of these patients. The goals of imaging are to accurately characterize the distribution of inflammation, determine the relative contributions of inflammation and fibrosis within strictures, and exclude penetrating complications such as abscess and fistula.

Computed tomography

In the acute care setting, conventional intravenous and oral contrast-enhanced computed tomography (CT) is often employed given its broad availability. CT can be useful in detecting moderate to severe small bowel or colonic inflammation, intraabdominal or perianal abscess, and bowel obstruction with characterization of transition points and evaluation of enteric fistulas [43, 44]. With the added administration of large-volume, low-density, or neutral contrast, in addition to intravenous contrast, CT enterography (CTE) allows for increased detection of mucosal inflammation and increased wall thickness, better characterization of strictures, and visualization of extraintestinal findings, such as abscesses, with high resolution (see Figs. 44.1 and 44.2)

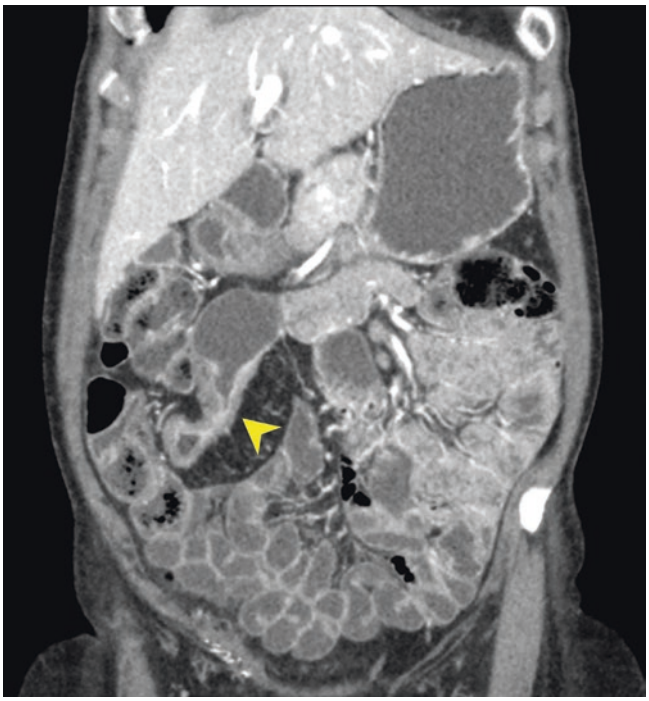

Fig. 44.2 CT enterography coronal images demonstrating an ileal stricture with pre-stenotic dilation in a patient with Crohn's disease

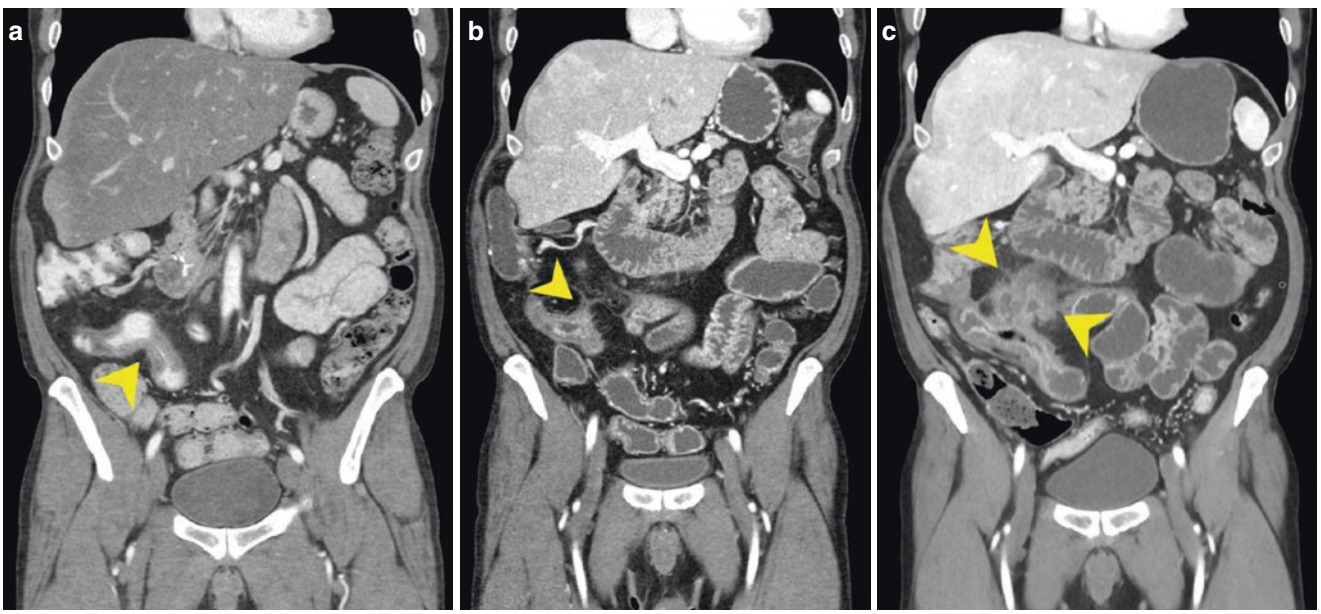

Fig. 44.1 Serial CT enterography coronal images for a patient with Crohn's disease with progression from (**a**) structuring disease to (**b**) early penetrating disease and to (**c**) complicated disease with localized perforation with mesenteric abscess

[43, 45, 46]. Specifically, the findings of luminal stenosis, increased wall thickness, and pre-stenotic dilation have been highly correlated with the severity of fibrosis within surgical specimens [43–45]. Given the concerns regarding cumulative radiation exposure with CT among CD patients, new protocols delivering a lower dose of radiation have been developed using iterative reconstruction algorithms resulting in dose reductions between 34 and 74% with inconsequential loss in image fidelity and diagnostic utility [45, 47].

Ultrasound

Given the high cumulative exposure to ionizing radiation among IBD patients, particularly those with CD, there has been increasing utilization of ultrasound (US) and magnetic resonance (MR) imaging [48]. Transabdominal small bowel US is a low-cost, radiation-free technique used primarily to assess small bowel involvement and characterize strictures [43, 49]. In a multicenter cohort study, among those newly diagnosed with CD, transabdominal US had a 66% sensitivity and 88% specificity for assessing extent of small bowel disease and 92% sensitivity and 91% specificity for the presence of small bowel disease [49]. In a smaller study, transabdominal US was demonstrated to have a 100% sensitivity and a 63% specificity for intermediate to severe fibrosis in surgical specimens [50]. Newer US techniques such as intravenous contrast-enhanced US and US elastography have demonstrated accuracy in small series, but further evidence is required to demonstrate a benefit over conventional US [43]. Transperineal and transanal US for the assessment of perianal fistulas and abscesses have demonstrated high sensitivity for detecting fistulas and abscesses in a meta-analysis of small series (>90%) and, thus, may have a role in following patients with known perianal disease given the lower cost compared to MR [51, 52].

Magnetic Resonance Imaging

Magnetic resonance enterography (MRE) has quickly become the preferred cross-sectional imaging modality of the small intestine in many centers; despite the issues of cost and availability of modern MR technology, utilization has increased with time [48]. In a multicenter cohort study, it was demonstrated that MRE had a low sensitivity for detection of colonic disease or extent of disease (64% and 22%, respectively) but high specificity (93% and 96%, respectively) – similar to that of US [49]. However, the sensitivity and specificity of MRE were significantly higher than US for both small bowel disease detection (97% and 96%) and extent of small bowel disease (80% and 95%) [49]. Novel MR techniques, such as diffusion-weighted imaging, magnetization transfer, and delayed enhancement MRE, may further enhance the accuracy of MR at determining the amount of fibrosis within a small bowel stricture [43, 44, 53, 54].

In several small series correlating these novel MRI techniques with surgical specimens, sensitivity for the detection of fibrostenotic disease was 86–96% and the specificity 89–100% (see Figs. 44.3 and 44.4) [3, 43, 44, 54]. However, these newer MR techniques require standardization of protocols, definitions of cutoff values for fibrosis, larger series for validation, and possibly comparative studies to determine the technique with the optimal diagnostic accuracy [43, 44]. MR

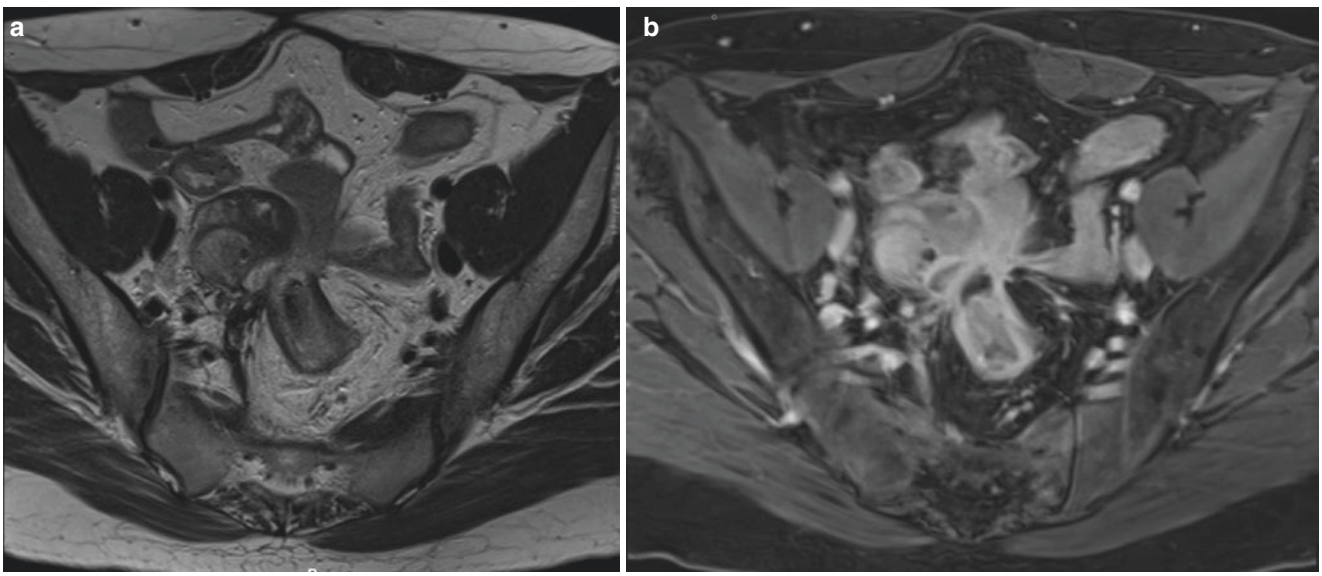

Fig. 44.3 MR enterography demonstrating penetrating ileal disease with a complex stellate fistula involving the sigmoid colon on (**a**) T2-weighted and (**b**) post-gadolinium axial images

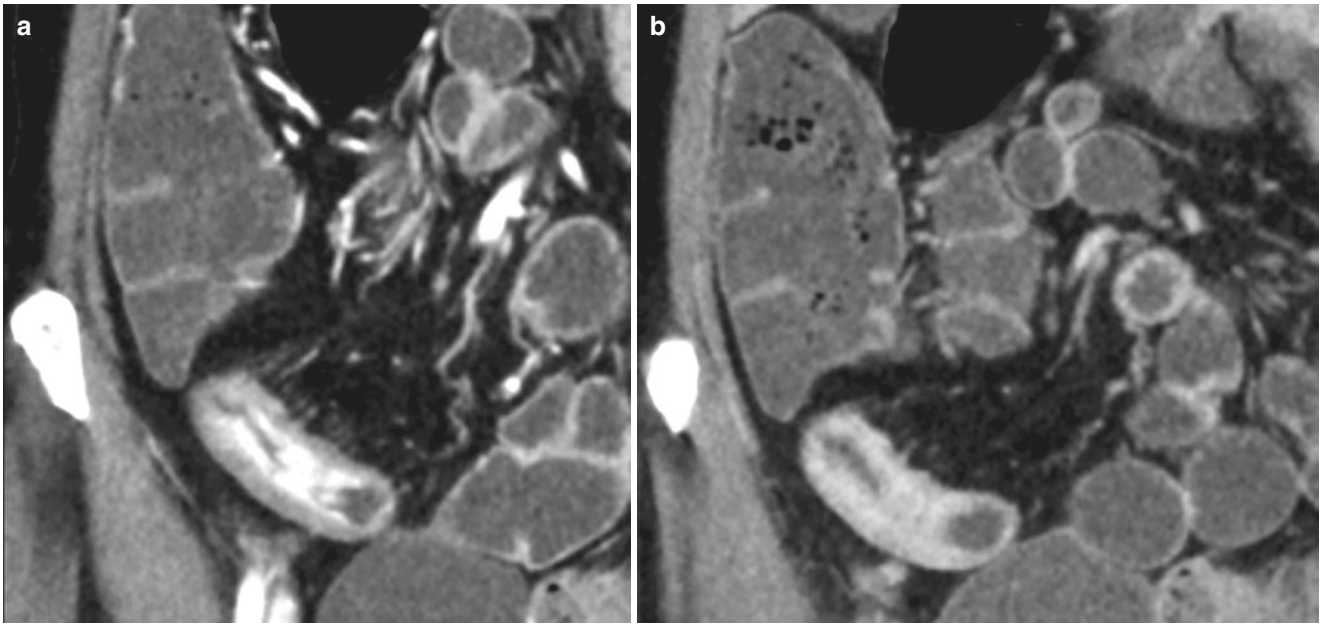

Fig. 44.4 Delayed enhancement MR enterography coronal images demonstrating (**a**) mucosal enhancement on initial imaging and (**b**) increased wall enhancement on delayed images which correlates to the amount of fibrosis

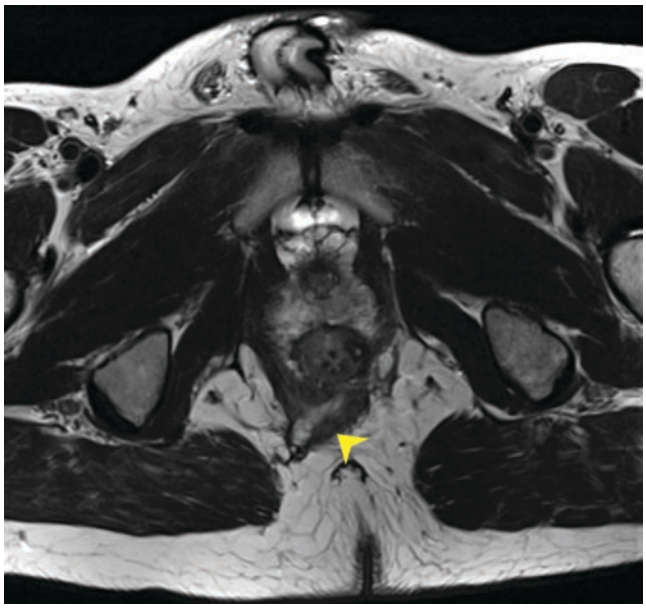

Fig. 44.5 MR pelvis axial T2-weighted images demonstrating a transsphincteric fistula tract

pelvis is the gold standard imaging investigation for those being evaluated for perianal Crohn's disease. It has demonstrated high sensitivity and specificity (80–100%) for the detection of fistula tracts and abscesses and modest specificity with respect to detection of the internal opening of a fistula tract (69%) (see Fig. 44.5) [55, 56].

Endoscopy

Colonoscopy with terminal ileal intubation is the gold standard diagnostic test in patients presenting with symptoms suggestive of IBD involving the colon and/or terminal ileum. A minimum of two representative biopsies should be taken from the terminal ileum; ascending, transverse, descending, and sigmoid colon; and rectum, retrieved in separate vials and reviewed by a GI pathologist, if available [57, 58]. Several endoscopic scores have been developed and are reviewed later in this chapter. These scores should be employed (using that most common in local practice) to improve communication across care providers. Standard terminology should also be employed to describe the endoscopic findings (see Table 44.3) [57]. In the setting of severe acute colitis, due to the extent of inflammation present and the risk of perforation, flexible sigmoidoscopy with biopsies is sufficient to establish a diagnosis and exclude other causes of colitis [57]. Upper GI endoscopy is not required for the assessment of adult patients with suspected IBD, unless symptoms specific to the upper GI tract are present [57]. In the setting of possible isolated small bowel Crohn's disease with spared terminal ileum on colonoscopy, patients may require capsule endoscopy or double-balloon or push enteroscopy, to establish a diagnosis if cross-sectional imaging studies are inconclusive or in the setting of occult small bowel bleeding [57, 59].

Table 44.3 Description and definitions of endoscopic lesions in IBD [57]

Finding	Description
Loss of vascular pattern	Loss of normal mucosal appearance without well-demarcated, arborizing capillaries
Erythema	Reddened mucosa
Granularity	Mucosal pattern produced by a reticular network of radiolucent foci of <1 mm of diameter with a sharp light reflex
Friability	Bleeding or intramucosal hemorrhage before or after the passage of the endoscope
Erosion	A definite discontinuation of mucosa <3 mm
Aphthous ulcer	White depressed center surrounded by a halo of erythema
Ulcer	Any lesion of the mucosa of unequivocal depth, with or without reddish halo; may be circular, linear, stellate, or serpiginous
Stenosis	Narrowing of the lumen
Inflammatory polyps (aka pseudopolyps)	Raised polypoid lesions, usually small, glistening; usually in areas of healed inflammation
Cobblestoning	Mucosal pattern with raised nodules, resembling the paving of a "Roman" road

Histology

Histopathologic assessment of endoscopic biopsies are a critical component in the workup of a patient with suspected IBD, as it can help exclude other diagnoses and assist with assigning a phenotypic diagnosis. The microscopic appearance of UC on endoscopic biopsies is characterized by crypt architectural distortion, with a diffuse transmucosal inflammatory infiltrate with cryptitis and crypt abscess, while in CD, the findings often show focal and often discontinuous chronic inflammation and focal crypt distortion, and there may be granulomas present (see Table 44.4 for all histological features) [58]. Given that there is no pathognomonic histological feature of either UC or CD, pathologists may not be able to accurately discriminate between the two classic phenotypes based on histology. Therefore, histology remains only a component of the diagnostic and phenotypic assessment, with only modest accuracy, even among expert GI pathologists (64–74%) [58]. However, histologic examination of specimens from colonoscopy is valuable in excluding other causes of colitis, such as Cytomegalovirus (CMV), microscopic and collagenous colitis, and, less so, infectious colitis [58].

Genetic Studies

Over 240 loci have been identified via genome-wide studies that are associated with IBD. Despite the strong evidence of a genetic contribution to the development of IBD based on twin studies, the clinical utility of genetic testing is limited for the diagnosis of IBD given the heterogenous disease presentation and phenotypes [60]. Current guidelines only recommend genetic testing in the setting of suspected monogenic disorders (such as IL-10 receptor mutations), in those with very early-onset (<5 years old), young patients with aggressive/refractory IBD, or to assess for mutations related to thiopurine metabolism (in TPMT and NUDT15 genes) when initiating thiopurine treatment [61–63].

Table 44.4 Histological findings in IBD [57]

	Ulcerative colitis	Crohn's disease
Crypt architectural irregularity	Diffuse (continuous)	Focal (discontinuous)[a]
Chronic inflammation	Diffuse (continuous), decreases proximally	Focal (discontinuous)[a], variable
Patchiness	Uncommon	Common
Localization	Superficial, transmucosal, occ. submucosal	Transmural
Serositis	Absent (except in fulminant colitis)	Present
Lymphoid aggregates	Frequent in mucosa and submucosa	Common, transmural
Granulomas	Absent (except in ruptured cysts)	Present
Acute inflammation	Diffuse (continuous)	Focal (discontinuous)[a]
Crypt epithelial polymorphs	Diffuse (continuous)	Focal (discontinuous)[a]
Crypt abscesses	Common	Uncommon
Mucin depletion	Present, pronounced	Uncommon, mild
Neuronal hyperplasia	Rare	Common
Muscular hypertrophy	Absent	Present
Paneth cell metaplasia	Present	Uncommon
Pyloric gland metaplasia	Rare	Present

[a]Discontinuous histological findings are often identified in Crohn's disease; however, continuous findings may also be observed

Classification and Grading of IBD

Given the diversity of clinical presentation and severity of IBD, classification and stratification of patients are exceedingly important for clinical decision-making, communication between health professionals, and monitoring of response and for research purposes. The Montreal classification and the Paris classification (for pediatric patients) remain the most well-accepted classification systems and have been demonstrated to have high inter-observer agreement [20, 64–66]. As IBD is a chronic disease, it is important to recognize that patient's disease course and behavior may change

over time and their classification may need to be modified. CD patients are classified by the age of diagnosis, disease sites, behavior, and presence of growth delay for children (see Table 44.5) [65, 66]. In UC, patients are classified by the extent of the inflammation and severity of inflammation (determined by the ACG guidelines and the Pediatric Ulcerative Colitis Activity Index; see Table 44.6) [65–68].

Endoscopic Scores

In addition to clinical classification systems, several IBD phenotype-specific endoscopic scores have been developed to assist in consistent grading of disease severity and to assess endoscopic response. In UC, the endoscopy subscore of the Mayo score is the most frequently employed in clinical practice (see Table 44.7 and Fig. 44.6); however, this score is a very simple four-point scale that only measures severity of colitis in the most inflamed segment of the colon/rectum, and inter-rater variability has been shown to be moderate [69, 70]. Over 15 other scores have been developed to summarize both the endoscopic severity of the inflammation and its extent, including the Modified Mayo Endoscopic Score (MMES), which employs the sum of Mayo score in all five segments of the colon, multiplied by the number of segments visualized, divided by the number of segments inflamed (see Table 44.7) [70, 71]. Despite being well correlated to disease activity and disease response, further validation of this score is required before wide clinical use [70, 71]. Based on current literature, there is insufficient evidence to recommend a single index in UC, and clinicians should employ the index that is most commonly used locally to improve communication with the other members of the treatment team [70].

In Crohn's disease, the simplified endoscopic activity score for Crohn's disease (SES-CD) is the most commonly employed in clinical practice and in research, has excellent inter-observer agreement, and demonstrates greater responsiveness than the more complex Crohn's disease endoscopic index of severity (CDEIS) [72–74]. The SES-CD consists of scoring the terminal ileum, right colon, transverse colon, left colon, and rectum in the domains of ulceration, ulcerated

Table 44.5 Montreal and Paris classification of Crohn's disease [65, 66]

	Montreal	Paris
Age at diagnosis	A1 < 17 years A2 17–40 years A3 > 40 years	A1a <10 years A1b 10–17 years A2 17–40 years A3 > 40 years
Location	L1 terminal ileum L2 colon L3 ileocolon L4 upper GI[a]	L1 distal 1/3 ileum L2 colon L3 ileocolon L4a upper disease prox. to the ligament of Treitz[a] L4b upper disease distal to the ligament of Treitz and proximal to distal 1/3 ileum[a]
Behavior	B1 nonstricturing, nonpenetrating B2 stricturing B3 penetrating p perianal disease modifierΔ	B1 nonstricturing, nonpenetrating B2 stricturing B3 penetrating B2B3 both penetrating and structuring disease p perianal disease modifierΔ
Growth delay		G0 no growth delay G1 growth delay

Δp may be added to B1–B3 (i.e., B1p)
[a]L4 and L4a/b may be added to L1–L3 (i.e., L2 + L4); upper GI is defined as any disease proximal to the terminal ileum

Table 44.7 Endoscopic evaluation in ulcerative colitis, the endoscopic subscore of the Mayo score, and the Modified Mayo Endoscopic Score (MMES) [71, 77]

	0	1	2	3
Mayo endoscopic subscore	Normal or inactive disease	Erythema Decreased vascular pattern Mild friability	Marked erythema Absent vascular pattern Friability Erosions	Ulcerations Spontaneous bleeding
MMES	Sum of Mayo score for all 5 colon segments[a] (max 15) × length of inflamed segment during withdrawal (in dm) ÷ number of segments[a] inflamed (>0 Mayo score, max 5)			

[a]Segments = rectum, sigmoid, descending, transverse, and ascending colon

Table 44.6 Montreal and Paris classification of ulcerative colitis [65, 66]

	Montreal	Paris
Extent	E1 ulcerative proctitis E2 left-sided UC (distal to splenic flexure) E3 extensive UC (proximal to pancolitis)	A1a <10 years A1b 10–17 years A2 17–40 years A3 > 40 years
Severity	S0 clinical remission S1 mild UC (≤4 BM/day, no systemic toxicity, normal ESR) S2 moderate UC (≥ 5 BM/day, mild signs of systemic toxicity) S3 severe UC (≥ 6 bloody BM/day, evidence of toxicity)	S0 never severe S1 ever severe[a]

[a]Severity defined by Pediatric Ulcerative Colitis Activity Index >65 [68]

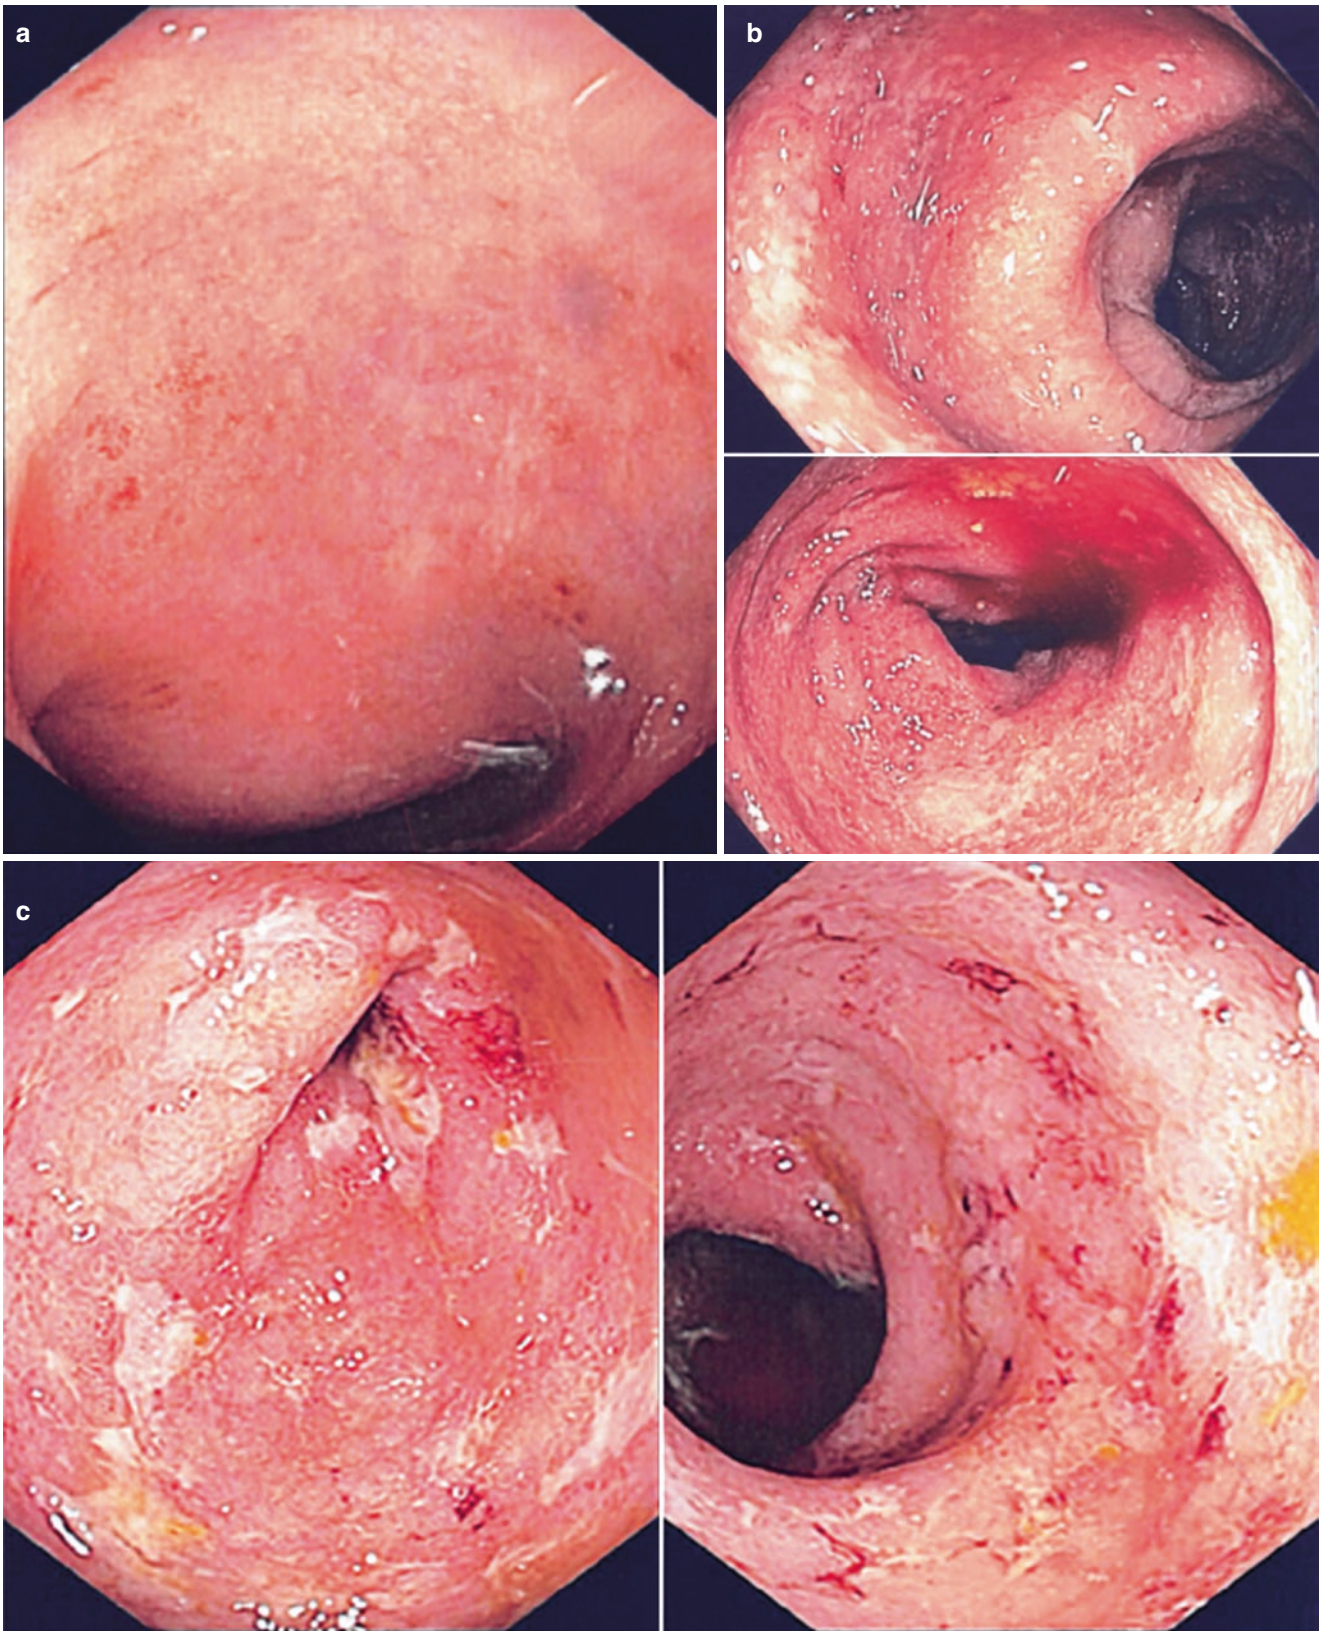

Fig. 44.6 Representative examples of Mayo endoscopic subscore for grading of colitis: (**a**) Mayo 1, (**b**) Mayo 2, and (**c**) Mayo 3 colitis

Table 44.8 The simplified endoscopic activity score for Crohn's disease (SES-CD) [73]

Domain	0	1	2	3
Size of ulcers	None	Aphthous (<5 mm)	Large (5–20 mm)	Very large (>20 mm)
Ulcerated surface	None	<10%	10–30%	>30%
Affected surface	Unaffected	<50%	50–75%	>75%
Presence of narrowings	None	Single, passable	Multiple, passable	Cannot be passed

Each segment (terminal ileum, right colon, transverse colon, left colon, and rectum) receives a score for each domain, and the sum of all the domain scores for all the segments is the total SES-CD

Table 44.9 Rutgeerts score to assess recurrent disease in the neoterminal ileum following an ileocolic resection

i0	i1	i2	i3	i4
No lesions	≤5 aphthous ulcers	>5 aphthous ulcers with normal intervening mucosa, skip areas of larger lesions confined to ileocolonic anastomosis	Diffuse aphthous ileitis with diffusely inflamed mucosa	Diffuse inflammation with large ulcers, nodules, and/or stenosis

i2 and greater are classified as endoscopic recurrence [75]

surface, affected surface, and presence of narrowing; each domain is scored from 0 to 3, and the sum of all domains for all five segments comprises the SES-CD for that patient (see Table 44.8) [73]. For patients who have previously had an ileocolic resection, the Rutgeerts score is commonly employed to grade the extent of inflammation within the terminal ileum and has been strongly associated with risk of symptomatic recurrence; however, it has been shown to have only modest inter-rater reliability (see Table 44.9 and Fig. 44.7) [75, 76].

At the time of endoscopy, it may assist the physician to accurately and systematically evaluate the extent of endoscopic disease by printing the commonly employed endoscopic indices directly on the synoptic colonoscopy report form, as done at our institution.

Activity Scores

In addition to endoscopic scores, several activity scores have been reported for grading the severity of IBD. For patients with UC, the Mayo score is often described in the literature and includes an assessment of stool frequency, rectal bleeding, a physician's global assessment, and the endoscopic subscore (see above) to generate a score from 0 to 12 [77]. Despite its simplicity, the Mayo score is rarely employed in routine clinical practice, and patients are more often described as having mild, moderate, or severe colitis based on Truelove and Witt's criteria (see Table 44.6) [78]. In addition, UC patients are often characterized by their response to treatment: medically/steroid refractory, steroid dependent, medically responsive, or in remission.

In Crohn's disease, the Crohn's disease activity index (CDAI) is often employed in clinical trials with a score of <150 consistent with remission; however, it is not used in routine clinical practice given the complexity in calculating the score itself [79, 80]. In contrast, the Harvey-Bradshaw index is a simplified score for CD and involves assessment of the patient's general well-being, abdominal pain, number of bowel movements per day, presence of an abdominal mass, and complications of Crohn's disease (see Table 44.10) [81]. This index is highly correlated with the CDAI, is easier to administer, and is used more broadly in the clinical setting (see Table 44.10) [80, 81].

More recently, there have been over 20 new patient-reported outcome measures (PROMs) that have been described in the literature, some of which include patient responses only (such as IBD-10), while others combine scores with laboratory investigations such as CRP or fecal calprotectin (such as Monitor IBD At Home questionnaire (MIAH)) and/or clinical assessment (such as HB-PROp/c) [82–85]. Although these indices have demonstrated accuracy in predicting endoscopic activity and correlation with other indices, they require external validation and direct comparative analyses in a single cohort to assess superiority of one over the other [82–85].

Surveillance Endoscopy in IBD

There is ample evidence based on population-based cohorts, cohort, and case-control studies that patients with IBD are at an increased risk of colorectal cancer (CRC) [86–90]. CRC in the setting of IBD is associated with a younger age of diagnosis, and patients have a higher risk of death (even after adjustment for stage) [86–88, 91]. Among IBD patients, those with an earlier onset of disease, longer duration of disease, active inflammation, colonic strictures, PSC, and a family history of CRC are at a higher risk of CRC [86, 89, 92]. The evidence for endoscopic surveillance for dysplasia and CRC is based solely on low-quality observational data, but surveillance has been consistently associated with a decreased risk of CRC, a lower stage of CRC when diagnosed, and a lower risk of death from CRC [93, 94].

Society guidelines recommend surveillance for all UC patients and CD patients with colonic involvement (but excluding patients with a history of proctitis alone) and to commence colonoscopy surveillance at 8 years following symptom onset or at diagnosis if PSC is present. Ideally, sur-

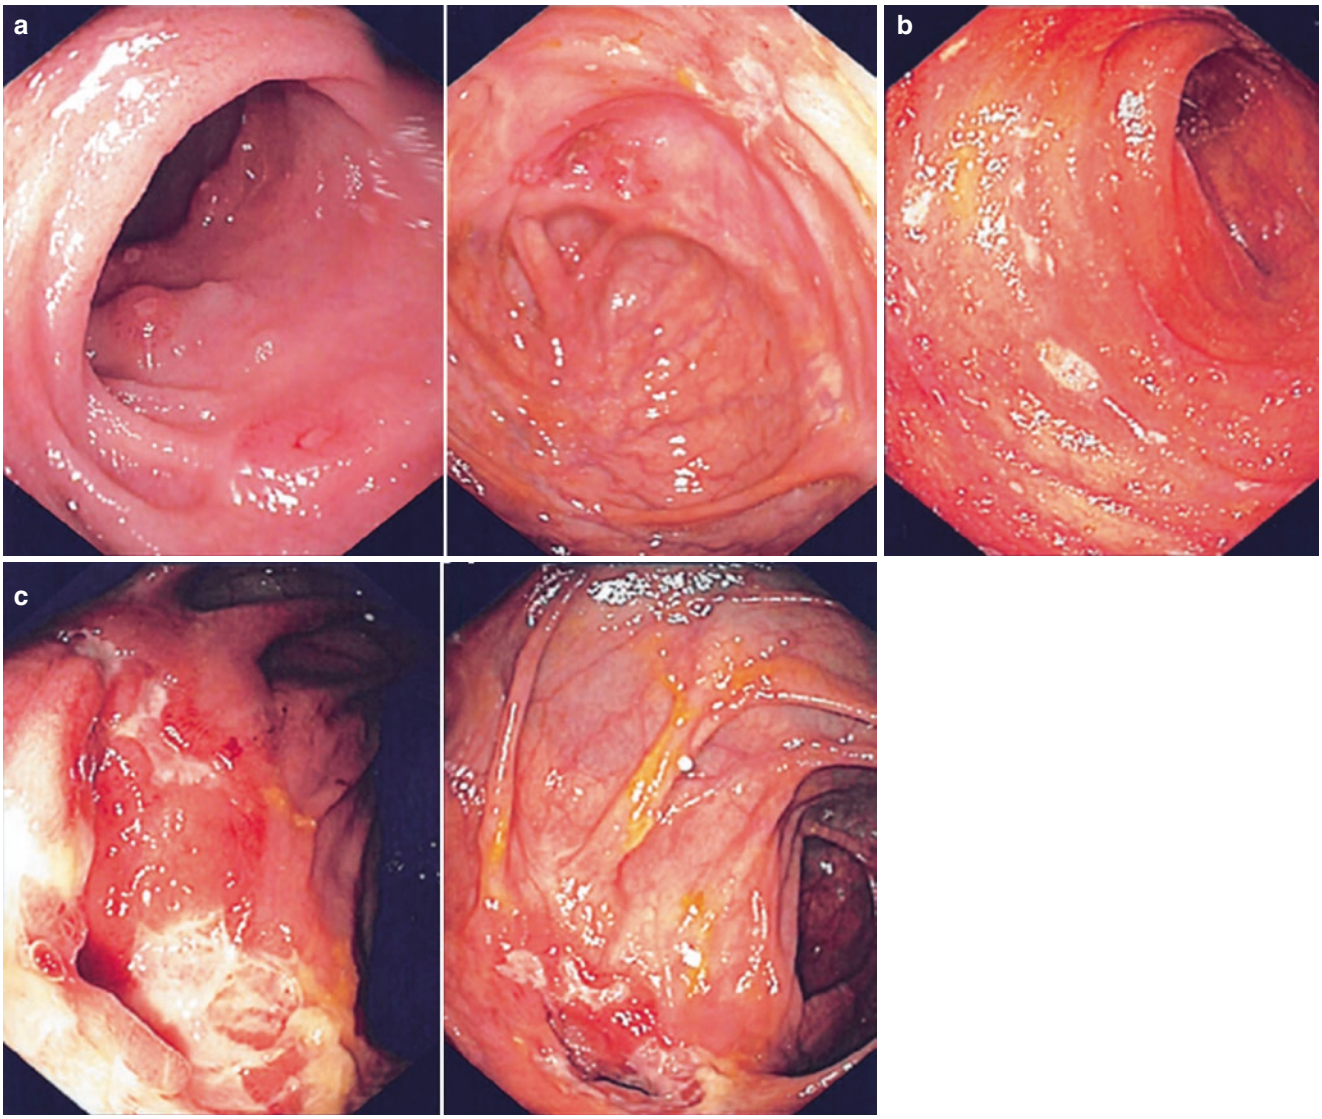

Fig. 44.7 Representative examples of Rutgeerts score for grading neoterminal ileal recurrence: (**a**) i2, (**b**) i3, and (**c**) i4

veillance should occur when the disease is in remission to increase the reliability of histopathology findings of dysplasia [61, 62, 92]. Chromoendoscopy may improve dysplasia detection compared to standard-definition colonoscopy; however, data are inconsistent with respect to the added value of chromoendoscopy in addition to high-definition colonoscopy [62, 95–97]. Two recent RCTs have demonstrated no added benefit of chromoendoscopy in detecting colitis-associated dysplasia [96, 97]. Therefore, guidelines recommend high-definition colonoscopy with chromoendoscopy if local expertise exists [61, 62, 92].

Based on current evidence, there is a lack of consensus on the incremental yield of random colonic biopsies in addition to targeted biopsies of abnormal mucosal findings [61, 62, 92]. Therefore, until further data are available, four random biopsies should be taken every 10 cm and reviewed by a GI pathologist [61, 62, 92]. Patients at high risk (PSC, family history of CRC, stricture, or dysplasia) should undergo annual surveillance colonoscopy, while those with intermediate risk (including those with active mucosal inflammation) should undergo surveillance colonoscopy in 1–3 years; and those at low risk should undergo surveillance colonoscopy every 3–5 years [61, 62, 92].

Based on the SCENIC guidelines, the terminology used to describe endoscopically detected dysplastic lesions in IBD patients has evolved [98]. The term dysplasia-associated lesion or mass (DALM) is no longer being employed, and lesions should be described based on the visibility, morphology, border, and presence of ulceration (see Table 44.11) [98, 99].

Table 44.10 Harvey-Bradshaw index for Crohn's disease activity [81]

Domain	Score
General well-being	0 = very well 1 = slightly below par 2 = poor 3 = very poor 4 = terrible
Abdominal pain	0 = none 1 = mild 2 = moderate 3 = severe
Number of liquid stools per day	# of liquid stools/day
Abdominal mass	0 = none 1 = dubious 2 = definite 3 = definite and tender
Complications	1 point for each of: Arthralgia Uveitis Erythema nodosum Aphthous ulcers Pyoderma gangrenosum Anal fissure New fistula Abscess

Table 44.11 SCENIC guidelines for reporting dysplastic lesions identified on colonoscopy surveillance [98]

Terms	Definitions
Visible dysplasia Invisible dysplasia	Dysplasia identified on targeted biopsies from a lesion visualized at colonoscopy Dysplasia identified on random biopsies without a visible lesion
Polypoid Pedunculated Sessile	Protruding into lumen >2.5 mm Stalk present No stalk; entire base is contiguous with mucosa
Nonpolypoid Superficially elevated Flat Depressed	No or little (<2.5 mm) protrusion above the mucosa Protrusion <2.5 mm No protrusion above the mucosa Any portion depressed below the level of the mucosa
Distinct border Indistinct border	Discrete border can be distinguished from surrounding mucosa Border cannot be distinguished from surrounding mucosa
Ulcerated	Ulceration (fibrinous-appearing base with depth) within the lesion

Medical Management of Ulcerative Colitis

45

Amy L. Lightner and Scott A. Strong

Key Concepts

- The goal of medical therapy for ulcerative colitis is steroid-free clinical remission with mucosal healing.
- 5-ASA medications are the first-line treatment for low-risk patients with mild-to-moderate UC.
- IV corticosteroids are first-line treatment for severe UC flare-ups requiring hospitalization.
- Cyclosporin and infliximab are appropriate second-line agents for patients with steroid refractory severe acute colitis.

Introduction

Appropriate treatment of ulcerative colitis includes a combination of medical and surgical therapies to safely resolve inflammation, lessen symptoms, improve quality of life, and minimize the risk for short- and long-term complications. Therapy is usually guided by the age of the patient, anatomic extent of inflammation, symptom severity, treatment response, and risk for adverse effects. Treatment can be intended to induce remission in patients with active disease or maintain remission in others. Operative intervention is generally reserved for patients with disease-related complications or disease that is refractory to medical therapy, with the latter indication being quite common. Consequently, it is important for the surgeon to understand the indications, dosing, benefits, and risks of the various types of medications used to treat ulcerative colitis.

Medications

Homeopathic agents, 5-aminosalicylate compounds, glucocorticoids, immunomodulators, and biologic agents/biosimilars are all modalities used for the medical treatment of ulcerative colitis depending upon the clinical scenario. Each drug within these therapeutic groups is distinguished by dosing parameters, short- and long-term side effects, and expected response intervals. Before initiating therapy with any medication, patients should be comprehensively counseled about these characteristics. Moreover, objective criteria for disease response should be initially discussed and then measured after a reasonable time interval. If the desired response is not achieved, prohibitive side effects ensue, or noncompliance transpires, the drug has failed, and another medication/approach should be trialed. When medical management has proven unsuccessful, operative intervention is generally indicated. The continuation of ineffective drug therapy risks the development of further disease complications that may adversely impact surgical outcomes.

Some patients will instead seek an operation before trialing all available medical modalities because they have concerns regarding the alternative drug(s). Interestingly, a survey of outpatients with ulcerative colitis, gastroenterologists, and colorectal surgeons quantified this behavior [1]. Participants were interviewed to measure their inclinations in five scenarios by using a prospective preference measure. When the scenario pitted escalating medical therapy against a proctocolectomy and ileal pouch-anal anastomosis, 80% of gastroenterologists were willing to gamble life expectancy while only 64% of patients, and 49% of colorectal surgeons were willing to similarly gamble. Conversely, 75% of patients were willing to gamble with escalating medical therapy to avoid a proctocolectomy and permanent ileostomy compared to 85% of gastroenterologists and 68% of surgeons.

Homeopathic Agents

Curcumin

Curcumin (diferuloylmethane), the yellow pigment in the large-leafed herb Indian saffron (i.e., *Curcuma longa*; turmeric, haldi, or haridara in the East; curry powder in the West) has been consumed for centuries to manage a variety of proinflammatory disorders [2]. Its postulated mechanism of action includes suppression of the nuclear factor k-light chain enhancer in B-lymphocytes as well as expression of Th1 and Th2 cytokines. Curcumin has also been reported to possess anti-interleukin (IL)-1 and anti-tumor necrosis factor (TNF) properties, and this makes it an attractive treatment option for inflammatory conditions. A recent meta-analysis of 7 studies with 380 patients (curcumin $n = 188$; placebo $n = 190$) reported a threefold increase in clinical and endoscopic response to curcumin as an adjunct to mesalamine compared to mesalamine plus placebo; only 21 adverse events were reported and all were of mild degree [3].

Probiotics

Probiotics are beneficial microorganisms that can potentially impact the gut's microbiota composition, metabolic activity, and immunomodulation to confer host benefit. These bacteria and fungi can alter microbial diversity through competitive inhibition of other microbes, enhance mucosal barrier function via the production of short-chain fatty acids, and interact with intestinal dendritic cells to instigate an anti-inflammatory response. The microorganisms must be of human origin, nonpathogenic, and able to survive the gastrointestinal transit in order to be beneficial. Although probiotics have not been approved by the US Food and Drug Administration (FDA) to prevent or treat any health condition, a recent meta-analysis suggested that probiotics containing bifidobacteria offer a promising role for the treatment of active ulcerative colitis [4].

5-Aminosalicylate Compounds

A number of 5-aminosalicylate (ASA)-containing compounds are available with active 5-ASA released at various locations throughout the intestinal tract depending on the design of each specific drug. These compounds work by activating a class of nuclear receptors involved in the control of apoptosis, cell proliferation, inflammation, and metabolic function. The gamma forms of the peroxisome proliferator-activated receptors are found at particularly high levels in colon epithelial cells, where their expression appears to be at least partially stimulated by gut bacteria. Sulfasalazine is the original 5-aminosalicylate and is comprised of 5-ASA bound to a sulfapyridine moiety that detaches when the drug is impacted by colonic bacteria.

Other 5-ASA-derivatives, such as mesalamine, are formulated for release in the colon through varied mechanisms including bacterial- and pH-mediated as well as time-dependent release. Patients with limited disease (e.g., proctitis, left-sided disease) may prefer transanal topical therapy (e.g., suppository, enema) because of less frequent dosing, lower cost, and shorter response time compared to oral treatment.

Although sulfasalazine and mesalamine are both associated with side effects, the sulfapyridine moiety of sulfasalazine appears to impart a wider range of more serious adverse events, including symptoms such as gastrointestinal upset and headaches. Rare side effects include bone marrow suppression, fever, hemolytic anemia, hepatitis, hypersensitivity reactions, pancreatitis, pneumonitis, and rash. Patients who take sulfasalazine must also take folic acid (1 mg daily) because the medication depletes folic acid stores. Whereas nausea and headaches are typically dose-dependent and slow titration of the dosage can minimize these problems, sulfasalazine should be discontinued for idiosyncratic drug reactions such as agranulocytosis, pancreatitis, pneumonitis, and skin rash. Conversely, mesalamine is a safe, effective medication, and it is rare for patients to develop side effects; interstitial nephritis can develop, so routine monitoring of kidney function is recommended [5].

Glucocorticoids

Glucocorticoid drugs were first used for the management of ulcerative colitis several decades ago, and their benefit originates from an ability to modulate the immune response, inhibit expression of adhesion molecules, and decrease trafficking of inflammatory cells to the intestine. However, the traditional glucocorticoids are associated with significant short- and long-term adverse effects that limit their usage to management of acute episodes. Budesonide, a glucocorticoid with an extensive first pass liver metabolism was consequently developed because it maximizes the amount of glucocorticoid locally available but theoretically has minimal systemic impact. Three formulations of budesonide currently exist with two standard capsules designed to release the drug in the terminal ileum and right colon and a newer budesonide capsule (i.e., budesonide MMX®) formulated to steadily release the drug throughout the entire colon.

Resistance and dependency are major concerns when treating patients with glucocorticoids. The occurrence and severity of most side effects are related to the dose and duration of treatment. Common findings include abdominal striae, acne, cataracts, fluid retention, glaucoma, hyperglycemia, hypertension, insomnia, mood disturbances, moon facies, and weight gain. Musculoskeletal complications such as myopathy, osteonecrosis, and osteoporosis are additional

side effects. Lastly, adrenal suppression can occur during the course of treatment and contribute to physiologic dependence.

Oral and rectal budesonide formulations are associated with little to no risk. Studies suggest a small alteration in systemic cortisol levels associated with budesonide therapy, but typical steroid-related side effects are only seen with oral budesonide chronically prescribed at high dosages [6].

Immunomodulators

The thiopurines are immunomodulators that can be used to allow glucocorticoid tapering in patients with "steroid-dependent" disease but are not generally employed as monotherapy to induce or maintain remission. Conversely, cyclosporin and tacrolimus are calcineurin inhibitors that can be prescribed in "steroid-refractory" patients to achieve remission; tofacitinib, a nonselective inhibitor of the Janus kinase enzyme, can both induce and maintain remission.

Thiopurines

Azathioprine and 6-mercaptopurine (6-MP) are thiopurines with azathioprine being the precursor of 6-MP. Although their exact mechanism of action in patients with ulcerative colitis is uncertain, they are known to cause immunosuppression by interfering with nucleic acid metabolism in the immunological sequence that follows antigenic stimulation. Genetic polymorphisms of thiopurine methyltransferase (TPMT), the primary enzyme responsible for 6-MP metabolism, have been identified, and drug metabolite levels can be measured. These clinical assays allow monitoring and dosing of the medications according to measurements of the metabolites 6-thioguanine and 6-methylmercaptopurine. Prior to starting thiopurine therapy, TPMT enzyme activity or genotype should usually be determined because the drugs should be avoided in patients with TPMT deficiency. Patients with heterozygous genotype of intermediate activity should begin therapy at reduced doses that are one-half the usual recommendations. If TPMT activity or genotype cannot be assayed in advance of initiating treatment, the drugs should be cautiously dosed at the outset with careful monitoring for leukopenia.

While the most common side effect linked to azathioprine and 6-MP is nausea, adverse events associated with these drugs include liver function abnormalities, leukopenia, and pancreatitis. Pancreatitis typically presents during the first 8 weeks of therapy, and reintroduction of either agent should be avoided because pancreatitis will likely recur. Routine monitoring of complete blood counts is recommended at 1- to 2-week intervals initially and subsequent to a dose change and then at least every 3 months thereafter to detect evidence of acute or delayed bone marrow suppression. Rare hypersensitivity reactions characterized by fever, liver dysfunction, and rash may occur. A slightly increased risk of lymphoma has also been reported [7, 8].

Data related to the risk of serious infections were obtained from a large prospective, observational cohort study of 6273 patients with a mean follow-up of more than 5 years [9]. On multivariate analysis, thiopurine therapy was associated with a trend towards an increase in serious infections (adjusted odds ratio: 1.23; 95% CI, 0.96–1.57). Patients treated with thiopurines had 10 more serious infections per 1000 patients compared with patients who were not managed with thiopurines.

Methotrexate

Methotrexate and its polyglutamate metabolites are folic acid analogues that demonstrate inhibitory activity against many enzymes in the metabolic pathway of folic acid. Chronic low-dose methotrexate therapy inhibits the production of thymidylate, purines, and methionine and leads to the accumulation of adenosine, a potent anti-inflammatory purine nucleoside. These actions decrease formation of antibodies, inhibit cellular proliferation, and reduce the production of inflammatory mediators. Methotrexate is administered each week by oral ingestion (12.5–15 mg) or intramuscular/subcutaneous injection (25 mg). Folic acid (1 mg daily) should be concomitantly prescribed. The most frequent side effects reported with methotrexate are gastrointestinal upset and stomatitis. Leukopenia can also occur but much less frequently than seen with thiopurine therapy. Rare complications of methotrexate therapy include hepatic fibrosis and hypersensitivity pneumonitis.

Calcineurin Inhibitors

Cyclosporine and tacrolimus bind with great affinity to a family of cytoplasmic proteins present in most cells. The resultant drug-receptor complex competitively and specifically inhibits calcineurin, leading to reduced production of interleukin (IL)-2 and a resultant reduction in T lymphocyte proliferation [10]. While both cyclosporine and tacrolimus can be administered by infusion (2–4 mg/kg/day; 0.01–0.02 mg/kg/day, respectively) or ingestion (4–8 mg/kg/day; 0.1–0.2 mg/kg/day, respectively), the serum trough levels achieve target more quickly with an intravenous approach. The principal side effects of these medications include gastrointestinal intolerance, gum hyperplasia, hirsutism, hypertension, renal dysfunction, and tremor [11]. In one cohort, 13.5% of patients treated with cyclosporine and/or tacrolimus had to discontinue treatment because of adverse events with gastrointestinal intolerance and hypertension cited as the most frequent reasons for drug discontinuation [12].

Janus Kinase Enzyme Inhibitors

Janus kinase inhibitors (JAKi) such as tofacitinib are oral, small molecule drugs that bind a group of four membrane-bound receptors and mediate regulation of genes that code for diverse inflammatory proteins through the signal transducer and activator of transcription proteins pathway [13]. Tofacitinib was initially approved (10 mg twice daily by mouth) for patients failing standard treatment (e.g., mesalamines, glucocorticoids) or those exposed to biologic agent(s). However, the indication for ulcerative colitis has been recently limited to adults with moderately to severely active disease who have had an inadequate response or who are intolerant to TNF blockers; there were concerns from rheumatoid arthritis post-marketing clinical trials regarding an increased occurrence of blood clots and death in patients treated with the 10 mg twice-daily dosing. Until further information is available, the lower 5 mg twice daily dose should be used for maintenance when feasible. This medication is also associated with increased risk for infections and hyperlipidemia [14]. No problems related to immunogenicity are expected with tofacitinib because it is a synthetic small molecule JAK inhibitor and not a biologic agent.

Biologic Agents/Biosimilars

Biologic agents have played an increasing and evolving role in the management of ulcerative colitis. All biologic agents approved by the Food and Drug Administration to manage patients with ulcerative colitis (i.e., infliximab, adalimumab, golimumab, vedolizumab, ustekinumab), demonstrate a positive correlation between drug concentrations and favorable therapeutic outcomes. Reactive therapeutic drug monitoring has become the new standard of care for optimizing biologic agent therapies, and some pundits now advocate for proactive therapeutic drug monitoring to enhance therapy with antitumor necrosis factor (TNF) medications [15]. Second, biosimilars have been developed and introduced at a lower cost because patents have expired for some of the original biologic agents. Despite initial concerns, mounting evidence from phase III/IV clinical trials and prospective observations has partially confirmed the short- and long-term efficacy, interchangeability, and safety of biosimilars.

Antitumor Necrosis Factor (TNF) Agents

The anti-TNF medications are designed to block the effects of TNFα, and three such medications (i.e., infliximab, adalimumab, golimumab) are currently approved for the treatment of ulcerative colitis. Infliximab is permitted for the treatment of moderate-to-severe ulcerative colitis that does not respond to standard therapies. Adalimumab is accepted for the treatment of moderate-to-severe disease that does not respond to conventional medications, but its effectiveness for patients who have lost response to or are intolerant of infliximab is uncertain. Golimumab was approved for therapy in patients with moderate-to-severe disease who demonstrate an inadequate response or intolerance to prior treatment or require continuous steroid therapy. Dose optimization of anti-TNF agents through the measurement of serum levels is an important step to complete before switching to another biologic agent [15].

Infliximab (5 mg/kg) is parenterally administered and usually well tolerated. After the initial infusion of infliximab, patients are generally administered another dose 2 and 6 weeks later and then at consistent 8-week intervals. If patients lose their initial response to infliximab, the medication dose can be increased (10 mg/kg), or the interval between infusions can be decreased (every 6 weeks) depending on individual pharmacokinetics. Infusion reactions are not uncommon, and most are successfully managed without discontinuing the infusion or preventing further use of infliximab.

Adalimumab (40 mg) is given as a single subcutaneous injection every other week after an initial induction regimen of four injections the first week and two during the third week. Although adalimumab may prove highly effective in the initial treatment stages, some patients lose response over time, and the medication may need to be administered each week.

Golimumab (100 mg) is indicated for patients who demonstrate an inadequate response or intolerance to prior treatment or require continuous glucocorticoid therapy. The drug is given by subcutaneous injection at weeks 2 and 6 and continued every 4 weeks after an initial induction with two injections.

Side effects associated with the anti-TNF agents are well recognized and include an increased risk of infections, such as tuberculosis, as well as autoimmune reactions, heart failure, liver dysfunction, lymphoma, and multiple sclerosis. Ongoing infection is an absolute contraindication to treatment with any TNF inhibitor. Prior to initiating treatment with an anti-TNF agent, patients should be screened to ensure that they do suffer from occult infection secondary to hepatitis B or tuberculosis.

Integrin Receptor Antagonist

Vedolizumab is monoclonal antibody targeting a specific integrin, $\alpha_4\beta_7$, that reduces lymphocyte trafficking by blocking interactions with mucosal vascular address in cell adhesion molecule (MAdCAM-1) [16]. The medication is indicated for patients with moderate-to-disease who have failed glucocorticoid or immunomodulator therapy. After an initial infusion of vedolizumab (300 mg), patients are administered another dose 2 and 6 weeks later and then at consistent 8-week intervals. If patients have not experienced a therapeutic benefit by 14 weeks of induction therapy or can-

not discontinue glucocorticoids within 6 months of starting therapy, the drug should be discontinued.

In a pooled analysis of 6 randomized controlled trials with 2830 inflammatory bowel disease patients, vedolizumab was associated with a favorable safety profile over an extended treatment period with low incidence rates of serious infections, malignancies, and infusion-related reactions [17].

IL-12 and IL-23 Inhibitor

Ustekinumab is a monoclonal antibody targeting the p40 subunit shared by IL-12 and IL-23. Ustekinumab is approved for use in moderate-to-severe ulcerative colitis; standard dosing includes an initial, weight range-based (260 mg, 390 mg, or 520 mg) infusion followed by 90 mg subcutaneous injections every 8 weeks. Ustekinumab has not been linked to increased rates of adverse events or serious adverse events including major cardiovascular events, malignancy, and mortality.

Disease Severity

The clinical severity of ulcerative colitis is classified as mild, moderate, or severe disease. The definition of mild-to-moderate disease is less than four to six bowel movements per day, mild to moderate rectal bleeding, no signs of systemic toxicity, normal C-reactive protein (CRP) and/or erythrocyte sedimentation rate (ESR), and absence of features suggestive of high inflammatory activity based upon the Truelove and Witt's criteria (Table 45.1) [18], the Mayo Clinic score (Table 45.2), and the Mayo Clinic endoscopic severity score (Table 45.3) [19]. Moderate disease is defined as more frequent bowel movements (4–6 times per day) that may be loose and bloody, mild anemia not requiring transfusion (hemoglobin >10 g/dL), non-severe abdominal pain, no or minimal signs of systemic toxicity, and maintenance of body weight. Severe disease is defined as frequent, loose bloody stools (>6 per day) with severe cramps and evidence of systemic toxicity (e.g., fever, tachycardia), anemia (hemoglobin <10 g/dL), elevated CRP and/or ESR, and weight loss.

The exact definition of moderate-to-severe disease can vary in the literature depending in which index or scoring system is utilized (e.g., Truelove and Witts severity index, Mayo Clinic score, Montreal classification). Most often, however, patients with moderate-to-severe disease are defined as those dependent on or refractory to glucocorticoids, have severe endoscopic disease activity (presence of ulcers), are at high risk of colectomy based on Truelove and Witts criteria, or have a Mayo Clinic score of 6–12 with an endoscopic subscore of 2 or 3. Similar to severe colitis, acute severe ulcerative colitis (ASUC) is defined as six or more bowel movements per day plus at least one sign of systemic toxicity including tachycardia, fever, anemia

Table 45.1 Truelove and Witts score [18]

	Mild[a]	Moderate	Severe[b]
(1) Frequency of defecation	4 times or less	Intermediate between mild and severe	6 times or more
(2) Bloody stool	(−) or (+)		(+++)
(3) Fever[c]	Absent		37.5 C or higher
(4) Tachycardia[d]	Absent		90/min or more
(5) Anemia	Absent		Hb 10 g/dL or less
(6) ESR	Normal		30 mm/h or more

[a]Rated as "mild" when all six criteria are satisfied
[b]Rated as "severe" when criteria (1) and (2), and either of systemic symptoms (3) and (4) are satisfied, and at least 4 of the 6 criteria are satisfied
[c]Mean evening temperature of 37.5C or a temperature of ≥37.8C at least 2 of 4 days
[d]Mean pulse rate of >90/min

Table 45.2 Mayo score system for ulcerative colitis [19]

Measure	Scoring system
Stool frequency (per day)	0 = normal number of stool for patient
	1 = 1–2 more stools than normal
	2 = 3–4 more stools than normal
	3 = 5 + more stools than normal
Rectal bleeding	0 = no blood seen
	1 = streaks of blood with stool <50% time
	2 = obvious blood with stool most of the time
	3 = passes blood without stool
Findings on endoscopy	0 = normal or inactive disease
	1 = mild disease
	2 = moderate disease
	3 = severe disease
Physician's global assessment	0 = normal
	1 = mild disease
	2 = moderate disease
	3 = severe disease

Table 45.3 Mayo endoscopic severity score [19]

Score	Disease activity	Endoscopic features (descriptors)
0	Normal or inactive	None
1	Mild	Erythema, decreased vascular patter, mild friability
2	Moderate	Marked erythema, absent vascular pater, friability, erosions
3	Severe	Spontaneous bleeding, ulceration

(hemoglobin <10.5 g/dL), or elevated inflammatory markers (ESR >30 mm/hour) [18].

The majority of ulcerative colitis patients fall into the cohort of mild-to-moderate disease with intermittent periods of disease remission or activity. However, some patients who begin in the mild-to-moderate category will transition to moderate-to-severe if they begin having more frequent bowel movements, rectal bleeding, or an increased overall inflammatory burden. Similarly, while most patients in this mild-to-moderate category are at low risk of needing a colectomy, certain features such as age less than 40 years at diagnosis, pancolitis, extraintestinal manifestations, presence of deep ulcers on endoscopy, and elevated inflammatory markers can predict a more aggressive disease course [20]. When these features are present, patients may benefit from more aggressive initial therapy or rapid intensification rather than repeated courses of glucocorticoids. Other risk factors for a more complicated disease course and an increased need for colectomy include the number of hospitalizations related to ulcerative colitis, number of disease flares, need for glucocorticoids, and infection with *Clostridium difficile* or cytomegalovirus [20, 21]. Overall, the cumulative risk of colectomy after 5–10 years of disease is 15–20%, but this can increase to 25–30% in a subset of patients with acute severe ulcerative colitis (ASUC) [22, 23].

Induction of Remission

The treatment goal for patients afflicted with ulcerative colitis is glucocorticoid-free clinical remission with demonstration of complete mucosal healing on endoscopy. Increasing evidence supports the use of histologic remission as a principal endpoint, but this is not yet defined as a primary treatment target [24].

Selecting an appropriate induction agent is becoming increasingly difficult as the number of potential pharmaceuticals approved for the treatment of ulcerative colitis continues to increase. The choice is largely driven by both the American College of Gastroenterology (ACG) and American Gastroenterological Association (AGA) guidelines focused on disease severity and extent and a collection of myriad factors including access to an infusion center, concomitant medication use, insurance coverage, patient characteristics, patient compliance, patient preference, prior therapy for ulcerative colitis, and risk of adverse events [24, 25].

Mild-to-Moderate Disease

5-ASA Compounds (Topical, Oral)

Up to 90% of patients with mild-to-moderate ulcerative colitis are initiated on a 5-aminosalicylate (ASA) compound (e.g., sulfasalazine, mesalamine, diazo-bonded 5-ASA) with or without induction using oral or topical glucocorticoids. Both systemic exposure and therapeutic efficacy are equivalent among the various 5-ASA formulations [26, 27]. The majority of patients treated with 5-ASA compounds achieve clinical and endoscopic remission and are able to continue the same medication to maintain remission [5]. The remaining minority of patients require immunomodulator or biologic agent therapy for long-term disease control [22].

The ACG and AGA guidelines recommend topical mesalamine as first-line treatment for inducing remission in low-risk patients with mild-to-moderate ulcerative proctitis or proctosigmoiditis [24, 25, 28]. Low-risk patients are those with mild-to-moderate symptoms; no systemic symptoms; lack of severe endoscopic disease such as deep ulceration, normal, or mild elevation in CRP and/or ESR; no extraintestinal manifestations; diagnosis at age >40 years; and a normal albumin [20, 21, 28]. Mesalamine comes formulated in a suppository or enema, and the preferred choice should be driven by the extent of disease. A suppository will only reach the rectum, whereas an enema can deliver agent to the splenic flexure in most patients.

Thus, for patients with mild-to-moderate disease isolated to the rectum, a mesalamine suppository (1 gram daily) can be initiated. If the patients do not experience any improvement in symptoms after 2 weeks, the dose should be increased (1 gram twice daily) for 4 weeks followed by a reduction back to daily dosing. For patients with mild-to-moderate disease extending into the sigmoid colon, mesalamine enemas (1 gram daily) are more effective than suppositories. If patients achieve symptomatic relief, the dose can be increased to twice daily or stay as once daily. While some patients may experience relief after only 1 week of treatment, clinical remission usually requires 4–6 weeks of treatment.

When patients tolerating topical mesalamine do not demonstrate any improvement after 4 weeks of therapy, subsequent treatment options include supplementing the existing therapy with a daily topical glucocorticoid, an oral 5-ASA derivative, or an oral glucocorticoid (i.e., budesonide, prednisone) [29–31].

Topical glucocorticoids include formulations as a suppository or an enema delivered once daily, depending on the extent of disease; an enema is used if the inflammation extends further than 18 cm proximal to the anal verge [28]. Symptomatic improvement typified by decreased stool frequency and absence of blood in the stool should be seen within 3–4 weeks of initiating therapy. The use of topical glucocorticoids longer than 8 weeks is not recommended due to potential adverse events with chronic use [32, 33].

With regard to oral 5-ASA agents, the AGA recommends treating patients with extensive mild-to-moderate ulcerative colitis with standard-dose (2–3 grams/day) mesalamine or

diazo-bonded 5-ASA [25]. When low-dose (<2 grams/day) [19, 34–36], standard-dose (2–3 grams/day) [34–40], and high-dose (>3 grams/day) [19, 35, 37, 38, 41] 5-ASA concentrations were compared across 18 randomized control trials (RCTs), all were superior to placebo for the induction of remission. Standard- and low-dose were superior to placebo for the maintenance of remission, with the standard-dose being superior to low-dose mesalamine. A meta-analysis of four RCTs for left-sided ulcerative colitis found that a combination treatment with 5-ASA-containing enemas plus oral 5-ASA derivatives was more effective that oral 5-ASA-containing compounds alone for the induction of remission [42]. If there is more extensive or more active colitis, then higher doses of oral 5-ASA up to 4.8 grams/day may be necessary to achieve remission [43].

In patients who fail to reach remission with appropriately dosed 5-ASA, switching classes of 5-ASA medications is not recommended because there is no difference between formulations with regard to therapeutic benefit [26]. Therefore, the next best treatment strategy is initiating oral glucocorticoids in patients who have not responded to oral 5-ASA-based compounds [26].

Glucocorticoids (Topical, Oral)

In patients who are unresponsive or intolerant to oral and rectal 5-ASA derivatives, the ACG recommends patients with left-sided ulcerative colitis start oral colonic-release budesonide (budesonide MMX®) at 9 mg/day, and patients with extensive ulcerative colitis begin oral systemic glucocorticoids [44]. In a prospective RCT, ulcerative colitis patients achieved clinical remission 17.9%, 13.2%, 12.1%, and 7.4% of the time with budesonide MMX® (9 mg daily), budesonide MMX® (6 mg daily), 5-ASA compound, and placebo, respectively, with statistical significance seen in the higher-dose budesonide MMX® group.

For patients who do not respond to budesonide MMX® or have more extensive disease, oral prednisone at a dose of 40–60 mg should be initiated. A meta-analysis demonstrated that traditional glucocorticoids are more effective than both budesonide and placebo for the induction of remission and prevention of relapse [45]. Most patients will respond within a week of starting treatment and can then begin a taper by 5–10 mg per week after 1 week at a higher dose. This approach prevents possible side effects of long-term use [45]. Once induction is achieved, glucocorticoids should not be used for maintenance of remission due to potential side effects. If patients cannot be tapered within 3 months without symptom relapse to less than 10 mg daily of prednisone (or its equivalent), they are considered to have steroid-dependent ulcerative colitis and typically require escalation to other longer-term maintenance therapy to avoid chronic steroid dependency.

Moderate-to-Severe Disease

Selecting induction therapy for patients with moderate-to-severe ulcerative colitis should account for several factors including access to an infusion center and medical care providers, coverage of medication costs by payers, patient characteristics (e.g., age, comorbidities), patient compliance, patient preferences, prior therapies for ulcerative colitis, risk of adverse events (e.g., infection, malignancy), and plan for long-term maintenance therapy [46]. Due to the complexity of the decision, significant variability in treatment patterns exists among ulcerative colitis patients [47].

5-ASA Compounds (Topical, Oral)

While 5-ASA-based therapy is effective in mild and moderate disease, it is not useful for treating severe disease. One meta-analysis showed that patients with moderately active disease demonstrated benefit with 2.4 grams/day of oral 5-ASA, but glucocorticoid therapy remained more effective for patients with severe disease [48]. Thus, 5-ASA derivatives are not often prescribed for this cohort of patients.

Glucocorticoids

For moderate disease, oral budesonide or colonic-release budesonide (budesonide MMX®) can be used for induction of remission. In both a dose-finding RCT and multicenter RCT of budesonide MMX® (9 mg daily) in mild-to-moderate disease, improved efficacy for induction of combined clinical and endoscopic remission at week 8 as compared to placebo was demonstrated [40]. In addition, patients in the budesonide and control groups experienced similar rates of adverse events.

However, systemic glucocorticoids remain the cornerstone of induction therapy for moderate-to-severe disease of any extent according to both small prospective studies and meta-analyses of these trials, which reported significant benefit with the use of systemic glucocorticoids compared to placebo [40].

Immunomodulators

Thiopurines and methotrexate are slow acting and do not induce remission in moderate-to-severe ulcerative colitis [49–52]. In a multicenter study using methotrexate for induction, an increased number of patients achieved steroid-free remission, but this did not reach statistical significance [53]. For this reason, the ACG and AGA do not recommend immunomodulator monotherapy for the induction of remission [24, 25, 28, 47]. Thus, most patients with moderate-to-severe ulcerative colitis are given a biologic agent or small molecule JAK inhibitor for induction of remission.

Tofacitinib, the only approved small molecule, is a non-selective inhibitor of the Janus kinas enzyme and preferred

Table 45.4 Pivotal trials for induction of UC

Drug	Approval by the FDA for UC	Pivotal studies	Number of patients randomized	Dosage	Measure of induction	Rate of induction/clinical response	Side effects
Infliximab [108]	2005	ACT 1 and 2	364; 364	5 mg/kg and 10 mg/kg	Clinical response: decrease in Mayo score by 3 or 30%	Week 8 ACT 1:69% (5 mg/kg); 61% (10 mg/kg) vs 37% placebo; ACT 2: 64% (5 mg/kg) and 69% (10 mg/kg) vs 29% placebo	Serious events and infection rates were similar between treatment and placebo
Adalimumab [109]	2012	ULTRA 1 and 2	576; 494	160, 80, 40, 40 mg SC	Clinical remission: Mayo score ≤ 2 and no subscore >1 and bleeding subscore of 0	Week 8 16.5% versus 9.3%	Serious events and infection rates were similar between treatment and placebo
Golimumab [110]	2013	PURSUIT-SC	761	100, 200, 400 mg	Clinical response: decrease in Mayo score by 3 or 30%	Week 6 51.4% (200 mg), 54.9% (400 mg) and 30.3% placebo	Serious events and infection rates were similar between treatment and placebo
Vedolizumab [55]	2013	GEMINI	374 randomized; 521 open label	300 mg every 4 or 8 weeks	Clinical response: decrease in Mayo score by 3 or 30%	Week 6 47.1% in vedo vs 25.5%in placebo	Serious events and infection rates were similar between treatment and placebo
Ustekinumab [56]	2019	UNIFI	968	130 mg or weight adjusted dose or 6 mg/kg	Clinical remission: Mayo score ≤ 2 and no subscore >1 and bleeding subscore of 0	8 weeks 16% versus 16% versus versus 5%	Serious events and infection rates were similar between treatment and placebo
Tofacitinib [54]	2019	OCTAVE 1 and 2	598; 541	10 mg po BID	Clinical remission: Mayo score ≤ 2 and no subscore >1 and bleeding subscore of 0	8 weeks OCTAVE 1: 18% vs 8% OCTAVE 2: 17% vs 4%	Increased zoster; increased overall infection and serious infection

by some because it is an oral agent. Tofacitinib was studied in the OCTAVE 1 and OCTAVE 2 induction and maintenance trials. Both trials, each with over 500 patients, reported significantly increased clinical remission at 8 weeks with 10 mg daily of tofacitinib compared to placebo (18.5% versus 8.2%; $p = 0.007$) and significantly increased maintenance of remission at 52 weeks with 5 or 10 mg compared to placebo (34.3% versus 40.6% versus 11.1%; $p < 0.001$); there was a significantly increased rate of infectious complications, particularly herpes zoster in the tofacitinib cohort (Table 45.4) [54].

Biologic Agents/Biosimilars

Three anti-TNFα agents (infliximab, adalimumab, golimumab), an $\alpha_4\beta_7$ anti-integrin (vedolizumab), an anti-IL-12/23 (ustekinumab), and a small molecule JAK inhibitor (tofacitinib) are all effective for the induction of remission in moderate-to-severe ulcerative colitis as compared to placebo. A total of 16 RCTs have compared all these agents individually to placebo; each trial looked at induction of remission at the 6- to 8-week timepoint and maintenance of remission at 30–54 weeks. All agents were superior to placebo with regard to both induction and remission. The potential benefit of vedolizumab is its gut selectivity offering a theoretically improved safety profile. The induction trial, GEMINI 1, randomized 374 patients to vedolizumab versus placebo and found that 16.9% and 40.9% had achieved clinical remission and mucosal healing, respectively, at 6 weeks as compared to 5.4% and 24.8% in the placebo arm [55].

Ustekinumab, the most recently approved biologic agent for ulcerative colitis, also should have good safety profile and low rate of alloimmunity. One trial randomized patients to treatment or control and found significantly improved rates of 8-week clinical remission among both doses of ustekinumab compared to placebo (15.6% versus 15.5% versus 5.3%; $p < 0.001$) [56].

Until the recent VARSITY trial, no clinical trials have compared each of the anti-TNFs to one another [57–59]. Observational trials that have compared infliximab to adalimumab in biologic-naïve patients suggest that the rates of glucocorticoid usage and hospitalization were lower in infliximab-treated patients [60, 61]. In addition, a network meta-analysis recently compared infliximab, adalimumab, golimumab, vedolizumab, ustekinumab, and tofacitinib and found superiority of infliximab to adalimumab (Table 45.4) [62].

The VARSITY trial compared vedolizumab to adalimumab in moderate-to-severe ulcerative colitis and found the rate of clinical remission at week 52 was significantly higher in vedolizumab- versus adalimumab-treated patients (31.3% versus 22.5%; $p = 0.006$) as well as endoscopic improvement (39.7% versus 27.7%; $p < 0.001$). Based on all this data, the AGA now recommends the use of infliximab or vedolizumab for induction of remission in biologic-naïve patients rather than adalimumab. The AGA also recommends that in those patients who are biologic-naïve, tofacitinib only be used in the context of a clinical trial or registry study [25, 47].

In patients naïve to both immunomodulators and anti-TNF agents who also have a normal thiopurine methyltransferase activity, the UC-SUCCESS clinical trial reported that combination therapy of infliximab and azathioprine had superior rates of 16-week remission compared to monotherapy [63]. Therefore, the ACG recommends combining monoclonal antibodies with a thiopurine or methotrexate rather than monoclonal antibody or thiopurine monotherapy, despite a lack of evaluation of thiopurines with other monoclonal antibodies that likely have a lower immunogenicity profile [64].

The first biosimilar to infliximab, CT-P13, was approved by the European Medicines Agency in 2013 and the US Food and Drug Administration in 2016 [65, 66]. In 2015, the first prospective observational study of CT-P13 was published, reporting that 56% of ulcerative colitis patients achieved remission at week 14 [67]. A later study of 144 patients with ulcerative colitis found that 56% achieved remission at week 14 [68]. The efficacy of CT-P13 for induction therapy on mucosal healing was evaluated in a prospective multicenter study of 63 consecutive ulcerative colitis patients. Mucosal healing was detected in 48% and clinical response in 83% at 14 weeks, both of which are higher than the results reported in the original infliximab trials [69]. This suggests biosimilars may be quite effective for induction, although not mentioned in either the ACG and AGA guidelines.

Severe/Fulminant Disease

As previously stated, acute severe ulcerative colitis (ASUC) is defined as 6 or more bowel movements per day plus at least one sign of systemic toxicity including tachycardia, fever, anemia (hemoglobin <10.5 g/dL), or elevated inflammatory markers (ESR > 30 mm/hour) [18]. Patients with ASUC should be admitted to the hospital for inpatient management, disease evaluation, intravenous medication delivery when needed, and surgical consultation. Up to 25% of patients with ulcerative colitis may develop ASUC [70], and those who require a colectomy (40%) represent a higher risk cohort [70]. At the time of hospitalization, patients should be tested for *Clostridium difficile* toxin and have a flexible sigmoidoscopy to assess disease severity and assay for cytomegalovirus (CMV) infection. Patients should be started on venous thromboembolism prophylaxis, and pain should be managed without opioids or nonsteroidal anti-inflammatory medications when possible.

Glucocorticoids

Intravenous systemic glucocorticoids are the mainstay of treatment of ASUC. If a patient fails to respond after 3–5 days, then medical therapy with either infliximab or cyclosporine should be introduced. If a patient achieves remission with infliximab, then he/she should continue with the same therapy for maintenance. If a patient reaches remission with cyclosporine treatment, then the ACG and AGA guidelines recommend transitioning to thiopurines or vedolizumab for the maintenance of remission [24, 47].

The efficacy of glucocorticoids for ASUC was first established in an open-label series of 49 patients given 60 mg of daily prednisolone along with topical hydrocortisone enemas that found 73% of patients were in remission at day 5. Of the patients in remission, 47% maintained their remission, and 18% required surgery [71]. In a larger systematic review of 32 studies including 1948 adult patients, the mean response rate to intravenous glucocorticoids was 67% with only 27% requiring colectomy during the index hospitalization [72]. Further analysis revealed no benefit to a daily dose greater than 60 mg and that the dose could be given in one or more infusions without any change in efficacy. Due to these studies, the AGA recommends using methylprednisolone (60 mg/day) or hydrocortisone (100 mg 3–4 times/day) to induce remission in patients with ASUC [47].

If a patient fails to respond after 3–5 days, then he/she is unlikely to respond to further glucocorticoids alone, and salvage medical therapy with either cyclosporine or infliximab and surgery should be considered. The exception to this recommendation is if the patient is infected with *Clostridium difficile* or CMV. In this case, it is most important that the infectious etiology is evaluated and treated prior to induction with cyclosporine or infliximab.

Immunomodulators (Calcineurin Inhibitors)

The first study investigating cyclosporine for ASUC was a randomized trial of 20 patients relegated to cyclosporine

4 mg/kg/day versus placebo. At 7 days, 9 of 11 patients treated with cyclosporine demonstrated a clinical response versus none in the placebo arm [73]. In other studies, short-term efficacy has been reported [74], but long-term follow-up suggested 80% ultimately required a colectomy [74, 75]. Interestingly, these colectomy rates were lower in thiopurine-naïve patients who were prescribed thiopurines as maintenance at the same time as cyclosporine [75–77]. One study aiming to understand the variable efficacy with different dosages found that clinical response and colectomy rates were similar with 2 mg/kg/day of cyclosporine as compared to 4 mg/kg/day. Thus 2 mg/kg/day is the recommended dose for the treatment of ASUC.

A RCT comparing cyclosporine versus infliximab in patients with ASUC randomized 115 patients across 27 institutions to cyclosporine (2 mg/kg/day for 1 week followed by oral cyclosporine) or infliximab (5 mg/kg at weeks 0, 2, and 6) [78]. In the short-term follow-up, treatment failure, defined as absence of day 7 clinical response, relapse between day 7 and day 98, or absence of steroid-free remission at day 98, was similar in both groups (60% versus 54%). During the long-term follow-up, there was no difference in colectomy-free survival at 1 and 5 years between the treatment arms (70.9% and 61.5%, respectively, in patients who received cyclosporine and 69.1% and 65.1%, respectively, in those who received infliximab) [78]. Another RCT, the CONSTRUCT trial, compared differences in quality of life and healthcare costs. No differences were reported between cyclosporine and infliximab with regard to quality-adjusted survival, frequency of colectomy, time to colectomy, or adverse events (including mortality) [79]. Another multicenter study using registry data from 740 patients treated with cyclosporine or infliximab reported similar colectomy and mortality rates [80].

Biologic Agents/Biosimilars

A key RCT of infliximab for ASUC included 45 patients not responding to 4 days of glucocorticoid therapy. These patients were randomized to a single infusion of infliximab 5 mg/kg versus placebo. Among the 24 randomized to infliximab, only 7 patients required a colectomy at month 3, which was significantly less compared to the 14 of 21 in the placebo group [81]. Many studies have since followed and confirmed the short-term efficacy of infliximab in ASUC with long-term colectomy-free survival of 71%, 64%, 59%, and 53% at 3, 12, 36, and 60 months, respectively [82–84]. Due to the apparent efficacy of infliximab, additional trials have been focused on how to optimize infliximab dosing, owing to the significant fecal drug loss during a colitis flare [85]. It is possible to significantly decrease colectomy rates with three induction doses within 24 days as compared to standard dosing in the first month (7% versus 40% colectomy rates). However, by 3 months no differences were seen in colectomy rates [86].

No safety or efficacy data exist regarding the use of adalimumab, golimumab, vedolizumab, and ustekinumab as rescue therapy in ASUC. Therefore, formal societal recommendations do not support their use in this setting, and medical salvage therapy remains confined to cyclosporine or infliximab. The decision to choose one over the other is related to physician preference and overall familiarity with the drug. This likely explains why infliximab is more often used, as providers are typically more familiar with prescribing, dosing, and managing adverse events associated with infliximab contrasted to cyclosporine.

The ability to use either infliximab or cyclosporine after the other in the setting of failed salvage therapy is not well supported. A small retrospective review of 10 patients receiving infliximab after failing cyclosporine and 9 patients receiving cyclosporine after infliximab had remission in the 30–40% range and severe adverse outcomes in 16% including 1 death [87]. However, other studies have shown that cyclosporine induction can be safely used after infliximab failure, but colectomy rates are as high as 60% at 1 year in this setting [88]. Overall, systematic reviews of this approach suggest an increased risk of adverse events and a significant colectomy rate [89]. Thus, an attempt at salvage therapy with multiple agents is not generally recommended.

Limited studies on the safety and efficacy of CT-P13, the first biosimilar to infliximab, show that CT-P13 is safe in the setting of ASUC with similar efficacy to infliximab. The first study included 63 patients of which 24 were in an acute flare. Mucosal healing was achieved in two-thirds of patients by the end of induction therapy [69]. The second study investigated infliximab versus an infliximab biosimilar among 83 patients and found the biosimilar to be just as effective as infliximab for rescue therapy; clinical response following three induction doses was 81% and 77% in the infliximab and biosimilar groups, respectively, with endoscopic remission rates of 42% with infliximab and 32% with the biosimilar. The authors concluded that either could be used with comparable efficacy for rescue therapy, but maintenance should be continued following induction [90].

Maintenance of Remission

Once clinical remission has been achieved from the aforementioned treatment options, the management goal changes to maintenance of remission or preventing clinical and endoscopic relapse. Some patients, with ulcerative proctitis and less than one flare per year responsive to topical mesalamine, do not require ongoing maintenance therapy. These patients typically enjoy long-term remission without relapse, and their disease generally responds to topical mesalamine if it does. In contrast, the patients that most often require maintenance therapy are those with ulcerative proctitis and more

than one disease flare per year, all patients with ulcerative proctosigmoiditis, and all patients with ulcerative colitis proximal to the sigmoid colon which includes left-sided colitis and extensive colitis [91]. The choice of maintenance therapy depends on the specific agent used to induce remission, anatomical distribution of disease, patient preferences, clinician preferences, and insurance coverage and cost.

5-ASA Compounds (Topical, Oral)

In patients with previous moderate-to-severe disease, 5-ASA therapy is not recommended as it is unlikely to be effective. Similarly, in patients with mild-to-moderate disease who have achieved remission with immunomodulators, monoclonal antibodies, or tofacitinib, there is no utility in continuing 5-ASA agents for the maintenance of remission. However, in patients with mildly active proctitis, rectal 5-ASA (1 gram/day) can be used for maintenance of remission. A meta-analysis of seven trials reported improved remission in patients treated with 5-ASA as compared to placebo [92]. In addition, time to relapse was longer in those treated with 5-ASA agents as compared to placebo.

If the patient has mildly active left-sided or extensive ulcerative colitis, then oral 5-ASA derivative therapy (at least 2 grams/day) can be used as maintenance therapy. A meta-analysis of 11 trails demonstrated superior efficacy of oral 5-ASA-containing compounds compared to placebo for the maintenance of remission [92]. While standard- to high-dose approaches were significantly better than a low-dose prescription, the type of 5-ASA compound was not predictive of relapse.

Glucocorticoids

Budesonide MMX® has not been studied for the maintenance of remission of previously mild-to-moderate or moderate-to-severe ulcerative colitis. Both the ACG and AGA recommend that systemic glucocorticoids not be used for maintenance of remission but rather tapered over the course of 8–12 weeks due to their side effect profile and potential complications [38, 93–95].

Immunomodulators

Four trials have compared thiopurines versus placebo, and three trials have compared thiopurines to 5-ASA-containing compounds for the maintenance of remission [49, 52, 96–100]. Remission was defined either as prevention of relapse or ability to maintain glucocorticoid-free remission. On meta-analysis, thiopurines were more effective than placebo and 5-ASA. Thiopurine therapy also provided clinical benefit when treating patients who had failed or could not tolerate sulfasalazine or mesalamine [101]. Thus, the ACG and AGA recommend thiopurines can be used for maintenance of remission.

In contrast, methotrexate was not found to be superior to placebo in the maintenance of remission in two separate RCTs [102, 103]. In one of the studies, the US-based Methotrexate Response in Treatment of Ulcerative Colitis (MERIT-UC) trial, 66% of methotrexate-treated patients experienced relapse as compared to 63% given placebo [102, 103]. Therefore, the AGA does not recommend using methotrexate as monotherapy for the maintenance of remission.

Tofacitinib has shown efficacy in maintenance after control of moderate-to-severe ulcerative colitis. The maintenance tofacitinib trial compared 52-week remission rates among tofacitinib at 5 mg twice daily and 10 mg twice daily versus placebo and found remission rates were 34.3%, 40.6%, and 11%, respectively. Of note, there were no increased adverse events (e.g., venous thromboembolism) except for increased rates of herpes zoster infection in the tofacitinib group (Table 45.5) [54].

Biologic Agents/Biosimilars

In moderate-to-severe colitis, the ACG recommends using infliximab, adalimumab, golimumab, or vedolizumab for maintenance of remission in patients who have previously achieved successful induction with each of these agents. However, the AGA does not support or refute the use of infliximab, adalimumab, golimumab, or vedolizumab for maintenance of remission [47].

In patients who had an initial response to anti-TNF agent therapy during their induction dosing, anti-TNF agents are significantly better compared to placebo for maintaining remission [57]. A systematic review and meta-analysis of six placebo-controlled double-blinded RCTs demonstrated that infliximab, adalimumab, and golimumab were all superior to placebo in the maintenance of remission [58]. In addition, the study also reported no one particular agent was superior to another in the maintenance of remission.

Similar to the anti-TNF agents, vedolizumab is more effective in maintenance of remission as compared to placebo [58, 104]. A systematic review of 4 studies of 606 vedolizumab-treated patients found that vedolizumab was significantly superior to placebo without differences in adverse events. In addition, a trial of maintenance therapy of those that responded to induction found that 40% of vedolizumab patients maintained remission at week 52 compared to 16% who received placebo [55]. Similarly, a maintenance trial using ustekinumab reported significantly improved maintenance of clinical remission at week 44 compared to

Table 45.5 Pivotal trials for maintenance of UC

Drug	Approval by the FDA for UC	Pivotal studies	Number of patients randomized	Dosage	Measure of remission/ clinical response	Rate of Induction	Side effects
Infliximab [108]	2005	ACT 1 and 2	364; 364	5 mg/kg and 10 mg/kg	Clinical response = decrease in Mayo score by 3 or 30% at week 30 and 54	More likely to have clinical response at week 30 and 54	Serious events and infection rates were similar between treatment and placebo
Adalimumab [100]	2012	ULTRA 1 and 2	576; 494	160, 80, 40, 40 mg SC	Clinical remission: Mayo score ≤ 2 and no subscore >1 and bleeding subscore of 0	Week 52 17.3% vs 8.5%	Serious events and infection rates were similar between treatment and placebo
Golimumab [110]	2013	PURSUIT	144	100, 200, 400 mg	Clinical remission: Mayo score ≤ 2 and no subscore >1 and bleeding subscore of 0	Week 54 47% (50 mg), 49.7% (100 mg) and 31.2% (placebo)	Serious events and infection rates were similar between treatment and placebo
Vedolizumab [55]	2013	GEMINI	374 randomized; 521 open labels	300 mg every 4 or 8 weeks	Clinical remission = decrease in Mayo score by 3 or 30% at week 52	Week 52 41.8% vedo Q 8 weeks and 44.8% of vedo Q 4 weeks versus 15.9% placebo	Serious events and infection rates were similar between treatment and placebo
Ustekinumab [56]	2019	UNIFI	968	130 mg or 6 mg/ kg	Clinical remission: Mayo score ≤ 2 and no subscore >1 and bleeding subscore of 0subscore of 0	Week 44 38.4% (Q 12-week dose) vs 43.8% (Q 8-week dose) and 24% placebo	Serious events and infection rates were similar between treatment and placebo
Tofacitinib [54]	2019	OCTAVE 1 and 2	598; 541	10 mg po BID	Clinical remission: Mayo score ≤ 2 and no subscore >1 and bleeding subscore of 0subscore of 0	52 weeks 34.3% in 5 mg, 40.6% in 10 mg and 111.1% in placebo	Increased zoster; increased overall infection and serious infection

placebo (18.4% with 12-week dosing versus 43.8% with 8-week dosing versus 24% with placebo) (Table 45.5).

With regard to biosimilars, a recent study looking at the switch from infliximab to CT-P13 reported the move was safe and found no changes in 6-month disease activity scores, CRP, hemoglobin, fecal calprotectin, or drug antibody levels [105]. A later meta-analysis of 8 studies comprised of 594 inflammatory bowel disease patients found that switching patients from infliximab to CT-P13 is an effective and cost-effective strategy [106]. In addition to the ability to switch from infliximab for maintenance therapy, a multicenter observational cohort study also found that CT-P13 achieved long-term mucosal healing at week 54, again underscoring its success for maintenance of remission [107].

Conclusion

The expanding plethora of medications used to treat ulcerative colitis challenges a thorough understanding of the optimal timing and use of each agent. Appropriate triaging of medications to optimize clinical and endoscopic outcomes is based upon numerous patient and disease-specific factors including patient age, extent of inflammation, symptom severity, treatment response, and risk for adverse effects. It is important for surgeons to understand the indications, dosing, benefits, and risks of the various types of medications in order to participate in multidisciplinary care discussions and ensure optimal perioperative care following preoperative exposure to various medications. National guidelines by gastroenterologists provide a useful tool to help guide clinical practice and offer a starting point to facilitate discussions between gastroenterologists, surgeons, and patients concerned with optimizing and individualizing treatment pathways.

Medical Therapy for Crohn's Disease

46

Radhika K. Smith and Stefan D. Holubar

Key Concepts

- Antibiotics, probiotics, diets, and fecal transplant do not appear offer clinically significant benefit for treatment of Crohn's disease.
- Exclusive enteral nutrition is beneficial in children but has not yet be shown to be of benefit in adults.
- 5-Aminosalicylates are widely recognized to have role in treatement of mucosal ulcerative colitis, but have a very limited role in the treatment of CD.
- Budesonide is efficacious for induction of clinical remission for CD patients when compared with placebo.
- Systemic steroids are indicated for induction of remission, but not for maintenance of remission due to its side effects; steroid dependency is an indication for surgery.
- Thiopurine and methotrexate monotherapy is not efficacious for induction of remission, but for maintenance of remission as a steroid-sparing agent; these medications are most commonly used in combination with biologics to decrease immunogenicity to the biologic agent.
- Biologic agents are indicated for induction and maintenance of remission in patients with moderate-to-severe Crohn's disease.
- Biosimilars present no differences in efficacy or safety compared to their originator compounds and have the advantage of lower cost.
- Therapeutic drug monitoring (TDM) of drug levels and anti-drug antibodies (ADA) allows more precise management of patients with Crohn's disease.

History

The first case series describing regional enteritis was published in 1932 by a group of physicians at Mount Sinai Medical Center in New York City [1–3]. A senior surgeon, Dr. A.A. Berg, operated on 12 patients with terminal ileitis, and Drs. Leon Ginzburg and Gordon Oppenheimer wrote the initial manuscript. Of note, after Dr. Berg declined to be involved as a coauthor, Dr. Burrill Crohn was brought in as a third contributing author with two additional patients. At that time, the journal's publication policy was to order the authors alphabetically – thus Dr. Crohn was the first author, and regional enteritis subsequently became known as Crohn's disease, not Berg's disease, nor Ginzburg-Oppenheimer disease [3, 4].

Introduction

As surgeons who care for patients with inflammatory bowel diseases (IBD), just as we expect IBD-gastroenterologists (GI) to be facile with surgical treatment options, it is their expectation that we be facile with the medical therapies to which our patients are exposed. The treating colorectal surgeon should be able to manage these medications in the perioperative period, and may be called upon as part of the multidisciplinary team to provide perspective on initiation, continuation, or escalation of medical therapies as part of surgical decision-making. The types and timing of medical therapy may also have implications for the type and timing of surgical intervention. In this chapter, we will review the profiles of the most commonly prescribed medical therapies for Crohn's disease (CD). We will focus the role of each class of medications has in the induction and maintenance of remission, efficacy, commonly prescribed forms and dosing schedules, side-effect profiles, and perioperative management for these complex patients. Interested readers are referred to the recommendations of the American

S. R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, https://doi.org/10.1007/978-3-030-66049-9_46

Gastroenterology Association (AGA) 2013 Guideline on Medical Management in Crohn's [5], the American College of Gastroenterology (ACG) 2018 Crohn's Guideline [6, 7], and the European Crohn's and Colitis Organization (ECCO) 2020 Crohn's Guideline [8]. A summary of the treatment recommendations for these guidelines is shown in Table 46.1.

The AGA guideline [5], which is now the oldest and due to be updated, was limited to 9 recommendations on the use of thiopurines, methotrexate (MTX), and TNF inhibitors (TNFi's) for the induction of remission and maintenance of remission, while the ACG guideline is the most comprehensive and made a total of 60 recommendations which were stratified based on the severity of illness; mild-to-moderately severe disease/low-risk disease vs. moderate-to-severe disease/moderate-to-high-risk disease vs. severe fulminant disease vs. perianal disease. The ACG guideline also made recommendations regarding postoperative prophylaxis including smoking cessation and that intra-abdominal abscesses should be treated with antibiotics and either radiologic or surgical drainage [2]. Finally, the recently updated ECCO guideline recommendations were stratified in a manner similar to the AGA's based on induction (10 recommendations) and maintenance (13 recommendations) of remission, plus perianal disease (7 recommendations) for a total of 30 recommendations.

In contrast to ulcerative colitis (UC), for which surgery is curative for the colonic and rectal manifestations of disease, patients with CD have a life-long disease for which surgery only manages the complications of the inflammatory, fibrostenotic, penetrating, and neoplastic manifestations of disease. Surgery will often "reset the clock," and many patients will be able to be managed expectantly without ongoing medical therapy and a colonosocpy 6 months after ileocolic resection to assess disease activity. However, those with high-risk phenotypes (Table 46.2) will require active postoperative medical therapy to prevent or delay post-operative recurrence (POR).

Table 46.2 Example of high-risk features as indications for more aggressive medical therapy in luminal CD

Male sex	Short-interval recurrence(s)
Young onset of disease	Multifocal disease (*i.e.*, diffuse jejunoileitis)
Active smokers	Granulomas
Penetrating phenotype	Perianal disease

Table 46.1 Summary of medication treatment recommendations by the various society guidelines. Note AGA and ECCO recommendations based on induction vs. maintenance, ACG based on severity.

	Induction of remission in CD			Maintenance of remission in CD			
Medication	AGA[5]	ACG[6]	ECCO[8]	AGA[5]	ACG[6]	ECCO[8]	Notes
Antibiotics	--	No*	No	--	--	No	* Role limited to treatment of intra-abdominal abscesses, perianal cellulitis, or to decrease perianal fistula drainage amount
Oral 5-ASA	--	No*	No	--	No	No	*For mild colonic symptoms
Rectal 5-ASA	--	--	No	--	--	No	--
Antimotility, diet, etc.	--	Yes	--	--	--	--	--
Topical steroids (budesonide)	--	Yes	Yes	--	No (>4 mo.)	Yes	Ileal or right colonic disease
Systemic steroids	--	Yes	Yes	--	No	No	Short-term only
TPMT testing	--	Yes	--	--	--	--	Before TP initiation
TP monotherapy	No	No	No	Yes	Yes +/−TNFi	Yes*	*For steroid sparing/fistulae otherwise recommend *against* early introduction in new patients; recommend continuation in those already on TP in remission due to risk of relapse
MTX monotherapy	No	Yes	--	Yes	Yes +/−TNFi	Yes*	*Steroid sparing; parenteral recommended
TNFi monotherapy	Yes	Yes	Yes	Yes	Yes	Yes	Steroid and IMM resistance; severe disease; fistulae; perianal disease
TNFi combo-therapy	Yes	Yes, if naïve to both	Yes	Yes	Yes, over monotherapy	Yes	TPs or MTX; see SONIC trial [70]
Vedolizumab	--	Yes	Yes	--	Yes	Yes	+/− IMM
Ustekinumab	--	Yes*	Yes	--	Yes	Yes	*In TNFi exposed or naïve
Cyclosporine	--	No	--	--	--	--	--
Tofacitinib	--	--	No	--	--	No	Not yet FDA-approved for CD

Microbiome Therapies

Antibiotics

Overall, antibiotics are probably not efficacious for induction or maintenance of remission in CD [9–11]. A systematic review with meta-analysis from 2011 found that in active CD, compared to placebo, antibiotics may be efficacious (RR 0.85, 95% CI 0.73–0.99, $p = 0.03$); however this pooled analysis combined a number of different antibiotics, and the excessive heterogeneity precluded definitive conclusions. The Cochrane collaboration updated their review in 2019 and found 13 randomized controlled trials (RCT) examining the role of antibiotics for the induction and maintenance of remission [12]. They concluded that although antibiotics may be modestly beneficial, this may not be clinically significant based on moderate- to high-quality evidence. Although there was high-quality evidence that antibiotics are safe, efficacy for maintenance of remission was not demonstrated and remains uncertain. Therefore, the ACG and ECCO guidelines do not recommend them for induction or maintenance of remission, nor for maintenance of remission, consistent with North American practice [11].

Although antibiotics likely do not have a definitive role in the induction or maintenance of remission for luminal or perianal CD, they obviously have a role in the management of septic complications of penetrating CD; aspirates from percutaneously or intraoperatively drained abdominopelvic abscesses should be sent for aerobic, anaerobic, and fungal cultures with sensitivities to guide optimal management [6, 13]. The Toronto Consensus statement concluded that antibiotics only have a role in initial symptomatic control of perianal disease [14]. Of note, ciprofloxacin has recently had a black box warning for tendinopathy, especially in older patients also receiving corticosteroids [15]. Low-dose metronidazole may be used to decrease drainage. The principles of management of perianal CD are covered in another chapter.

Probiotics

Probiotics are beneficial microorganisms that can alter the gut's microbiota, metabolic activity, and immunomodulation to confer patient benefit. These bacteria and fungi alter microbial diversity through competitive inhibition of other microbes, enhance mucosal barrier function via the production of short-chain fatty acids, and interact with intestinal dendritic cells to instigate an anti-inflammatory response. The microorganisms must be of human origin, nonpathogenic, and able to survive the gastrointestinal transit in order to be beneficial. Unfortunately, multiple meta-analyses suggest that probiotics are ineffective for induction and maintenance of remission in patients with CD and may not be without risks [16–18].

Dietary Interventions

Similarly, dietary interventions have failed to demonstrate efficacy for the induction and maintenance of remission [19]. The Cochrane group performed a meta-analysis of 18 RCTs including 1,878 patients who received dietary intervention. Interventions included high-fiber, low-refined carbohydrate diets, low-microparticle diets, low-calcium diets, symptom-guided diets, and highly restricted organic diets. In general, efficacy was suggested by several of the diets, particularly the symptom-based and several restrictive diets; but overall the studies were heterogenous, prone to bias, and of low- or very-low quality of evidence. The authors made no firm conclusions but did note that there are several well-designed ongoing RCTs in over 500 patients examining this topic, and that the meta-analysis would be updated subsequently.

Fecal Transplant

The other manner in which a patient's microbiota can be altered is via fecal microbiota transplant (FMT). This management has proven useful in treating recurrent *Clostridium difficile* infections (CDI), but has not been adequately studied nor shown efficacy in CD. A recent small pilot RCT of 17 patients with CD who achieved remission with steroids and underwent FMT did not demonstrate the primary efficacy endpoint, although endoscopic scores and C-reactive protein (CRP) levels were significantly better in the FMT-treated patients [20]. A meta-analysis suggested FMT may have efficacy in UC but not Crohn's; no safety concerns were raised by this study [21]. The Cochrane groups meta-analysis on this topic suggested a lack of available studies of FMT for CD, with no studies examining the role of FMT for induction of remission in CD [22]. Interestingly, a separate meta-analysis of FMT for CDI in IBD patients demonstrated efficacy, just as in the non-IBD population [23]. Of note, on March 12, 2020 the Food & Drug Administration (FDA) released a Safety Alert after 2 patients with chornic medical conditions who received FMT for CDI died of complications related to FMT-related transmission of enteropathogenic and/or shigatoxin-releasing *E. coli*.

Exclusive Enteral Nutrition

A promising form of nutritional intervention specific to CD is exclusive enteral nutrition (EEN). EEN is a nutritional intervention where patients are placed on a full-liquid monodiet with a commercially available nutritional supplementation [24]. In pediatric CD patients, EEN has been shown to

be more effective than steroids for induction of remission, but this has not yet been replicated in adult CD patients [25]. Presently, some centers use EEN in adults while they are tapered off steroids as they await elective surgery [26].

5-ASA Therapy

5-Aminosalicylate (5-ASA) moieties, which have a large role in the medical treatment of UC, are widely recognized to have a limited role in the treatment of CD. The indication for this class of medications is for the induction and maintenance of remission in mild-to-moderate UC. These medications are covered more fully in the Medical Therapy of UC chapter. The mechanism of action of 5-ASAs is as topical anti-inflammatory agents, which explains their efficacy in mucosal UC as opposed to CD, which is a full-thickness bowel disease.

Multiple well-designed double-blinded placebo-controlled RCTs of oral formations with varying dosages and meta-analyses have concluded that oral 5-ASAs lack efficacy for the induction of clinical remission for ileal, ileocolic, or colonic CD. In addition, as noted in the meta-analysis within the ECCO CD guidelines, oral 5-ASAs also lack efficacy for the maintenance of remission (RR 1.03, 95% CO 0.92. 1.16) [8].

Isolated Colonic Crohn's

Nonetheless, the question remains if there is a role for 5-ASAs in isolated colonic CD. The largest trials of 5-ASAs for colonic disease were the National Cooperative Crohn's Disease Study (NCCDS) and the European Cooperative Crohn's Disease Study (ECCDS) [27, 28]. There were mixed results in the early clinical trials with mild-to-moderate disease, but these studies also lacked endoscopic or biochemical data [29]. Thus, a need exists to replace this older data with new studies which include modern assessments tools [30]. Some providers will use 5-ASAs in patients with mild colonic CD and assess response, in a treat-to-target manner with mucosal healing as the endpoint. 5-ASAs are not approved for CD in the USA but are approved in Europe, Canada, Australia, and Japan. Of note, the ACG and ECCO treatment guidelines also concluded that 5-ASAs lack efficacy for induction of remission in CD [6, 8].

Crohn's Proctitis

Despite the overall lack of efficacy for the induction or maintenance of remission of CD, there may be a role for 5-ASA rectal formulations for patients with proctitis [31]. Proctitis may result in disabling fecal urgency, tenesmus, and agoraphobia. 5-ASA enemas and suppositories may have a role in palliating these symptoms as adjuncts to primary medical therapy. Mesalamine suppositories are typically prescribed at doses of 500–1000 mg per rectum at bedtime, with mesalamine enemas at 4 grams/60 cc enemas 1–2 times per day. These formulations are typically well-tolerated but often require prior authorization and/or may be non-formulary for many commercial insurance plans.

Side-Effects and Perioperative Management

5-ASA medications have an excellent safety profile and may be resumed postoperatively. The most common side-effects of these medications include gastrointestinal (GI) upset, headaches, and skin hypersensitivity to sun [29]. Rare side-effects include bone marrow suppression, fever, hemolytic anemia, hepatitis, hypersensitivity reactions, pancreatitis, pneumonitis, and rash. Patients who take sulfasalazine must also take folic acid (1 mg daily) because the medication depletes folic acid stores [29, 31].

Corticosteroids

Topical Corticosteroids

Budesonide is a synthetic glucocorticoid which is administered as an oral enteric-coated capsule which resists gastric degradation. Budesonide has high first-pass metabolism and very limited systemic absorption and is generally well-tolerated [32]. It comes in 3 mg capsule and is dosed up to 9 mg per day. Of note, budesonide is the mainstay of therapy for induction of remission in microscopic and collagenous colitis. In order to target small bowel proximal to the terminal ileum, the "open-capsule technique" may be chosen for administration; half of the daily dose (one full 3 mg capsule and half of one 3 mg capsule) is opened and sprinkled on food. The Multimatrix® (MMX®) formulation allows for controlled release for use in the colon [33].

A Cochrane meta-analysis found that budesonide was efficacious in the induction of clinical remission for CD patients, when compared with placebo [34]. This meta-analysis also stated that budesonide was not as effective as conventional steroids but was significantly safer. They also found a lack of efficacy for maintenance of remission. The ACG and ECCO guidelines recommend budesonide for the induction of remission in mild-to-moderate ileal or right-sided colonic disease [6, 8]. For maintenance of remission, the ACG guidelines suggest it not be used for more than 4 months, but the ECCO guidelines allow for maintenance therapy with budesonide [6, 8].

Table 46.3 Side-effects of budesonide with long-term use

Frequency	Organ system	Effect
Common	Endocrine	Cushingoid features, hypokalemia
	Psychiatric	Mood changes
	Optic	Blurry vision
	Cardiac	Palpitations
	GI	Dyspepsia
	Skin	Skin reactions
	Reproductive	Altered menses
Uncommon	Nervous system	Tremor
Rare	Musculoskeletal	Reduced growth velocity
	Systemic	Anaphylaxis

Side-Effects and Perioperative Management

Although well-tolerated and safer than traditional steroids, budesonide may have side effects (Table 46.3), especially when used for prolonged periods of time. When used for less than 1 year, the side-effect profile is similar to that of placebo with rare occurrences of the clinically important side effects typically associated with traditional glucocorticoids [35]. Given the excellent safety profile of budesonide with its limited systemic absorption, budesonide may be safely held immediately before and after surgery, stress-dose steroids are *not* needed, and resumption postoperatively may not be necessary.

Systemic Corticosteroids

Traditional corticosteroids are powerful systemic anti-inflammatory drugs which were first used by Truelove and Witt for the treatment of IBD in 1955 [36, 37]. Although they are extremely efficacious as anti-inflammatories, they have an unfavorable side-effect profile which limits their clinical utility to induction of remission in otherwise medically refractory disease. A meta-analysis limited to randomized controlled trials identified 2 trials including 267 patients using standard oral glucocorticoids to induce remission in active Crohn's disease [38]. Overall, 79 of 132 patients (60%) assigned to oral glucocorticoids achieved remission compared with 42 of 135 (31%) prescribed placebo. Moreover, the number needed to treat to achieve remission in one patient with standard glucocorticoids was 3 (95% CI, 2–11), which is very low and associated with high efficacy. Both the ACG and ECCO guidelines recommend systemic steroids for induction of remission, but not for maintenance of remission [6, 8]. Steroids should not be used chronically as long-term use carries have a high risk of serious adverse events. The need for systemic steroids represents a "bad omen" or "tipping point" for patients with CD, as it is associated with a more complicated disease course. Steroid dependency is an indication for surgery.

For outpatient induction of remission, prednisone is typically prescribed at 40 mg by mouth daily and tapered by 5–10 mg per week; but this depends on what other medical or surgical options the patient, gastroenterologist, and colorectal surgeon are contemplating. Steroid conversion calculators and tables (Table 46.4) [37], widely available on the Internet, allow for conversion between enteral, parenteral, and various formulations.

Safety

Despite the substantial efficacy for induction of remission in CD, chronic corticosteroid treatment is among the most significant risk factors for postoperative infectious and/or wound complications. A summary of the toxicity of corticosteroid therapy is shown in Table 46.5 [37]. The side effects are organ-based and wide-ranging and for the most part dose- and duration-dependent. Cessation of steroid therapy will ameliorate some, but not all, of the risks of exposure to these medications. The side effects would not likely be considered acceptable, if not for the wide therapeutic effect across a wide range of human auto-inflammatory and autoimmune diseases. Many of these diseases lacked any efficacious therapy other than corticosteroids until recently. Chronic steroid use, loosely defined as more than several months, has largely fallen by the wayside as new biologic treatments with better short- and long-term safety profiles continue to be developed and marketed.

Stress-Dose Steroids and Tapering

Of note, several publications have examined the role of stress-dose steroids in the perioperative period for IBD [39–42]. In a series of steroid-dependent UC patients, only one patient developed postoperative adrenal insufficiency [39]. The authors concluded that stress-dosing was not beneficial, but all steroid-dependent patients should be monitored after surgery for symptoms of adrenal insufficiency. Two studies from Cedars Sinai had similarly questioned the utility of stress-dose steroids at the time of surgery for IBD [41, 42]. In the era of enhanced recovery, many patients receive 8 mg of intraoperative dexamethasone for postoperative nausea and vomiting prophylaxis which effectively replaces the

Table 46.5 Toxicity of chronic corticosteroid treatment

Organ system	Unwanted Effect	Notes
Systemic	Cushingoid appearance, weight gain	Occurs in >70%, 4–8% mean increase in body weight Adipose redistribution: truncal, facial, dorsocervical; occurs in ~25% >= 7.5 mg prednisone/day
	Immunosuppression	Mainly by sequestration of CD4+ T-lymphocytes in the reticuloendothelial system, and by inhibiting the transcription of cytokines; profoundly inhibits lymphocyte migration into lymph nodes
	Impaired wound healing	Decreased collagen synthesis and maturation, inhibited leukocyte/macrophage infiltration Potentially maybe overcome by epidermal-derived growth factor, TGF-beta, platelet-derived growth factor, tetrachlorodecaoxygen, and retinoic acid (vitamin A)
Endocrine	HPA-axis suppression	Wide-ranging, non-specific, symptoms may overlap with Crohn's (see Table 46.6). ***Avoid abrupt cessation of therapy***
	Hyperglycemia/diabetes	Increased insulin resistance; +risk of persistent diabetes
Musculoskeletal	Osteoporosis, avascular necrosis, fractures	Osteoblast and osteocyte suppression and apoptosis Reduced bone mineral density Osteonecrosis develops in 9–40% of adults, often misdiagnosed as lumbar symptoms
	Myopathy	Catabolic effect on skeletal muscle
Optic	Cataracts, glaucoma	Cataracts (reduced acuity) which require earlier surgical treatment -Painless glaucoma (decreased visual field) can cause permanent optic nerve damage
Cardiovascular	Hypertension, obesity, dyslipidemia, arrythmias	Higher CV event risk with >= 7.5 mg prednisone/day Risk of sudden death even with pulse therapy if pre-existing kidney/heart disease
GI	Gastroesophageal ulceration, acute pancreatitis	Ulcer/hemorrhage risk increased if concurrent NSAID use pancreatitis may be secondary to systemic lupus erythematosus (SLE), or TP treatment, rather than drug effect
Psychiatric/ Cognitive	Various	Wide range: memory impairment, agitation, anxiety, fear, hypomania, insomnia, irritability, lethargy, mood lability, frank psychosis Heightened if concomitant pre-existing conditions
Skin	Various	Atrophic skin changes, thin fragile skin; purpura; red striae

need for stress-dose steroids [26]. For patients who received a short-term (1-2 weeks) of steroids preoperatively, it is our practice to simply stop them postoperatively, and for those on chronic steroids to continue post-operative corticosteroids at the same dose, or dose-equivalent, the patient was receiving preoperatively [43–45].

Chronic steroid therapy must not be stopped abruptly lest patients develop severe Addisonian crisis with circulatory collapse (Table 46.6). On the other hand, no evidence-based guidelines for steroid tapering exist [46]. When patients do present to surgery receiving corticosteroids, the rapidity with which they may be tapered depends on the chronicity of treatment. We typically reduce the dose by 50% every 5–7 days. Sometimes a slow taper with several additional weeks is required if the patient has been on steroids for a prolonged period to avoid withdrawal symptoms such as fatigue, lethargy, and depression. Testing for adrenal suppression in such cases is typically not needed; the patients can either be counseled that these uncomfortable symptoms will eventually pass, or their corticosteroid dose can be increased with a more prolonged tapering schedule. Readers are referred to the an excellent resource Glucocorticoid Therapy and Adrenal Suppression in the Internet book *Endotext* for further reading at www.endotext.org.

Immunomodulators

Thiopurines

Thiopurines (TPs), namely 6-mercaptopurine (6MP) and azathioprine (AZA), along with methotrexate (MTX), are known as immunomodulators (IMM) [5, 6, 9]. TPs are purine analogs and thus antimetabolites, which inhibit DNA and

have antiproliferative properties and proapoptotic action on activated T-lymphocytes [31]. The typical dose of AZA is 2 mg/kg daily, while 6MP is typically 1 mg/kg daily. AZA and 6MP are typically started at low doses (50 mg and 10 mg, respectively) with biweekly complete blood counts and liver function testing and given normal labs dose escalation every 2 weeks to the desired dose. Of note, the clinical effect of TP therapy takes several months, so patients are typically re-evaluated after 3 months of therapy [31].

TP Pharmacokinetics

AZA is a prodrug of 6MP, and both AZA and 6MP are prodrugs of 6-thioguanine (6TG). AZA and 6MP are converted by intracellular thiopurine methyltransferase (TPMT) to 6TG (Fig. 46.1) [47]. Clinical TPMT activity testing is critically important for patients prior to being placed on TG treatment [48]. While 80% of the population has normal TPMT metabolism, ~10% have hyperactive TPMT metabolic activity ("shunters") which leads to the accumulation of toxic secondary metabolite, increasing the likelihood of drug side-effects such as hepatotoxicity [49]. Shunters, as the name implies, also shunt drug away from the normal metabolic pathway, resulting in less clinical activity. The shunting can be overcome by using allopurinol, which inhibits secondary metabolite production, and prescribing 25% of the usual TG dose [49].

In addition to the shunters, 10% of the population are heterozygous for TPMT and have intermediate (lower than average) metabolic activity, and 0.3% of the population are TPMT deficient (homozygous). The intermediate activity patients require a higher than average dose to acquire the desirous effect, while the deficient population will not be clinically responsive to TP treatment [48, 49].

Monotherapy

Current guidelines agree that TP are efficacious at the maintenance of remission of luminal CD obtained by other means and that they are *not* efficacious for the *induction* of remission in mild-to-moderate luminal CD [5, 6, 9]. This is mainly due to their onset of action; thus they may be started concomitantly with other medications for the induction of remission, which can then be weaned (in the case of steroids) while the TPs take effect. Thus, TPs have traditionally served a role as monotherapy for the maintenance of remission in CD as a steroid-sparing agent.

Specifically, when patients were unable to be weaned off steroids, TP therapy would provide an exit strategy from the steroid dependency in patients who were able to achieve but not maintain remission without continued steroids. In a meta-analysis of placebo-controlled randomized trial in steroid-dependent patients, AZA was shown to be superior to placebo (RR 1.19, 95% CI 1.05–1.34) for maintenance of remission as a steroid-sparing agent [5]. Combination therapy will be covered below in the section on biologics.

Relative contraindications include patients with neoplasia or hematologic comorbidities [49]. MTX is a relatively safe and more widely acceptable alternative in older patients and especially in young men. The EBV status in young males is important, as young men with +EBV status are at a very small but demonstrable risk of developing hepatocellular T-cell lymphoma, a universally-fatal condition, thus TGs are avoided in these at-risk patients. In addition, EBV naïve patients are at risks of developing hemaphagocystosis.

Side Effects and Perioperative Management

The side effects of TG therapy can be significant and are shown in Table 46.7. Idiosyncratic pancreatitis is the most common dose-independent side effect; hepatitis, which is

Table 46.7 Side effects of TG therapy

Type	Toxicity	Frequency	Testing
Dose-independent	Pancreatitis	<15%	Lipase
	Flu-like symptoms	5%	Patient-reported
	Rash	4%	Patient-reported
Dose-dependent	Hepatitis	<30%	LFTs, TPMT testing
	GI intolerance	<20%	Patient-reported
	Leukopenia	10%	CBC, TPMT testing
	Agranulocytosis	0.3%	CBC, TPMT testing

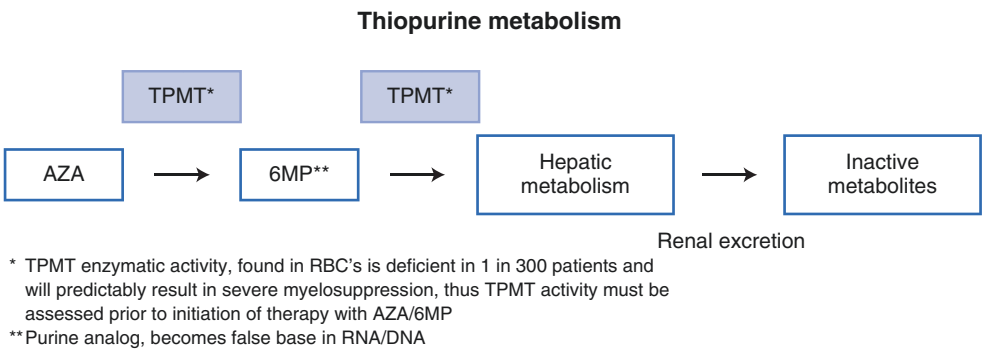

Fig. 46.1 Thiopurine metabolism

dose-dependent and whose risk increases with ongoing therapy, is the most common overall. Many patients have GI side-effects from TG therapy; CBCs are used to assess for hematologic consequences. It is controversial whether long-term use has been associated with malignancy. The best available population-based cohort data comes from the CESAME – Cancer and Increased Risk Associated with Inflammatory Bowel Disease in France study group. They suggest risk is increased in IBD patients receiving TP therapy for hematologic neoplasia including leukemia and lymphoma, non-melanoma skin cancer, cervical cancer, and urinary tract cancer. The risk of colorectal adenocarcinoma may actually be lower due to control of intestinal inflammation [50–52]. TG therapy also have a number of drug-drug interactions to be aware of including ACE inhibitors, allopurinol, anticoagulants, sulfamethoxazole/trimethoprim, and other immunomodulators including MTX and cyclosporine A [49].

TP may be safely used in the perioperative period. Although therapeutic efficacy takes several months to be observed, the half-live of these medications is very short. In addition, TPs have not been shown to be associated with postoperative complications in IBD patients [53]. Thus, most surgeons hold TP therapy in the immediate postoperative period and allow the referring gastroenterologist to reassess the need for ongoing IMM therapy.

Table 46.8 Side effects of MTX

Organ	Symptoms	Mitigation strategy
Gastrointestinal	Mucositis, diarrhea	5 mg folate weekly, switch from PO to SC/IM route
Bone marrow	Anemia, leukopenia	5 mg folate weekly
Hepatic	Steatosis, fibrosis, cirrhosis	Avoid dose >1 g
Pulmonary	Pneumonitis, PCP pneumonia	Monitor symptoms
Renal	Renal insufficiency (rare)	Monitor GFR/reduce dose
Reproductive	Teratogenic	Abstinence/contraceptive

Table 46.9 Summary of biologic medications for CD

		Dose	
Medication	Route	induction	Maintenance
Infliximab	Intravenous	5 mg/kg at weeks 0, 2, and 6	5–10 mg/kg every 8 weeks
Adalimumab	Subcutaneous	160 mg at week 0, 80 mg at week 0	40 mg every 2 weeks
Certolizumab pegol	Subcutaneous	400 mg at weeks 0, 2, and 4	400 mg every 4 weeks
Natalizumab	Intravenous	None	300 mg every 4 weeks
Vedolizumab	Intravenous	300 mg at weeks 0, 2, and 6	300 mg every 8 weeks

Methotrexate

The other drug in the immunomodulator class is MTX, which is also an antimetabolite, similar to the TGs. The discovery of MTX as a powerful inhibitor of cellular metabolism and mitosis was honored with a Nobel Prize in 1988, and the first trial demonstrating a benefit of MTX in CD was in 1989 [54, 55]. MTX has efficacy in the maintenance of remission of luminal CD obtained by other means and is not recommended for the induction of remission [5, 6, 9]. MTX inhibits TNF, MMPs, JAK 1/2, and IL-23 pathways [56]. It is typically prescribed at a dose of 25 mg subcutaneously (SC) or intramuscular (IM) weekly for active CD, and 15 mg PO/SC weekly for maintenance therapy, both with 5 mg of folic acid PO weekly.

Side-Effects and Perioperative Management

Similar to TPs, MTX may have dose-limiting toxicity (Table 46.8). For fertile young couples, pregnancy must be avoided as MTX is a known teratogenic agent and abortifacient, and abstinence and/or high-quality contraceptives should be used [57–60]. An effect of MTX on sperm counts and quality has also been described.

MTX inhibits dividing cells and thus may interfere with wound healing. However, it has a very short half-life. MTX does not appear to be associated with postoperative complications [61]. Thus, the perioperative management of MTX is the same as for TPs mentioned above; they may be safely discontinued prior to surgery and held in the postoperative period, and their ongoing therapeutics need to be reassessed by the GI team after recovery.

Biologic Therapy

Since the FDA approval of infliximab in 1998, biologic agents (summarized in Table 46.9) have revolutionized the treatment of CD. Rather than indiscriminate immunosuppression, biologic medications are monoclonal antibodies directed at particular proteins that drive the inflammatory cascade of IBD. They are approved to induce and maintain remission in moderate-to-severe CD. This is defined using clinical and endoscopic factors and typically includes a Crohn's disease activity index (CDAI) >220, a Crohn's disease endoscopic index of severity (CDEIS) >8, or a simple endoscopic score (SES-CD) >6. At present, there are three categories of biologic agents with six commonly used medications that are FDA-approved for this indication:

1. *Tumor Necrosis Factor inhibitor (TNFi) agents*
   - Infliximab
   - Adalimumab
   - Certolizumab pegol
2. *Anti-integrin agents*
   - Natalizumab
   - Vedolizumab
3. *Anti-interleukin agents*
   - Ustekinumab

Selection of biologic therapy should be driven by patient and physician preference; but in reality, insurance approval and cost are often factors into which agent is ultimately chosen. A 2017 review of insurance policies regarding biologic use for IBD reported that 90% of policies are inconsistent with AGA guidelines [62].

The positioning of biologic agents in the therapeutic algorithm is a matter of debate. Historically, a "step-up" strategy starting with 5-ASA compounds, IMM, and corticosteroids with escalation to biological therapy after failure to maintain remission has been employed. The top-down approach (early utilization of biologics) has been suggested for patients presenting with poor prognostic factors suggesting a complicated phenotype (Table 46.2). The goal of this approach is to optimally control disease and prevent complications such as fistula or stricture, where medical therapy is less or ineffective. Factors such as early age of diagnosis, stricturing or fistulizing disease, perianal or severe rectal disease, extensive involvement of the GI tract, deep ulcerations, prior surgical resection, or rapid onset should be considered for early biologic therapy. High-risk patients have shown benefit from the early use of TNFi's for an overall risk reduction of surgery, hospitalization, loss of response, and the development of disease-related complications [63].

Before initiation of biologic therapy, routine assessment for tuberculosis (typically using QuantiFERON-TB Gold) and viral hepatitis and selective assessment for histoplasmosis and blastomycosis should be initiated. Patients should be vaccinated against pneumococcus, varicella, human papilloma virus, influenza vaccine, hepatitis A vaccine, and herpes zoster.

Antitumor Necrosis Factor Agents

The TNFi agents are infliximab, adalimumab, and certolizumab pegol. These medications successfully modulate the immune system by binding to tumor necrosis factor alpha (TNF-alpha) and inhibiting signal transduction and limiting inflammation. These agents are proven to induce remission and provide maintenance therapy in patients with moderate-to-severe CD and are supported by the AGA, ACG, and ECCO guidelines [5, 6, 8]. Several meta-analyses of RCTs support their use in those who failed therapy with steroids or other forms of immunosuppression [64–66]. TNFi's- are particularly useful in the management of perianal or rectal disease, fistulizing CD, patients at high-risk for postoperative recurrence, and those with pyoderma. Response may be seen within the first few weeks after starting therapy, but maybe delayed up to 6 weeks after initiation.

Infliximab (IFX) is a chimeric mouse-human immunoglobulin (Ig) monoclonal antibody. This is typically administered with intravenous induction dosing at 5 mg/kg at weeks zero, two, and six followed by maintenance therapy every 8 weeks thereafter. IFX is the only agent with a phase 3 study demonstrating efficacy for the treatment of fistulizing disease, particularly perianal disease [67]. There are some data suggesting that infliximab is also associated with fewer hospitalizations, surgeries, and steroid use when compared with other TNFi agents for CD [68].

Adalimumab (ADA) is a fully human Ig monoclonal antibody given subcutaneously. This is started with induction dosing of 160 mg at week zero, followed by 80 mg at week 2, and then 40 mg every 2 weeks thereafter.

Certolizumab pegol is a PEG-ylated Fab fragment. This medication is self-administered subcutaneously at a dose of 400 mg at weeks 0, 2, and 4, followed by 400 mg every 4 weeks thereafter.

Adverse events with TNFi drugs include psoriasis, arthritis, hepatoxicity, rarely cytopenia, and an increased risk of melanoma and lymphoma formation [69]. Patents on combination therapy with immunomodulators may also have an increased risk of non-melanoma skin cancers and lymphoma [69]. Patients are also at risk for opportunistic infections.

Combination Therapy

The use of combination therapy with immunomodulators has been shown to increase TNFi serum concentrations while minimizing the risk of adverse drug reactions [70]. Unfortunately, combination therapy has also been associated with an increased risk of opportunistic infections [71, 72].

When starting IFX, combination therapy with a TP is generally recommended. The SONIC (Study Of Biologic and Immunomodulator Naïve Patients In Crohn's Disease) trial compared IFX with AZA to each therapy alone in treatment naïve patients [70]. Combination therapy was more likely to result in mucosal healing [RR: 1.82; 95% CI: 1.01–3.26] and clinical remission at 26 weeks. The authors also found significantly lower rates of serious adverse events in those on combination therapy [RR: 0.56; 95% CI: 0.32–0.97]. No controlled trial has addressed whether to continue immunomodulators (IMM) when starting a TNFi after failure of IMM monotherapy. A post hoc subgroup meta-analysis of controlled trials of these types of patients showed no added benefit for the continued use of IMM with TNFi regarding 6 month remission [OR: 1.02; 95% CI: 0.80–1.31], induction

of complete response [OR: 1.08; 95% CI: 0.79–1.4] or partial response [OR, 1.25; 95% CI, 0.84–1.88], maintenance therapy [OR: 1.53; 95% CI, 0.67–3.49], or fistula closure [OR: 1.10; 95% CI, 0.68–1.78] [73]. However, TNFi and other biologic agents are intrinsically antigenic, although the non-TNFi's are less antigenic and combination therapy is most commonly used with the TNFi's. The development of anti-drug antibodies (ADA) leading to loss of response is an important consideration; in the absence of direct evidence, an individualized approach to combination therapy seems appropriate [73].

The REACT [Early Combined Immunosuppression for the Management of Crohn's Disease] trial showed that the early use of biologic therapy combined with IMMs as compared with a more conventional stepwise management was associated with significantly lower rates of complications including need for hospitalization, serious disease-related outcomes, or surgery in patients with early CD [63]. Of note, there was no significant difference between the two groups of patients in steroid-free remission, the trial's primary outcome. The "Enhanced Algorithm for Crohn's Treatment Incorporating Early Combination Therapy [REACT2]" is currently enrolling with a primary endpoint based on mucosal healing.

The DIAMOND [Deep Remission of Immunomodulator and Adalimumab Combination Therapy for Crohn's Disease] trial is the only RCT that studied the use of combination therapy of adalimumab with thiopurines versus monotherapy for inducing remission [74]. Combination therapy was not superior for remission [RR: 0.95; 95% CI: 0.78–1.15]. While combination therapy was associated with endoscopic improvement at week 26 [RR: 1.32; 95% CI: 1.06–1.65], this benefit was lost at 1 year. There was no increase in adverse events associated with combination therapy [RR: 1.03; 95% CI: 0.60–1.78], but the dose of AZA used in this trial was lower than what is typically used in CD. Given the ability of immunomodulators to reduce the rate of ADA formation, long-term combination therapy in ADA may very well have a benefit outside of short-term clinical remission or maintenance.

Leukocyte-Trafficking Agents

Leukocyte-trafficking agents, or integrin receptor antagonists, prevent margination of leukocytes by blocking the surface integrins and preventing adhesion to endothelial cells. Natalizumab inhibits the α4 integrin, while vedolizumab blocks the α4β7 heterodimer and is gut selective.

Natalizumab is an infusional drug dosed at 300 mg every 4 weeks and is effective in the treatment of CD [75]. Because this medication is not specific to the GI tract, there is a rare but increased risk of progressive multifocal leukoencephalopathy (PML) resulting from infection with the John Cunningham (JC) virus [76]. This risk is reported to be as high as 1 in 100 who are antibody positive for JC virus, so patients should be surveilled for infection before starting treatment and at every 6 months after. Fear of this dreaded complication, combined with the demonstrated efficacy of novel biologics, has largely led to the abandonment of this medication for CD.

Vedolizumab is also an intravenous medication, with a 300 mg dose at 0, 2, and 6 weeks followed by maintenance every 8 weeks thereafter. The onset of action is quite slow, and initial response is typically seen within 12 weeks of starting the drug [77]. Vedolizumab has historically been used in those patients who have had an inadequate response, lost response, or could not tolerate anti-TNF, corticosteroids or IMM therapy. Failure of other therapies is not a requirement, however, and it can be positioned as first-line agent in patients with active disease. Vedolizumab has been shown to achieve clinical response, clinical remission, and steroid-free remission, and use is supported by the ACG and ECCO guidelines [6, 8, 77–79]. Because it is selective to the GI tract, there is no known risk for PML, unlike natalizumab. Patients who have received prior treatment with TNFi agents may require longer treatment to reach efficacy [80]. Those patients appear to have the same efficacy at 10 weeks that TNFi-naïve patients experience at 6 weeks. Prospective clinical trials comparing vedolizumab monotherapy with combination therapy has not been reported.

A recent network meta-analysis suggests that ADA or combination therapy with IFX and AZA is more effective than vedolizumab in inducing and maintaining remission in CD [81].

Interleukin-12 and -23 Antagonist

In 2016, the FDA-approved ustekinumab for use in moderate-to-severe CD. This drug targets the p40 subunit of interleukin-23 and interleukin-12. Induction should be given intravenously usually at 6 mg/kg followed by maintenance dosing of 90 mg subcutaneously every 8 weeks. The onset of action is usually seen within 6 weeks.

Ustekinumab is efficacious in treating patients with moderate-to-severe CD who have failed both conventional non-biologic therapy and TNFi medications but also can be positioned as a first-line agent [82]. Consistent with clinical trials, a large database study of patients undergoing treatment for psoriasis demonstrated an excellent safety profile without a significant increase in infections or malignancies [83]. There have been no trials directly comparing ustekinumab to integrin receptor antagonists or TNFi agents, and the choice of first biologic is at the discretion of the patient and provider. Ustekinumab may be less effective in

patients who have failed TNFi therapy [84]. Both the ACG and ECCO guidelines support its use for both induction and maintenance of remission [6, 8].

Biosimilars

Biosimilar medications are highly structurally and clinically similar to an already FDA-approved originator product, and they undergo an accelerated and abbreviated FDA-approval pathway. These mediations should present no differences in efficacy or safety compared to their originator compounds and have the advantage of lower cost. Biosimilars were approved for the treatment of IBD in September 2013 in Europe and in April 2016 in the USA.

Biosimilar TNFi agents are effective treatments for patients with moderate-to-severe CD and can be used for *de novo* induction and maintenance therapy. The major advantage of biosimilar therapy is cost. Five agents have gained approval for infliximab and adalimumab, with many more expected in coming years:

- Infliximab-abda
- Infliximab-dyyb
- Infliximab-qbtx
- Adalimumab-atto
- Adalimumab-adbm

While other generic small-molecule drugs are exact replicas, the same is not true for TNFi biosimilars. Exact replicas cannot be made of biologics because of their structural complexity and complicated manufacturing process. Their amino acid sequences remain the same, but they may differ in their glycosylation patterns. This influences a molecular solubility, stability, clearance, immunogenicity, and immune effector function [6, 55]. At present, there is not sufficient data to support the safety and efficacy of switching patients with stable disease from one biosimilar to another.

A large randomized, non-inferiority phase 3 clinical trial of patients with CD compared IFX to the biosimilar infliximab-dyyb in biologic naïve patients [85]. Patients were randomly assigned to receive infliximab-dyyb then infliximab-dyyb, infliximab-dyyb then IFX, IFX then IFX, or IFX then infliximab-dyyb; the medication switch occurring at week 30. A total of 220 patients were enrolled, and response rates at week 6 were similar for infliximab-dyyb [69.4%, 95% CI 59.9–77.8] and IFX [74.3%, 95% CI 65.1–82.2], establishing non-inferiority. Adverse events were similar in each group. There is still a significant paucity of data around interchangeability, limiting adoption at this time despite cost savings.

Induction and Maintenance of Remission

Principles of Induction Therapy

Mild Disease

Mild disease limited to the terminal ileum may be managed with symptom control and dietary changes or by using budesonide. Mesalamine and antibiotics have not been associated with significant benefit. For mild disease involving the colon, 5-ASA compounds or steroids can be used. Mild disease with upper gastrointestinal involvement should be treated initially with steroids and immunomodulators; for those with clinical features suggestive of a more aggressive phenotype, consideration should be given for early biologic therapy.

Moderate Disease

Moderate ileal disease should be treated with budesonide or steroids. If indicated for complications of local sepsis, antibiotics can also be added. Alternative strategies can include steroids plus an immunomodulator, early biologic therapy, or surgery. The LIR!C trial demonstrated that early laparoscopic resection may be considered a reasonable, cost-effective alternative to upfront infliximab therapy in patients with limited (< 30 cm), inflammatory (non-stricturing/non-penetrating) ileocecal Crohn's disease [86, 87].

Colonic disease should be treated with steroids or biologic therapy. In the setting of relapse, combination therapy with biologics and an IMM or an IMM with steroids (if relapses are infrequent) may be considered.

Severe Disease

Severe disease of the terminal ileum should be managed with biologic therapy with or without an IMM. Those with infrequent relapse may be treated with an IMM and steroids at the time of disease exacerbation. Early resection should also be considered. Colonic disease may be treated with steroids. Extensive upper gastrointestinal Crohn's disease should be managed with steroids and IMM. For patients who have relapsed, biologic therapy with or without combination therapy is an option.

Principles of Maintenance Therapy

Target to Treat

Recently, there has been a paradigm shift in the medical management of patients with IBD. Classically, treatment has focused on controlling symptoms with escalation of therapy and a "step-up" approach as the disease progresses or therapies fail. This escalation of therapy appears suboptimal with

respect prevention of disease progression. "Target to treat" is a shift toward to a more nuanced strategy, focusing on both control of symptoms and the objective signs of inflammation, that may occur before symptoms or complications develop. Inflammation can be assessed through blood and stool biomarkers such as fecal calprotectin and C-rective protein (CRP), cross-sectional imaging, and endoscopy. Goals of care are built on minimizing disease activity in the early stages of IBD to avoid progressive bowel damage such as fibrostenotic or penetrating disease.

The goals for target to treat are a combination of patient-reported and clinical outcomes as described by the "Selecting Therapeutic Targets in Inflammatory Bowel Disease" [STRIDE] International Organization for the Study of Inflammatory Bowel Diseases. These outcomes are defined as resolution of abdominal pain and diarrhea or altered bowel habit, endoscopic remission defined absent ulceration at endoscopy, or findings of inflammation on magnetic resonance enterography (MRE) or CT-enterography. The patient-reported endpoints should be assessed at a minimum of 3 month intervals during active disease, and the endoscopic endpoints should be assessed at 6–9 month intervals [88]. Other adjunctive measures include histological remission, and biomarker remission defined as a normal CRP and fecal calprotectin; mucosal healing is inversely associated with risk of relapse, surgery, hospitalization, and inability to wean steroids [88–93].

The "Effect of Tight Control Management on Crohn's Disease" [CALM] was a phase 3 multicenter study comparing a "tight control strategy" to symptom-driven care [93]. In the tight control arm, treatment was escalated with a CDAI >150, fecal calprotectin >250, CRP > 5, and prednisone use within the previous week. In the standard care cohort, treatment was escalated if there was not a decrease in the CDAI >70 or 100 (at randomization or post-randomization, respectively), a CDAI >200, or steroid use within the previous week. Tight control was associated with superior endoscopic remission and a lower rate of Crohn's disease-related hospitalizations when compared to symptom-driven care.

General Principles of Maintenance Therapy

If maintenance was initially achieved with steroids that have been successfully weaned, consideration may be given to no therapy with close observation typically by a 6-month follow-up endoscopic reassessment looking for inflammation. Additionally, isolated disease in the appropriate patient can also be managed by surgical resection followed by a surveillance colonoscopy 6 months post-resection.

IMM monotherapy may also be considered, but oral 5-ASA compounds have not been consistently shown to be effective in maintenance of remission. If induction was achieved with biologic agents, maintenance should be offered. However, combination therapy of biologics and IMM tend to have the best results. Annual endoscopy should be considered for those on biologic agents.

If patients experience a flair while taking a TNFi agent, drug concentrations and ADAs may be checked. Those with low drug level and low levels or absent ADAs may require higher dosing; those with high ADAs typically need to be switched to a different TNFi. Those with normal drug levels and no ADAs typically need to change to a new class of biologics for lack of response.

Therapeutic Drug Monitoring

Therapeutic drug monitoring (TDM) is the measurement of circulating levels of medications and ADA to inform therapy. The role of TDM in the management of transplant recipients has been well established; however, its role in patients with CD is emerging. While there is no definitive evidence to support routine TDM, there are clear theoretical advantages. Goals of care are based on maintaining medical remission while avoiding immunogenicity or loss of response. TDM would seemingly help in these endeavors as the trough concentrations of IMM and biologic therapy can vary. Factors effecting drug levels include disease severity, phenotype, degree of inflammation, combination therapy, patient sex, body mass index, and variability in drug clearance.

TDM can be done reactively following clinical evidence of active disease such as symptoms, endoscopic changes, elevation of CRP or fecal calprotectin, or proactively based on routine measurement done at set timepoints.

Patients usually become refractory to medical therapy for one of three reasons: lack of response, low drug concentrations, or development of ADAs. The AGA has clear guidelines for those on TNFi's for maintenance therapy in the setting of disease recurrence (Fig. 46.2). Adequate trough levels are defined as ≥5μg/mL for IFX, ≥7.5μg/mL for ADA, and ≥20μg/mL for certolizumab pegol. However, there is no consensus of optimal trough concentrations, and those with perianal disease may require higher concentrations for efficacy:

- If the drug level is *normal,* then the dose should be increased or the medication changed
- If the drug level is absent or *low,* check ADAs:
  - If ADAs are *absent or low* assure compliance, then consider:
    1. Shorten the dosing interval
    2. Increase the dose
    3. Combination therapy with an immunomodulator
  - If ADAs are *high* then switch medications

High serum trough levels have been shown to be associated with mucosal healing. A retrospective study of 145

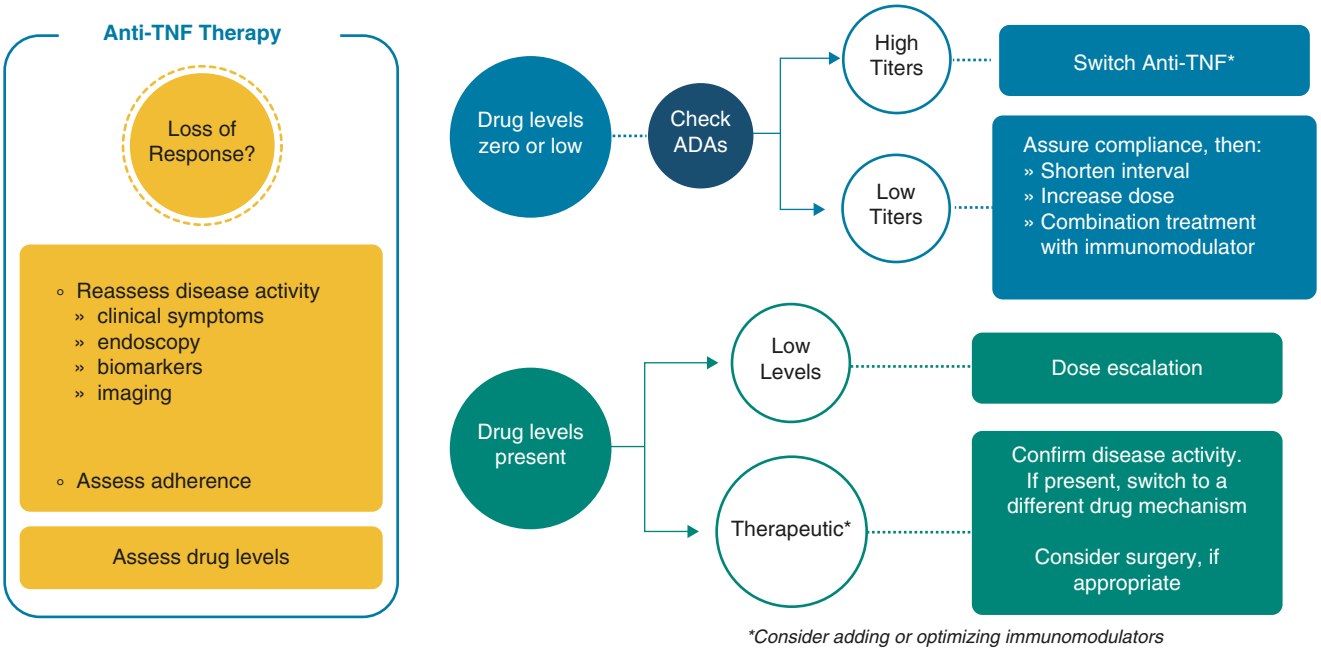

Fig. 46.2 Reactive therapeutic drug monitoring

patients over 5 years examined mucosal healing and associated this with trough levels of IFX and ADA at the same time points [94]. They found IFX levels >5μg/mL and ADA levels >7.1μg/mL identified patients with mucosal healing with 85% specificity. They also noted that higher levels of IFX and ADA beyond 8μg/mL and 12μg/mL, respectively, conferred no significant additional benefit [7].

A post hoc analysis of ACCENT I [A Crohn's Disease Clinical Trial Evaluating Infliximab in a New Long-term Treatment Regimen I] evaluated the association between IFX trough concentrations and CRP at 14 weeks after induction treatment [95]. Patients with a durable sustained response had higher post-induction trough levels than patients without sustained response. Similarly, a study of 71 patients on ADA correlated high trough serum concentrations with remission [96].

Three large RCTs have been published on the role of TDM. Trough Concentration Adapted Infliximab [TAXIT] randomized 263 IBD patients on maintenance infliximab to dose adjustment for a target concentration of 3–7μg/mL versus empiric dosing [97]. All patients initially had a starting level of 3–7μg/mL and were dose adjusted if appropriate. The study found that those patients who required an increase in dosing to achieve target trough level had a higher rate of remission and a decrease in CRP. They also identified 67 patients who started at drug level >7μg/mL and were able to be dose reduced. This translated to a 28% reduction in cost. TDM did not affect levels of clinical remission at 1 year, but patients did experience fewer flares.

A more recent double-blind RCT known as "Study Investigating Tailored Treatment with Infliximab for Active Crohn's Disease" [TAILORIX] included 122 biologic-naïve patients with active disease [98]. All patients underwent induction with combination therapy (immunomodulator plus IFX). At 14 weeks subjects were randomized to three groups: the control arm (dose increase 10 mg/kg based on clinical symptoms alone) or one of two dose intensification strategies based on clinical symptoms, biomarker analysis, and/or serum infliximab concentrations <3μg/mL. The authors found no benefit of TDM over symptom-guided management in achieving corticosteroid-free remission at 1 year. This study, however, was underpowered, and there was a very low threshold for dose escalation in the control arm.

The Pediatric Crohn's disease Adalimumab-Level-based Optimization Treatment [PAILOT] was a prospective study comparing proactive versus reactive TDM in pediatric patients [99]. The study included 78 biological-naïve children with CD who responded to adalimumab induction therapy and were then randomized to either proactive dose optimization (with a target of 5–10 mg/mL) or reactive testing. They found that clinical improvement was significantly higher in the proactive group versus reactive TDM group.

De-escalation

When contemplating de-escalation of therapy, strong consideration should be given not only to disease control but also to the overall disease characteristics, prior treatment history,

tolerance to medications, and risk for adverse events. Some patients who are at lower risk for serious complications related to CD may benefit from de-escalation of medical therapy. This reduces the risk of immunosuppression and drug toxicity and can improve quality of life and provide for cost savings. De-escalation can mean moving from combination therapy to monotherapy or withdrawing medications completely. However, in the setting of subclinical inflammatory changes, de-escalation can increase the risk of flares, use of steroids, and hospitalizations and can lead to irreversible complications and surgery [100]. Patients discontinuing biologic therapy may develop drug resistance by producing ADAs, limiting future therapeutic options.

De-escalation of combination therapy can be considered in those with well-controlled disease with no prior Crohn's-related resections or significant complications related to their disease course (Fig. 46.3) or after surgical resetting of the clock. Those with upper GI tract CD, repeated penetrating complications, surgeries, or escalated dosing of TNFi's should not be considered for de-escalation. Once selected, patients have to be confirmed to be in deep remission defined by clinical symptoms, normal biomarkers, endoscopy with normal histology, or normal imaging of the small bowel for those with ileal disease. Surveillance after de-escalation includes clinical monitoring of inflammation every 12 weeks for a year with CRP and fecal calprotectin. Prior to de-escalation from biologics, consideration should be given to obtaining drug levels. If low, this suggests the biologic is probably not the source of remission and de-escalation is more likely to be successful.

If biomarkers start to rise, endoscopy or imaging should confirm recurrence, and other sources like infection should be ruled out. If recurrence of active Crohn's is confirmed, the previously successful maintenance medication should be restarted. If needed, budesonide or steroids can be provided as a bridge.

Postoperative Prophylaxis

Off medical therapy, the rate of endoscopic disease approaches 90% at 3 years, while clinical recurrence may reach 60% [101]. The goal of postoperative prophylaxis is medical maintenance of remission, as we know 50% of those who undergoing ileocolic resection will require additional surgery within 10 years [102].

After ileocolic resection, all patients should undergo endoscopic surveillance at 6–12 months [103]. Only one RCT has been performed pertaining to the timing of prophylaxis [104]. The study randomized patients to routine AZA starting early at 8 weeks or to endoscopically guided therapy at 6–12 months. This study found no difference in the two groups; however, potential flaws included mismatched cohorts, high attrition, low accrual, and the use of non-biologic therapy.

Many factors have been associated with the risk of postoperative recurrence, and more aggressive initiation of medication is recommended in these patients. Risk factors for early recurrence include younger patients, male gender, tobacco abuse, penetrating or fistulizing disease, prior operative intervention, and short disease duration. A recent meta-analysis demonstrated a significantly increased risk of postoperative recurrence (OR, 1.7; 95% CI, 1.3–2.1; $p < 0.001$) based on the presence of histopathologically positive margins or presence of plexitis (OR, 2.3; 95% CI, 1.1–4.9; $p = 0.02$) [105].

Numerous RCTs have examined which agent should be utilized for postoperative prophylaxis. Probiotics, 5-ASA, and budesonide show no benefit over placebo [67, 106–108]. Antibiotics may reduce recurrence; but the best evidence to prevent postoperative disease is monotherapy with either biologics or IMM. Early and aggressive prophylaxis is particularly important in patients with risk factors for recurrence. Those patients who are low risk for recurrence (e.g.,

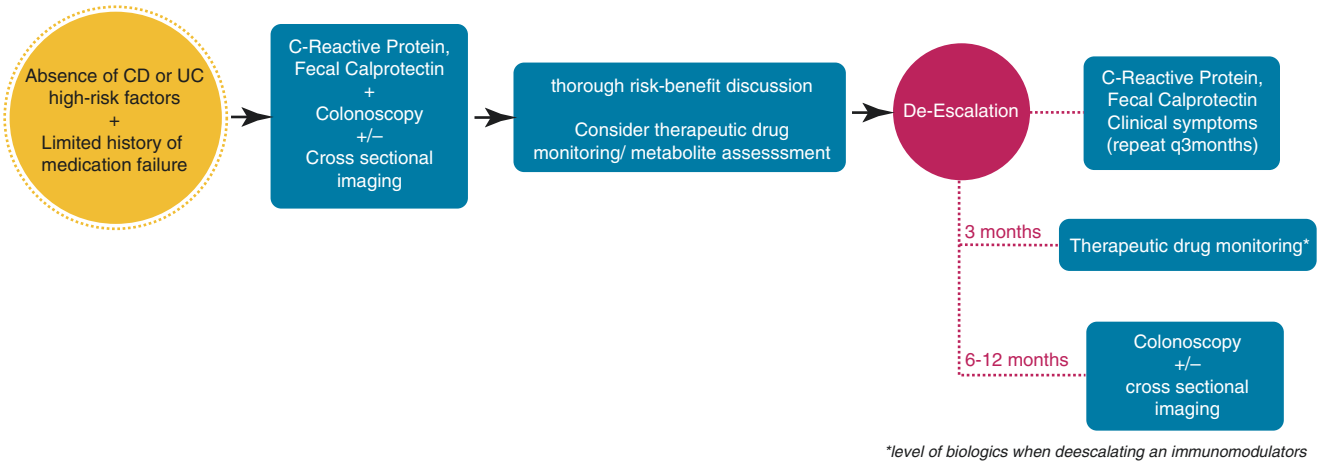

Fig. 46.3 De-escalation of therapy in IBD

isolated short segment ileocolic disease present for a long duration in an elderly non-smoker) can be surveilled 6–12 months after surgery off therapy.

Conclusions

The last two decades have seen unprecedented advances in the medical management of CD. All current strategies for therapy focus on symptom management and control of inflammation to prevent or slow bowel damage. As we improve our understanding of the disease, so too does the capacity to provide new, innovative, safer, and more effective therapies. The approach to medical management over the recent years has shifted to more proactive utilization of medications with targeted assessment to verify efficacy prior to the development of complications. The armamentarium of drug options has expanded considerably. However, the efficacy of these medications remains limited, and surgical intervention is still commonly required to manage complications and to improve or restore patient quality of life.

Anorectal Crohn's Disease

47

Emily Steinhagen and Andrea Chao Bafford

Key Concepts

- Control sepsis: Infection must be addressed before starting immunosuppressive medications.
- Treat underlying luminal disease and control diarrhea, but avoid steroids for perianal Crohn's disease.
- Perineal care: Perineal hygiene should include gentle cleansing with sitz baths or showers and skin protection with barrier creams.
- Avoid surgery in patients who are asymptomatic or in the setting of active proctitis.
- In patients who are optimized, fistulas may be treated with long-term draining setons, advancement flaps, or LIFT.
- Skin tags or hemorrhoids should generally not be treated.
- Diversion may appropriate as component of the management of perianal Crohn's disease for some patients.

Introduction

Crohn's disease (CD) is a chronic, relapsing, inflammatory condition that can affect any part of the gastrointestinal tract, from mouth to anus. Perianal involvement was first described by Penner and Crohn in 1938 [1] and includes fistulizing (abscesses, fistulas) and non-fistulizing (hemorrhoids, skin tags, anal fissures/ulcers, anorectal stricture, malignancy) complications. Approximately 13–38% of CD patients have perianal involvement and more than 80% require surgery [2–5]. Perianal CD may cause a range of disabling symptoms, including pain, discharge, bleeding, and both sexual and defecatory dysfunction. The evaluation and treatment of patients with perianal CD requires a careful history and physical examination, endoscopic evaluation, occasional imaging, and often both medical and surgical intervention. Physicians should maintain close and candid relationships with patients and care approached in a multidisciplinary fashion. The overarching goal of treating patients with perianal CD is to provide symptom resolution while avoiding incontinence and proctectomy where possible.

General principles for management of patients with perianal CD:

- Control sepsis: Infection must be addressed before starting immunosuppressive medications.
- Treat underlying luminal disease.
- Control diarrhea.
- Perineal care: Perineal hygiene includes gentle cleansing with sitz baths or showers and skin protection with barrier creams.
- Avoid steroids: Steroids do not typically have a role in the treatment of perianal CD.
- Avoid surgery in patients who are asymptomatic.
- Avoid surgery in the setting of active proctitis when possible.

Fistulizing Complications

Epidemiology and Risk Factors

Perianal fistulas are a common feature of CD, accounting for 50–87% of perianal lesions [6]. In one population-based study, 20% of patients with CD had at least one anorectal fistula during a 25-year period [4]. Approximately 10% of CD patients present with perianal fistulas as their initial manifestation, most of whom go on to develop intestinal manifestations in the year following diagnosis [7–9]. Only about 5% of patients maintain disease isolated to the peri-

anal region [10, 11]. The incidence of fistulizing perianal disease increases with greater disease duration and severity and more distal disease involvement [2–4, 10, 12]. Hellers reported the incidence of perianal fistulas to be 12% in patients with ileal disease, 15% in those with ileocolonic disease, 41% in patients with colonic disease sparing the rectum, and 92% in patients with colonic and rectal disease [2]. Tang found that patients with perineal fistulas had a more than threefold higher likelihood of having colonic rather than isolated ileal disease [13]. CD-related perianal fistulas frequently recur, with one prospective cohort study showing the risk of recurrent fistula activity being 48% at 1 year and 59% at 2 years [14].

Pathogenesis

Two leading mechanisms exist with regard to the pathogenesis of anorectal fistulas and abscesses: (1) Rectal inflammation causes ulcers and/or shallow fistulas, which then extend deeper with persistent exposure to feces and pressure caused by defecation [15]; and (2) infected anal glands penetrate the intersphincteric space and then progress to form fistulas or abscesses [16]. CD-related fistulas are thought to arise from the former, while the latter explains idiopathic fistulas.

Clinical Presentation and Classification

Patients with fistulizing perianal CD may present acutely with abscesses or chronically with draining fistulas. Abscesses typically cause acute onset pain, perianal swelling and tenderness, and fever. Additional signs of systemic sepsis may also occur. Fistulas without abscess typically cause chronic anorectal discomfort and mucoid, bloody, or feculent discharge from an external opening in the perianal skin, groin, or vagina or, in the case of urinary fistulization, may be associated with pneumaturia or fecaluria.

Abscess

Up to 62% of patients with perianal CD develop an anorectal abscess [17]. Abscesses occur in the perianal, ischiorectal, interspincteric, and supralevator spaces (Fig. 47.1). Ischiorectal abscesses are most common, accounting for 40% of CD-related perirectal abscesses [18]. Perianal and ischiorectal abscesses result in erythema, swelling, tenderness, induration (early), and fluctuance (late) on the affected side. Intersphincteric and supralevator abscesses may cause few overt clinical signs, and therefore imaging studies, such as CT [19], endorectal ultrasound [20], or MRI [21], are often needed for diagnosis.

Management

Prompt surgical drainage of perianal abscesses is required to control sepsis and limit damage to the sphincters and surrounding anorectal tissues [3, 22]. General anesthesia is typically advised except for the most superficial abscesses, which may be amenable to drainage under local anesthesia with incisions placed over areas of obvious fluctuance. Ischiorectal abscesses are best drained with incisions made close to the sphincter complex to result in shorter subsequent fistula tracts. Intersphincteric abscesses may be palpated via

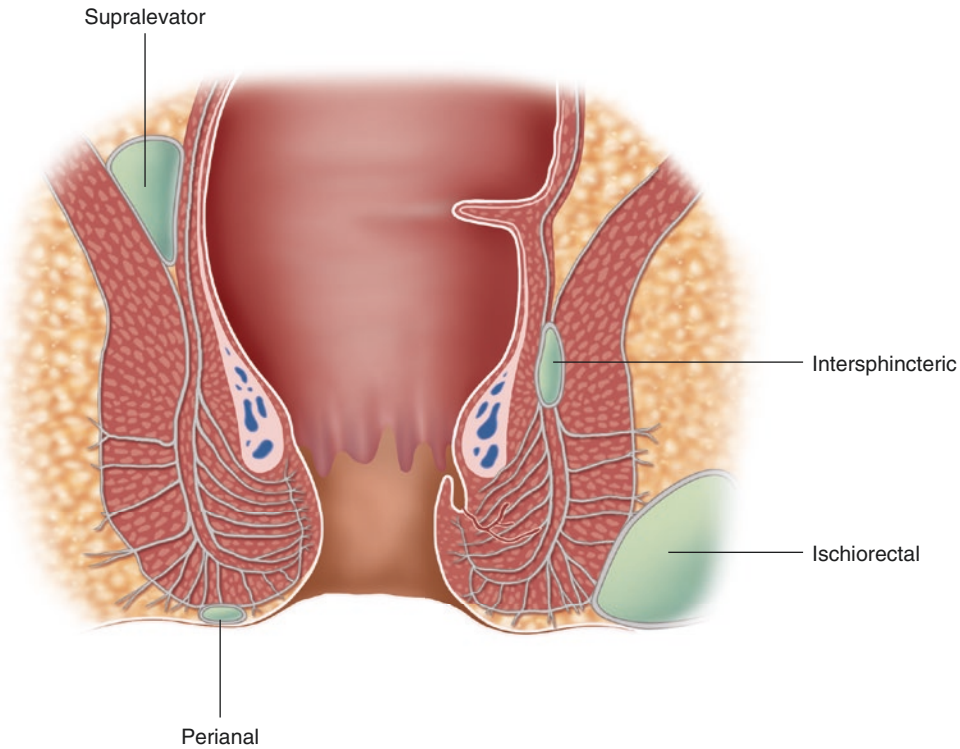

Fig. 47.1 Anorectal abscess locations

digital rectal examination as fluctuant masses within the anorectal wall. Drainage into the rectal lumen is accomplished via division of mucosa and internal sphincter muscle overlying the abscess. When fluctuance cannot be determined, needle aspiration may allow for localization of the abscess cavity. Larger abscesses are best treated with mushroom catheter drainage as wound healing is often poor in the face of acute inflammation and infection; wound packing can impede drainage and dressing changes are often poorly tolerated. For similar reasons, when an internal fistula opening is identified at the time of abscess drainage, seton drainage rather than fistulotomy should be performed even when fistulas are low-lying. The addition of aerobic and anaerobic culture and antibiotic treatment should be considered in immunosuppressed patients and those with significant cellulitis or systemic signs of sepsis.

Anorectal Fistula

A fistula is a chronic track of granulation tissue connecting two epithelial-lined surfaces. CD-related perianal fistulas can connect the anorectum with the perianal, buttock, perineal, thigh, or inguinal skin, the vagina, and the urinary tract. In 1976, Parks proposed an anatomical classification system for anal fistulas defined by their relationship to the external sphincter [16]. In order to also describe additional perianal manifestations of CD, the American Gastroenterological Association developed an empiric approach to fistula classification based on physical and endoscopic examinations [3]. Fistulas are classified as either "simple" or "complex." A simple fistula is low (superficial, low intersphincteric, low transsphincteric), has a single external opening, has no pain or fluctuance to suggest perianal abscess, is not a rectovaginal fistula, and is not associated with an anorectal stricture. A complex fistula is high (high intersphincteric, high transsphincteric, extrasphincteric, or suprasphincteric), may have multiple external openings, may be associated with the presence of pain or fluctuance suggestive of an abscess, may be associated with the presence of a rectovaginal fistula, may be associated with the presence of an anorectal stricture, and may be associated with the presence of active rectal disease at endoscopy.

Diagnosis

Precise determination of fistula anatomy is required for treatment of CD-related perianal fistulas. Fistula anatomy is typically determined using a multimodal approach combining physical examination, examination under anesthesia (EUA), and imaging techniques. On physical examination, external fistula openings may be visualized and underlying infection/inflammation determined by inspecting for erythema, purulence, and swelling, and palpating for induration, fluctuance, warmth, and tenderness. Occasionally, fistula tracks may be identified by palpating a firm "cord" of indurated tissue between the external fistula opening and the anus. Digital rectal examination may identify defects in the anorectal wall, fluctuance, an underlying stricture, or decreased sphincter tone. Anoscopy may identify internal fistula openings and underlying proctitis.

However, office examination, particularly DRE, and anoscopy are often limited by patient discomfort and are rarely therapeutic, making EUA favored in most situations. MRI and endorectal ultrasound (ERUS) have largely replaced CT and fistulography for imaging evaluation of perianal fistulas due to better accuracy. A triple blinded study comparing ERUS, MRI, and EUA showed excellent accuracy of all three modalities in determining fistula anatomy, rates being 91%, 87%, and 91%, respectively [23]. Combining any two modalities led to 100% accuracy. More recently, Sahni concluded that MRI exceeds EUA and ERUS in distinguishing complex from simple fistulas, based on a comprehensive review combining data from literature review, consensus guidelines, and consultations with experts [24]. The likelihood ratio for MRI confirming complex disease was found to be 22.7 compared to 2.1 and 6.2 for clinical examination and ERUS, respectively. Further, several societies, including the Shanghai Group and the European Society of Crohn's and Colitis (ECCO), also regard MRI as the gold standard imaging technique for perianal CD [25]. EUA without preceding imaging is likely adequate for patients with simple fistulas. For patients with complex fistulas, preoperative anatomic mapping via pelvic MRI should be considered prior to EUA.

Management

The first step in the management of patients with CD-related perianal fistulas is to eradicate infection. This is accomplished primarily with surgical drainage. Once sepsis is cleared, endoscopic evaluation is necessary to detect any luminal disease, in particular active proctitis also requiring treatment.

Medical Management

Antibiotics

Antibiotics are frequently used as the initial medical therapy for perianal CD in conjunction with treatment of underlying luminal disease; however the evidence for this is somewhat limited. Two randomized placebo-controlled trials (RCTs) have assessed antibiotic use combined with biologic therapy. Ciprofloxacin combined with infliximab had a higher response than infliximab alone (73% vs. 39%, $P = 0.12$) [26]. Given with adalimumab, ciprofloxacin also led to an improved 12-week clinical response (71% vs. 47%, $P = 0.047$) [27]. One small RCT comparing ciprofloxacin, metronidazole, and placebo was underpowered to detect any statistically significant effect [28].

In a prospective, open-label study, half of patients receiving either an 8-week regimen of ciprofloxacin (500–1000 mg/

day) or metronidazole (1000–1500 mg/day) in addition to azathioprine had significantly improved perianal disease scores (PDAI 8.4 ± 2.9 to 6 ± 4; $P < 0.0001$), with 25% achieving complete healing [29]. In a systemic review and meta-analysis including 3 trials of 123 patients with perianal CD fistula, treatment with either ciprofloxacin or metronidazole significantly reduced fistula drainage (RR = 0.8; 95% CI = 0.66–0.98), with a number needed to treat of 5 (95% CI = 3–20) [30]. In another meta-analysis, ciprofloxacin was effective in reducing perianal fistula drainage but not providing closure (RR, 1.64; 95% CI, 1.16–2.32; $P = 0.005$) [31]. However, recurrence following antibiotic discontinuation is common, and both side effects and potential for antibiotic resistance limit their use. Antibiotics should therefore be used primarily as a bridge to immunosuppressant therapy and not as sole therapy.

Thiopurines

Thiopurines are best used in combination with anti-TNF therapy or in patients who cannot tolerate anti-TNF therapy, rather than as first-line agents [32]. In a meta-analysis of RCTs comparing azathioprine (AZA) or 6-mercaptopurine (6-MP) to placebo, perianal fistula response, defined as complete healing or decreased discharge, was seen in 54% (22/49) of treated patients compared to 21% (6/29) in the placebo group (pooled OR 4.44, 95% CI 1.50–13.2) [33]. Lecomte found that 29% of patients with CD-related anal fistulas, fissures, and/or strictures responded to AZA or 6-MP; however, absence of fistula, age >40, and shorter disease duration predicted better response [34]. Due to delayed response times of 3 of more months, these immunomodulators should typically be initiated in conjunction with other medications and used to maintain rather than induce fistula closure [35].

Calcineurin Inhibitors

A small and short-term RCT by Sandborn showed that tacrolimus at 0.2 mg/kg/day was effective in improving fistula drainage (43% vs. 8%, $p < 0.05$), but not closure ($p = 0.86$) [36]. Cyclosporine has also been shown to have some efficacy in CD-related perianal fistulas in multiple non-controlled trials. In a retrospective study, intravenous cyclosporine followed by oral cyclosporine achieved symptomatic improvement in 80–85% of patients acutely and closure in 45% of patients chronically; however, recurrence occurred after discontinuation [37]. Present also reported high initial response (88%) and closure (44%) rates with parenteral and then oral cyclosporine with loss of response after treatment discontinuation [38]. These agents, however, have significant side effects including nephrotoxicity, and close drug monitoring is required. Their role appears to be limited to some patients with severe CD intolerant or unresponsive to multimodality therapy, including anti-TNF agents, in whom the options of fecal diversion or proctectomy are being considered as a last resort [3].

Biologics

Infliximab was the first anti-TNF agent to show efficacy in the treatment of CD-related perianal fistulas in two RCTs as well as in multiple non-controlled trials [39–43]. In an RCT, 85 patients with CD-related perianal fistulas were randomized to treatment with infliximab 5 or 10 mg/kg at 0, 2, and 6 weeks versus placebo [39]. Closure of at least 50% of fistulas was maintained for at least 4 weeks in 68% of patients treated with infliximab 5 mg/kg and 56% of patients treated with infliximab 10 mg/kg, compared with 26% of patients treated with placebo ($p = 0.002$ and $p = 0.02$, respectively). Closure of all fistulas was maintained for at least 4 weeks in 13% for placebo, 55% for infliximab 5 mg/kg, and 38% for infliximab 10 mg/kg ($p = 0.001$ and $p = 0.04$, respectively). The median time to response was 2 weeks and fistulas remained closed for approximately 3 months.

However, more patients treated with infliximab developed perianal abscesses than placebo-treated patients, thought possibly due to closure of the external fistula opening before the fistula tract itself. In the ACCENT II trial, 306 patients with fistulizing CD were treated with infliximab 5 mg/kg at weeks 0, 2, and 6. Patients who responded to therapy were then randomized into maintenance doses of placebo every 8 weeks beginning at week 14 or maintenance doses of infliximab 5 mg/kg every 8 weeks beginning at week 14 [40]. The median time to loss of response through week 54 was 14 weeks for patients in the placebo group and >40 weeks for patients treated with infliximab 5 mg/kg ($p < 0.001$). At week 54, 39% of patients in the infliximab maintenance group had complete closure of all draining fistulas compared to 19% of those in the placebo group ($p = 0.009$).

Adalimumab has also been shown to close CD-related fistulas in infliximab-naïve patients as well as those who previously failed infliximab treatment in two RCTs and multiple retrospective studies [44–49]. In the CHARM trial, 30% of patients with perianal fistulas treated with adalimumab for 26 weeks had fistula closure compared to 13% of patients treated with placebo ($p < 0.04$) [44]. Fistulas were closed in 33% of treated patients vs. 13% of controls at week 56 ($p < 0.02$). The efficacy of certolizumab in fistulizing perianal CD was evaluated within the PRECiSE trials [50, 51]. Fifteen of 28 (54%) of patients had fistula closure compared with 13/30 (43%) in the placebo group; this difference did not reach statistical significance ($p = 0.069$) [52].

Combining anti-TNF agents with additional therapies including thiopurines [53, 54], ciprofloxacin [26, 27], and exam under anesthesia [55] may further improve clinical response, remission durability, and patient tolerance. Feagan evaluated the efficacy of maintenance vedolizumab, an α4β7 integrin monoclonal antibody, in a subpopulation of patients

from the GEMINI 2 trial [56, 57]. Fistula closure was achieved in 28% of vedolizumab-treated patients versus 11% of control patients at 14 weeks. Vedolizumab-treated patients also had faster time to fistula closure and higher rates of fistula closure at week 52 (33% vs. 11%; HR 2.54; 95% CI, 0.54–11.96). Finally, in limited, small, retrospective studies, ustekinumab, an anti-IL12/23 IgG1 kappa human monoclonal antibody, has been shown to improve fistula symptoms and achieve closure in 61% and 31% of patients, respectively [58, 59].

Surgical Management

Fistula anatomy, underlying inflammation, and presence of complicating factors, such as proctitis and abscess, determine surgical options for CD-related perianal fistulas. In the setting of active proctitis or abscess, both fistulotomy and definite repair should be avoided due to risks of poor wound healing and failure. Unfortunately, complex fistulas are seen in 80% of CD patients, and these are associated with higher rates of recurrence and failure to heal [9, 60, 61]. As a result, patients with CD are more likely to have setons placed and less likely to undergo curative treatment for their anal fistulas [62].

Fistulotomy

Conventional fistulotomy by laying open the fistula tract and any side tracts can be safely performed in the absence of proctitis. This procedure is usually performed in the operating room under anesthesia in either prone or lithotomy position. A metal probe is passed from the external fistula to the internal fistula opening. Saline, diluted hydrogen peroxide, or diluted methylene blue injection may be used to help identify the internal fistula opening. The tissue overlying the probe is palpated and, if minimal or no sphincter muscle involvement is confirmed, divided with cautery. The wound is then gently debrided and may be marsupialized. In a study by Williams, 41 fistulotomies were performed in 33 patients with subcutaneous [17], intersphincteric [19], or low transsphincteric [5] fistulas with a 73% and 93% rate of wound healing at 3 and 6 months, respectively. Twelve percent of patients experienced minor degrees of incontinence [63]. Other retrospective studies have reported similar results [64–66]. A Crohn's Disease Activity Index (CDAI) of greater than 150 has been suggested as a contraindication to fistulotomy [67].

Draining Seton

Patients with complex perianal fistula without abscess typically require EUA with seton placement in conjunction with medical therapy. Loose, thin, silastic setons should be placed after identifying the fistula tracts as described above for fistulotomy. Draining setons maintain fistula tract patency, decrease inflammation around the tract, and often prevent the development of recurrent abscesses [62, 68]. Studies have demonstrated higher rates of fistula healing and longer duration of closure when draining setons are added to anti-TNF and other medical therapies [53, 69, 70]. A recent systematic review by de Groof included 10 non-controlled studies, with a total of 305 patients treated with setons and anti-TNF therapy. Complete fistula closure rate varied between 13.6% and 100% and recurrence ranged from 0% to 83% [71]. Setons may remain in place for months to years, or even permanently. After active proctitis is addressed medically, seton removal can occur in up to 98% of patients at a median of 33 weeks [53]. Timing of seton removal should be coordinated between the patient's colorectal surgeon and gastroenterologist, typically after anti-TNF induction is complete [68].

Endorectal Advancement Flap

Endorectal advancement flaps can be used in CD patients without active proctitis. The internal fistula opening is identified, and the crypt-bearing tissue as well as a rim of anoderm below is excised. The internal anal sphincter opening is then closed and a U-shaped flap of mucosa, submucosa, and internal anal sphincter advanced over this closure and sutured down without tension. Success rates of about 60–64% have been reported; however recurrence rates of 57% and incontinence rates of 9.4% were also found [72–74]. Joo showed that the presence of concomitant small bowel disease predicted poorer outcome [73]. Smoking has also been found to negatively impact results of flap repair [75]. In addition to proctitis, cavitating ulceration and anal stenosis are also considered relative contraindications to this technique [76]. The advancement rectal sleeve procedure involves circumferential excision, lifting the anal canal mucosa from the dentate line to the anorectal ring, mobilization of a full-thickness rectal flap, and anastomosis of the rectal sleeve to the dentate line; Marchesa described this as an alternative technique in patients with severe, complex fistulizing disease in whom proctectomy is being considered [77].

Ligation of the Internal Fistula Tract (LIFT)

The LIFT procedure involves ligating and transecting the fistula tract within the intersphincteric space. Two small retrospective studies examined the use of this technique in CD-related perianal fistulas. Gingold reported a 67% rate of clinical healing at 12 months in 15 patients, with no patient experiencing incontinence [78]. Kaminski reported healing in 6 of 8 (75%) patients at less than 1-year follow-up and 5 of 15 (33%) patients with more than 1-year follow-up [79]. In multifocal CD, success was higher in patients with small bowel disease ($p = 0.04$) compared with colonic disease ($p = 0.02$).

Fibrin Glue and Fistula Plugs

Fibrin glue treatment involves the injection of biodegradable glue into the fistula tract in order to stimulate fibroblasts to form a fibrin clot seal [80]. This technique has the advantage of maintaining the integrity of the anal sphincters, and therefore repeat injections can be performed. Highly variable success rate between 0% and 100% has been reported, and data in CD patients is limited to small case series with relatively short-term follow-up [80–82]. Anal fistula plugs are bioprosthetic grafts that provide a collagen scaffold over which a patient's endogenous cells populate. Similar to fibrin glue, published results vary widely with studies showing a 15–100% rate of healing [83–86]. In a systematic review, the success rate of the plug was 55% [85]. One multicenter RCT in 106 CD patients reported that fistula plug treatment had similar efficacy as seton removal alone [87].

Mesenchymal Stem Cell Therapy

Local injection of mesenchymal stem cells is a promising new therapy for nonhealing perianal fistulas. In a phase 3 trial of 212 CD patients with complex fistulas, higher rates of fistula closure were found for patients who received adipose-derived stem cell injection compared to placebo (56.3% vs. 38.6%, respectively; 95% CI 4.2–31.2, $p = 0.010$) [88]. Study patients also had significantly shorter time to clinical remission (6.7 vs. 14.6 weeks). Other trials have similarly shown this procedure is safe and efficacious in patients with CD [89–94].

In a recent systematic review and meta-analysis of 11 studies, Lightner reported improved healing with mesenchymal stem cells compared with placebo at primary end points of 6–24 weeks [OR = 3.06 (95% CI, 1.05–8.90); $p = 0.04$] and 24–52 weeks [OR = 2.37 (95% CI, 0.90–6.25); $p = 0.08$] [95]. Another meta-analysis showed higher healing and clinical response rates in patients with baseline CDAI >150 than those with baseline CDAI <50 (79.17 vs. 47.53, $P = 0.011$), higher healing rate and lower recurrence rate with a moderate dose of 2–4 × 107 cells/mL compared to other dosages, and lower recurrence with adipose-derived MSCs therapy compared to bone marrow-derived MSCs (RR 7.4 ± 4.28 vs. 13.39 ± 0.89) [96]. These studies, however, were limited by heterogeneous patient populations, variable medication dosing, non-standardized methods of drug delivery, and differing definitions of success. One study reported fistula relapse-free survival of 37% for 4 years after treatment and cumulative probabilities of surgery- and medical-free survival of 63% and 25% at 5 and 6 years, respectively; however, the majority of reports lack long-term follow-up [97].

Rectovaginal Fistula

The incidence of anovaginal or rectovaginal fistula (RVF) in women with CD is approximately 10%; the median age of onset is 34 years [4, 98]. They are caused by an inflammatory process in the anus or rectum that is severe enough to erode through the vaginal wall. The most frequent disease distribution associated with RVF is colonic rather than small bowel disease [99, 100]. While some RVFs cause minimal or no symptoms, many significantly impact quality of life. Patients may experience seepage or incontinence of gas or stool via the fistula, leading to vaginal and perineal irritation. Sexual dysfunction, including dyspareunia, and urinary tract infections may also be present.

Prior to considering repair of an RVF, control of perianal sepsis and optimization of medical management should be accomplished. Examination under anesthesia with drainage of any abscesses and placement of setons can often accomplish the former; close collaboration with a gastroenterologist is essential for the latter. It may be helpful to establish the extent of sphincter damage and whether it is intact either via MRI or ultrasound [101]. Options for repair include advancement flaps from the anal or vaginal side, interposition either with gracilis or Martius (bulbocavernosus) flaps, episioproctotomy, or abdominal approaches such as pull-through procedures. Other approaches that have been described include fibrin glue or stem cell injection, fistula plugs, mesh interposition, and other novel techniques. The data on outcomes following RVF repair tends to be small case series, including fewer than 20 patients. As such, predictors of successful healing are largely unknown.

One study of RVF repair with rectal advancement flap found a healing rate of 42% for initial repair in 12 patients; this rose to 83% after up to 3 attempts [102]. This technique is appropriate in women with an otherwise normal anal canal, as those with significant stricture or sphincter defect are less likely to heal. In cases of anal stenosis, a vaginal flap consisting of healthy, nondiseased tissue may be more appropriate [103]. Sphincter defects should be repaired simultaneously, when present.

The Martius flap utilizes a pedicle graft to interpose healthy tissue between the rectal and vaginal sides of the fistula. After perineal dissection separating the rectovaginal septum to above the fistula defect is completed, an incision is made over the labia majora and the bulbocavernosus muscle mobilized. A subcutaneous tunnel is then created to the mobilized rectovaginal septum and the anterior portion of the flap pulled through the tunnel and sutured to the posterior vaginal wall. Healing rates varying between 50% and 100%, with or without fecal diversion, have been reported [104, 105]. For gracilis flap repairs, the gracilis muscle is harvested from the thigh, preserving the neurovascular bundle. The flap is rotated into the rectovaginal space via a subcutaneous tunnel and secured in place. Series of RVF repair with gracilis flap formation report healing rates ranging from 33% to 80%; however none included more than 11 patients [106–109]. One study that assessed quality of life before and after gracilis flap repair found that while seven of eight women

were sexually active before surgery, only four remained active following repair [109].

There are two studies with just three and nine patients that described the use of biologic (porcine-derived) mesh for RVF; healing ranged from 50% to 78% [110, 111]. Plugs have a healing rate of 50% in CD patients based on limited studies [112]. In an RCT of stem cell injection, CD patients with RVF achieved a remission rate of 51% at 24 weeks compared to 35% in controls [113]. In studies that include more than one technique with the primary end point of overall fistula healing, success rates range from 50% to 80% at 5 years with a rate of proctectomy of about 20% [114, 115].

In general, starting with an advancement flap repair and proceeding to more complex procedures if there is failure often makes sense. In the setting of recurrent fistulas, diversion is more frequently considered. Stomas may also be used before repair to minimize symptoms and improve inflammation of the perineal tissues related to seepage and soilage. Up to 60% of CD patients with RVF require temporary fecal diversion, and up to half require a permanent stoma for their perianal disease [116].

Medical management plays an important role in healing of RVF. Immunomodulators improve healing rates, while smoking and steroid use decrease success [117, 118]. A study of RVF repair that included a number of different techniques in both CD and non-CD patients found that repair at a short interval from diagnosis, no previous repairs, major procedures, and fecal diversion were also prognostic of success [119].

Non-fistulizing Complications

Anal Fissures and Ulcers

In the setting of CD, the etiology of anal fissures may be similar to that in non-Crohn's patients – from repeated bowel movements traumatizing the anal canal – or as a sequelae of anal canal inflammation related to the disease itself. Idiopathic fissures are generally located in the anterior (10%) or posterior (90%) midline and are associated with sharp pain and bright red blood with bowel movements. These fissures are located between the anal verge and dentate line and are associated with a hypertonic internal anal sphincter. CD patients experience idiopathic fissures as well as atypical fissures, which are frequently multiple and located off midline [120]. Atypical fissures classically have a granulating base with overhanging edges and may extend beyond the verge onto the perianal skin (Fig. 47.2). Large cavitating ulcers with significant tissue loss may also be seen (Fig. 47.3).

Atypical fissures occur due to direct involvement of the perianal tissues with CD-related inflammation. They often cause pain, bleeding, and, occasionally, pruritus. Unlike idiopathic fissures, they are not associated with increased internal anal sphincter tone. Biopsies demonstrate non-necrotizing epithelioid cell granulomas in about three-quarters of cases [121]. When these lesions present in healthy patients not known to have CD, other ulcer-related anal diseases such as carcinoma, radiation-related changes, syphilis, herpes, AIDS, gonorrhea, chlamydia, tuberculosis, and leukemia must be ruled out [122].

If fissures appear to be idiopathic in nature, even in patients with CD, they should be treated with the same algorithm used in non-CD patients. When fissures are present in the context of numerous bowel movements, controlling stool frequency is an appropriate first goal. This is accomplished by treating the underlying luminal disease and may be aided by anti-diarrheal or bulking agents, such as psyllium-based fiber. Minimizing toilet time, gentle perianal skin care, and topical agents such as nitroglycerine, calcium channel block-

Fig. 47.2 Severe fissures and ulcers

Fig. 47.3 Cavitating ulcers

ers, and botulinum toxin injections may also be useful. Hot baths and perianal hygiene may relieve symptoms as well. While these measures are highly successful in non-CD patients, data regarding their use in CD patients is limited.

The safety and efficacy of lateral internal sphincterotomy (LIS) in patients with CD has been studied in a small series by Fleshner [120]. The authors concluded that if patients have a single, characteristic midline fissure associated with a hypertonic sphincter and a disease-free rectum, LIS is appropriate. Additionally, when medical management was compared to LIS combined with fissurectomy in 56 CD patients, there was 67% short-term healing in the surgical group compared to 50% in the medical group. In the subset of patients with luminal disease, the healing rate fell to 43%. In long-term follow-up, 60% of the surgical group healed compared with 49% of the medical group. Of the patients with non-healed fissures, one quarter eventually developed a fistula. However, in other series, nearly 60% of CD patients treated surgically for fissure (botulinum toxin +/− fissurectomy, or LIS) experienced complications, including poor wound healing, recurrence, and fistulas [123].

Fissures and ulcers associated with CD inflammation are challenging to treat. In the absence of sphincter hypertonicity, strategies that decrease tone should be avoided, both because they will not help and because they can threaten continence in patients who may already have impaired control and are prone to loose bowel movements. Topical metronidazole 10% has demonstrated improvement in pain, drainage, induration, and CDAI at 4 weeks [124]. Tacrolimus 0.1% has also been used successfully. Systemic treatments such as steroids, antibiotics, aminosalicylates, and immunomodulators have shown inconsistent results [125–129]. Other small studies have reported some success with thalidomide [130], cyclosporine [37], hyperbaric oxygen [131], and local infiltration of infliximab [132].

Systemic anti-TNF medications have become the gold standard for the treatment of perianal CD, including fissures and ulcers. One large retrospective study demonstrated a 43% rate of complete healing and symptom resolution with anti-TNF therapy; healing was maintained in 73% of responders at 175 weeks [53]. Local infliximab injection adds minimal benefit in patients already receiving systemic infliximab [132].

The presence of CD-related fissures and ulcers is not insignificant; the likelihood of anoproctectomy is approximately 80% in patients with cavitating ulcers [133].

Skin Tags

CD-related skin tags can be classified by their appearance [3]. Type 1 skin tags are edematous and hard and may be cyanotic and tender (Fig. 47.4). These typically arise as sequelae of fissures, ulcers, or hemorrhoids when there is lymphedema secondary to lymphatic obstruction. Type 2 skin tags are raised lesions with a range of shapes from broad to narrow and soft or firm; these painless tags are often referred to as "elephant ear tags" and generally occur in multiplicity (Fig. 47.4b). The cumulative 10-year incidence of skin tags among CD patients is about 19% [134]. Skin tags may be asymptomatic or cause discomfort, pruritus related to difficulty with hygiene, or poor cosmesis. Additionally, symptomatic skin tags may signify active intraluminal disease [135].

Patients with symptomatic skin tags and active proctitis should have treatment directed at controlling inflammation. This has the dual purpose of improving bowel movements and decreasing inflammation of the tags themselves. Sitz baths, moistened wipes for hygiene, and careful cleansing also help reduce the symptoms of irritated skin tags.

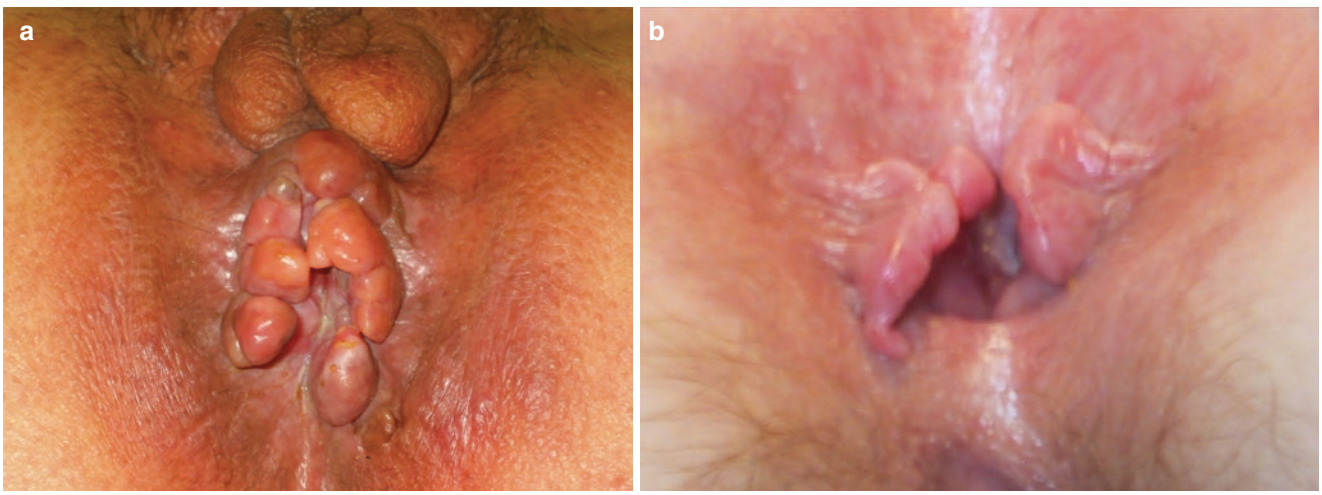

Fig. 47.4 (**a**, **b**) Type 1 and Type 2 skin tags

For patients in remission complaining of hygiene issues and impaired quality of life due to large or multiple skin tags, excision can be considered, particularly when tags are narrow-based and resulting defects will be small. However, it is difficult to truly quantify the risk in this situation, and a good understanding of the potential complications is critical.

Hemorrhoids

Hemorrhoidal disease is uncommon in the setting of CD; in a cohort of 50,000 hemorrhoid patients, only 20 had CD [136]. In studies specifically of IBD patients, 3–20% are reported to have hemorrhoids [137].

Studies show poor outcomes following hemorrhoid surgery in patients with CD; however the quality of this data is limited. Multiple early reports describe high rates of proctectomy following hemorrhoid surgery [137]. However, these studies likely demonstrate an association between hemorrhoids and skin tags with severe distal disease, rather than implicate that complications of hemorrhoid surgery lead to proctectomy. In other words, proctectomy is a reflection of the natural progression of severe disease rather than the hemorrhoid excision itself. Despite the dictum to avoid hemorrhoid surgery in CD patients, some authors have suggested that carefully selected patients may have acceptable outcomes [138]. While historically, poor wound healing has limited the application of hemorrhoid surgery to CD patients [137], a more recent study showed that of 36 patients who underwent excisional hemorrhoidectomy, only 4 had complications of nonhealing wound, anal stenosis, abscess/fistula, and recurrent bleeding. Three patients (8%) required fecal diversion for their perianal disease at a median follow-up of 31 months [139].

In patients with CD, addressing hemorrhoids surgically may be reasonable in those with luminal remission without the need for corticosteroids and a CDAI <150 [123]. However, conservative management is generally preferred.

Anal Stricture

Anal or rectal strictures typically arise as a consequence of prolonged transmural inflammation. They occur in 17% of patients with perianal CD and rarely occur without concurrent perianal disease [133]. While some patients are asymptomatic, most report symptoms of hematochezia, constipation, pain, or incontinence [140]. Digital rectal exam or proctoscopy easily establishes the diagnosis. Asymptomatic strictures do not require any specific treatment, although underlying proctitis or other perianal manifestations should be treated. When strictures obstruct defecation, dilation can be performed either manually or with balloon or Hegar dilators. Repeat dilations are frequently needed as strictures tend to recur. However, this should not be regarded as treatment failure so long as the patient experiences symptomatic relief between dilations. Rectal advancement has also been described for anal stricture with some success [141]. Nevertheless, about half of patients with an anorectal stricture eventually undergo proctectomy [140, 142].

Fig. 47.5 Squamous cell carcinoma in multiple fistula tracts

Anal Cancer

The risk of both adenocarcinoma and squamous cell carcinoma is increased in patients with long-standing perianal CD [143, 144]. These occur in the anal canal itself or within chronic fistula tracts (Fig. 47.5). Diagnosis is made by biopsy. Cancers are often discovered late and require a high index of suspicion [145]. A long-standing previously asymptomatic fistula that acutely causes symptoms is suspicious for malignant degeneration as is a newly inflamed chronic fissure. The treatment of anal cancer in patients with perianal CD mirrors that for sporadic cancer.

Diversion and Proctectomy for Perianal Crohn's Disease

Severe perianal CD may require temporary or permanent fecal diversion (Fig. 47.6). This occurs at a rate of 10–20% [22]. Risk is increased with active rectal disease and anal stricture [146]. Patients with active colonic CD and an anal stricture are also at increased risk of permanent diversion as well as proctectomy.

Fig. 47.6 Severe perianal CD requiring diversion

The risk of perineal wound complications following primary closure is up to 36% in patients with CD [147, 148]. Risk is higher with active inflammation and in patients with extensive perianal disease causing a "watering-can" perineum. Even after prolonged healing, some patients will have chronic perineal sinuses [149].

Depending on the presence of active inflammation, a staged approach to complete proctectomy may be most appropriate. During the first stage, the rectum is transected at the level of the levator muscles, and a permanent stoma is created. Once the patient has recovered, the perianal disease is often substantially improved allowing for a limited perineal anoproctectomy with decreased risk of wound complications [150]. An intersphincteric dissection sparing the external sphincter muscle should be utilized when feasible to minimize the risk and size of the perineal wound. Primary closure is associated with poor healing in up to one-third of patients [151]. Nonhealing wounds lead to significant morbidity and may necessitate skin grafting or myocutaneous flap reconstruction.

Conclusions

Perianal CD is a source of significant morbidity for those affected by it. Early treatment of perianal sepsis is essential. Straightforward problems, such as skin tags, hemorrhoids, and simple fistulas, can often be managed similarly to their non-CD forms. Combined medical and surgical therapy and close collaboration between surgeons and gastroenterologists are essential for optimal outcomes, particularly in more complex cases. The goals of treatment should be elimination of infection, adequate symptomatic control, preservation of continence and function, and maximizing quality of life.

Crohn's Disease: Surgical Management

48

Lisa M. Cannon and Alessandro Fichera

Key Concepts

- Despite significant advances in medical management, surgery for Crohn's disease remains a vital component of many treatment paradigms.
- Optimal timing of surgery is critical in order to achieve the best outcome.
- Preoperative patient optimization is of critical importance.
- The surgeon treating Crohn's disease should be familiar with bowel-sparing principles and properly apply them while not compromising long-lasting remissions.
- Different anastomotic configurations should be considered based on severity and location of the disease.
- For all the abovementioned aspects, Crohn's disease requires a multidisciplinary approach to achieve optimal and lasting outcomes.
- Risk stratification should guide postoperative medical management.

Introduction

Medical therapy and our understanding of the pathophysiology of Crohn's disease have advanced during the last two decades. Surgical treatment has become less invasive, selective, and targeted. Now more than ever, it must be properly timed and planned. Patients affected by the disease ought to be managed in the context of a multidisciplinary approach. Surgery should be performed by properly trained surgical teams, and like our gastroenterology colleagues, many colorectal surgeons have subspecialized to become "surgical IBDologists" working in the context of a specialty medical home (SMH). It has been shown that an IBD SMH significantly reduces unplanned care and disease activity and increases patient quality of life [1].

Changing Trends in the Surgical Management of Crohn's Disease

Crohn's disease is not cured by surgery; however, surgery retains an important role in disease management. The goals of a well-timed surgical intervention are to relieve symptomatic complications such as obstruction or fistula, improve quality of life, preserve small bowel, and minimize treatment interruptions in order to reduce risk of surgical recurrence.

Significant advances in medical therapy including the advent of immunomodulators and biologic therapies have altered the natural history of Crohn's disease. The need for surgery based on time from diagnosis has declined compared to patients managed in earlier decades. For example, in a population-based cohort of patients diagnosed with Crohn's between 1955 and 1989, 73% of patients overall required surgery: 44% at 1 year, 61% at 5 years, and 71% at 10 years after the diagnosis [2]. In a cohort of patients diagnosed from 2003 to 2004 and followed to 2011, 29% of patients required surgery: 14.6% at 1 year, 24.6% at 5 years, and 28.5% at 7 years after diagnosis [3]. Comparably numbers are seen in other studies based on decade. Interestingly, the largest drop in need for surgery predates the introduction of biologics and appears reflective of the increased use of corticosteroids. Immunomodulators and biologics have likely decreased the need for surgery, but the attributable impact is hard to measure. Improved diagnostic modalities in this same timeframe have led to earlier diagnosis and initiation of therapy, and treatment paradigms have shifted to individualized and risk-stratified medical management algorithms. Both of these evolutions have likely decreased the rate of complicated surgical disease.

After recovery from intestinal resection, health-related quality of life improves as early as 2 weeks after surgery and remains high in the long term. Postoperative complications and disease recurrence may limit improvement in quality of life [4]. Overall, patients are satisfied with their surgery and generally wish they had undergone surgery earlier in their disease course [5].

Indications for Surgery

The indications for operative management of Crohn's disease are varied and listed in Table 48.1. Free perforation, toxic colitis, and major hemorrhage are true surgical emergencies; these are far less common than the host of nonemergent Crohn's complications that require individualized surgical decision-making.

Failed Medical Therapy

Despite the introduction of entirely new classes of Crohn's therapies in the past decade, failure of medical management remains a common indication for surgical intervention. The phrase "failure of medical therapy" carries multiple meanings. Some patients are unable to achieve acceptable symptom control despite aggressive medical therapy; the patient is transitioned to the next medical agent or combination of agents until all options have been exhausted. Other patients may be able to achieve good symptom control but suffer side effects or reactions to the medications. In pediatric inflammatory bowel disease, growth retardation is a manifestation of failure of medical therapy as well. Steroid-refractory patients are those who have active disease despite prednisolone up to 1 mg/kg/day for a period of 4 weeks. Steroid-dependent patients are those who are unable to reduce their steroid dose below the equivalent of prednisolone 10 mg/day without disease reactivation or who have relapse within 3 months of stopping steroids [6].

Table 48.1 Operative indications for Crohn's disease

Failure of medical management

Bowel obstruction
Free perforation
Penetrating disease/fistula/phlegmon/abscess
Cancer/dysplasia
Toxic colitis
Bleeding

Bowel Obstruction

Several Crohn's phenotypes can lead to bowel obstruction; taken together, about one-quarter of Crohn's disease surgery is secondary to obstructive symptomatology. Untreated and poorly controlled Crohn's disease causes progressive transmural intestinal injury. Histologic examination of a Crohn's stricture reveals thickening of the muscularis mucosa and muscularis propria with fibrotic change, as well as increased volume and density of the submucosa [7]. There is a slow evolution, and the bowel slowly accommodates to the progressive obstruction. The patient experiences intermittent abdominal pain, bloating, and progressive food intolerance. Eventually intervention is necessary due to acute on chronic obstruction or intolerable symptoms as the occlusive disease progresses. Currently no antifibrotic therapies for stricturing disease exist. Other etiologies of Crohn's disease-related obstruction include anastomotic stricture and neoplasm.

Once the diagnosis of obstruction has been established, the relative contribution of fibrosis and inflammation is assessed. CT or MR enterography is the current standard for assessing the small intestine. CT enterography findings of tissue inflammation include mucosal hyperenhancement, mesenteric fat stranding ("comb sign"), and mesenteric hypervascularity. However, CT enterography is not as successful at identifying degree of fibrosis, and upstream dilation is not reliable at distinguishing inflammation from fibrosis. On multivariate analysis, mesenteric hypervascularity was the only CT radiologic finding that predicted fibrosis. This highlights the pathophysiologic continuum between inflammation and fibrosis [8]. MRI findings indicative of inflammation include T2 hypersignal, mucosal enhancement, presence of ulceration, and blurred margins. A homogenous pattern of enhancement, and the percent of enhancement gain over time, can discriminate severe fibrosis deposition. Again, most lesions have a mixed pattern of fibrosis and inflammation [9].

Inflammatory stenoses are likely to respond to medical therapy, while fibrotic strictures typically require surgery. For localized ileocecal disease with obstruction, surgery is indicated if the patient does not respond to a trial of medical management with bowel rest and intravenous corticosteroids; upfront surgical management is indicated if clinical and radiologic findings suggest marked fibrosis with low levels of inflammation (Fig. 48.1). Ileocecectomy for Crohn's disease has a high rate of disease control. Retrospective studies performed even prior to the era of biologic therapy indicated that over half of patients never require another surgery [10]. Though postoperative endo-

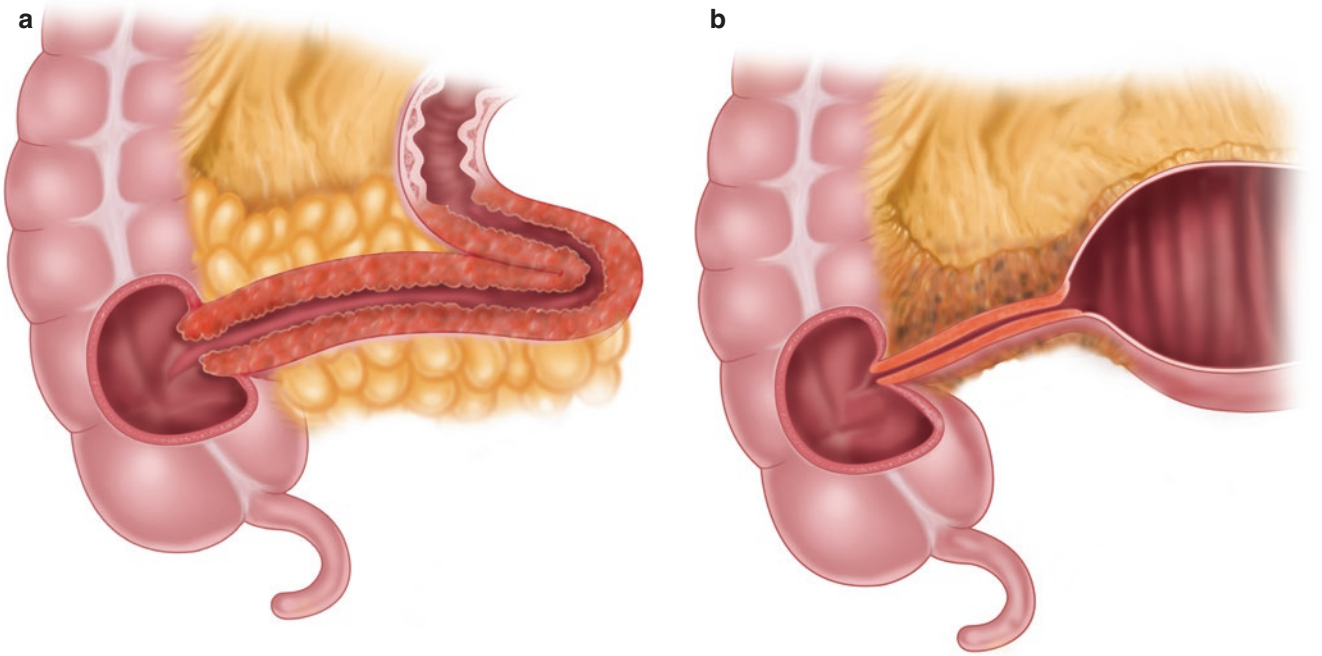

Fig. 48.1 (**a**, **b**) Crohn's-related bowel obstruction (**a**). Active inflammation with creeping fat, mural thickening, and luminal narrowing representing active disease which may respond to medical therapy. (**b**) Fibrotic change with luminal narrowing and upstream dilation, representing fibrotic stricture that is unlikely to respond to medical therapy

scopic recurrence is the rule, aggressive postoperative medical management paradigms based on endoscopic, disease-related, and patient-related risk stratification enable many patients to avoid the disease progression that led to their initial operation [11].

Endoscopic balloon dilation is an alternative therapeutic option for bowel obstruction due to stricturing disease in some patients and has been shown to delay and even prevent the need for surgery when successful. The ideal candidate for this procedure is a patient with a single short-segment (<4 cm) fibrostenotic stricture or a patient with an anastomotic stricture. The stricture should not be associated with marked angling of the bowel lumen and be without associated fistula or abscess [12]. Dilation diameter should be at least 14 mm; dilation to 16–18 mm is associated with the need for less frequent follow-up procedures; dilation of small bowel strictures to greater than 20 mm may contribute to increased rates of perforation and bleeding [12, 13]. Multifocal stricturing disease is an independent risk factor for clinical failure of balloon dilation [14].

In a recent pooled analysis, Bettenworth evaluated 1463 patients with Crohn's disease who underwent over 3000 balloon dilation procedures. Overall technical success was achieved in 89% of cases. Anastomotic strictures comprised 62% of the procedures. At 2-year follow-up, three-quarters of patients had required re-dilation, and half had undergone surgical resection. Major adverse events including perforation, bleeding, and sepsis occurred in 2.8% of patients and highlight the need for a skilled and capable endoscopist in close communication with the surgical team [15].

Perforation

Free perforation in Crohn's disease is a rare occurrence. It is typically associated with toxic colitis or complete obstruction due to multifocal small bowel stricturing disease. If the perforation is associated with small bowel strictures, it is usually immediately proximal to a completely obstructing stricture, when a more proximal stricture has created a relative closed loop obstruction. This is best treated with resection and primary anastomosis if the patient's condition allows. In the setting of an obstructing colonic stricture, the site of perforation is more commonly the cecum; this is best treated with total abdominal colectomy and ileostomy. The extent of distal resection may be tailored somewhat to the site of the stricture if the distal colon and rectum are free of disease. Toxic colitis leading to perforation is managed with total abdominal colectomy and ileostomy.

Penetrating Disease: Fistula and Abscess Formation

Approximately 11–16% of adult patients have penetrating intestinal disease manifestations [16–18]. Risk factors for penetrating disease include a number of serologic and genetic markers and tobacco [19]. Transmural inflammation of the bowel wall promotes phlegmon, abscess, or fistula formation to a nearby organ or viscera. Hirten characterized the relative frequency of fistula formation by location; 29% are enterocolonic, 18–24% enteroenteric, 6–16% enterocutaneous, 4–9% rectovaginal, and 2–8% enterovesical, and rarely enterosalpingeal and enterogastric. The originating site is usually the ileocecal region and terminal ileum [17]. Only fistulas that are symptomatic require intervention (Fig. 48.2). When surgery is indicated, the diseased segment of bowel requires resection, but often the targeted organ or bowel can be primarily repaired or a small patch excision and transverse closure performed. Penetration to the retroperitoneum can cause a psoas abscess, which requires special mention. These cavities are prone to epithelialize and become a recalcitrant source of recurrent abscess and usually require surgical intervention. After resection of the diseased bowel, the psoas abscess cavity may be unroofed and curetted; an omental pedicle flap may facilitate healing.

Patients with small abscesses or phlegmon should typically be initiated on antibiotic therapy. When a phlegmon is associated with active inflammatory disease, it is safe to administer antibiotics in combination with corticosteroids. Felder examined 24 patients with Crohn's disease and palpable inflammatory mass treated with high-dose corticosteroids. Two-thirds of patients resolved their phlegmon completely, and in the remaining 1/3, it reduced in size by greater than 50%. Though 58% of the patients did require resection for persistence or recurrence of symptoms, most were performed in the elective setting [20].

Fig. 48.3 Crohn's interloop abscess found during operative exploration. (Reproduced with permission from F Michelassi, MD)

Intra-abdominal abscess in the setting of active disease often presents a management dilemma (Fig. 48.3). Patients with accessible abscesses greater than 3 cm in average diameter should usually undergo percutaneous drainage and be initiated on antibiotic therapy. The technical success of percutaneous drainage is >90% [21, 22]. A meta-analysis by Clancy performed in 2016 of 333 patients from 6 studies compared the outcomes of primary surgery versus percutaneous drainage alone. Intra-abdominal abscess was defined as extra-luminal fluid collections identified on various imaging modalities [23]. Primary surgical resection was performed in 184 (55%) patients, and percutaneous drainage was performed in 149 patients (45%). There was a significantly higher rate of recurrent abscess in the percutaneous drainage group (OR 6.54), and the pooled proportion of these patients requiring subsequent surgery was 70.7%. The proportion of patients who underwent initial surgery and required surgery for recurrence was 17.9%.

Patients whose abscess resolves both clinically and radiologically with percutaneous drainage may present more of a therapeutic dilemma; it is unclear whether they should all proceed to elective resection. There is much interest in identifying patients who may be able to avoid surgery in the setting of successful percutaneous drainage or medical management. The prior meta-analysis suggested that up to 30% of patients undergoing percutaneous drainage can avoid surgery [23]. The MICA trial is prospectively examining predictive factors of anti-TNF response in luminal Crohn's disease complicated by abscess formation. This trial is sponsored by the Groupe d'Etude Therapeutique des Affections Inflammatoires Digestives (GETAID).

There are a number of studies that have examined percutaneous drainage as a bridge to surgery for Crohn's-related abscess. Müller-Wille examined the influence of preoperative percutaneous abscess drainage on postoperative septic complications. Twenty-five of the patients with spontaneous

intra-abdominal abscess were treated with percutaneous abscess drainage (48%) on average 37 days (range 6–83 days) before surgery. The rate of postoperative septic complications was significantly lower in the group who underwent preoperative intra-abdominal abscess drainage (25% versus 69%) [24].

Similarly, Zhang demonstrated that intra-abdominal abscess, not penetrating behavior, is associated with poorer outcome after resection. In this study, 288 patients, 180 of whom had penetrating behavior including 54 with intra-abdominal sepsis, underwent surgical resection. Patients with intra-abdominal sepsis, not penetrating behavior alone, were more likely to have postoperative septic complications, superficial surgical site infection, and stoma formation [25]. Percutaneous drainage may improve the nutritional and general medical conditional of the patient and enable a less invasive operation. Given that penetrating disease is a risk factor for recurrence, initiation of prophylactic therapy is typically recommended after intestinal resection [6].

Cancer and Dysplasia

Patients with Crohn's disease are at increased risk of developing both intestinal and non-intestinal cancers, compared to the general population. Colorectal cancer is the cause of 1 in every 12 deaths of patients with inflammatory bowel disease [26]. Colitis-associated cancer has many of the molecular alterations also found sporadic colorectal cancer, but with different timing and frequency. For example, loss of adenomatous polyposis coli (APC) functions occurs early in sporadic colon cancer and late in colitis-associated cancer. In contrast, loss of p53 function occurs early in colitis-associated cancer [27]. Development of cancer in chronic colitis is accelerated by inflammatory activity [26]. Patients with Crohn's disease have a twofold to threefold increase in colorectal cancer compared to the general population. The mean age at diagnosis is 51.5 years, about 20 years earlier than the general population [28]. The risk of cancer is also associated with disease duration; the cumulative risk of colorectal cancer in Crohn's disease is 2.9% at 10 years, 5.6% at 20 years, and 8.3% after 30 years with the disease [27]. With equivalent disease duration, the risk of colorectal cancer in Crohn's disease appears to be lower than that of ulcerative colitis, but this may be informed by differences in disease distribution [28].

Colorectal strictures in the setting of Crohn's disease are particularly associated with an increased risk of cancer. Yamazaki analyzed 132 patients with 175 strictures identified between 1959 and 1980. A total of ten malignant strictures were identified *in nine patients*, three with ileocolic and six with colonic disease. The frequency of cancer in patients with a stricture was 6.8% [29]. The authors further observed that all of the malignant strictures were short-segment. A group out of Hungary similarly analyzed 640 patients with Crohn's disease over a 30-year period, including 62 patients with ileocolic or colonic strictures. The group observed a 6.5% rate of colorectal cancer in those patients with stricture. The authors observed that all four patients with stricture-associated colorectal cancer were male smokers [30].

The surgical management of colitis-associated dysplasia in Crohn's disease follows the same principles as ulcerative colitis and is reviewed elsewhere in this textbook.

Toxic Colitis

Up to 50% of cases of toxic colitis from IBD may be attributed to Crohn's colitis. Severe colitis is defined by Truelove and Witt as six or more bloody bowel movements daily, temperature greater than 37.8 °C, heart rate greater than 90 beats per minute, anemia with a hemoglobin less than 10.5 g/dL, and an elevated erythrocyte sedimentation rate greater than 30 mm/h. These criteria, combined with imaging demonstrating dilation of the colon and a disturbed or absent haustral pattern, constitute toxic megacolon. The medical management of toxic colitis is covered in another section of this textbook. When surgery is required due to clinical deterioration or failure to respond to rescue therapy, total abdominal colectomy with end ileostomy is indicated, with or without mucous fistula. The extent of resection and surgical management in the setting of medically refractory colitis is reviewed later in this chapter, under operative considerations for colonic and rectal disease.

Bleeding

Acute severe gastrointestinal hemorrhage is a rare complication of Crohn's disease, with an incidence of 1–2%. There are few studies that describe the epidemiology of this condition. Bleeding does not always correlate with disease activity. The site of bleeding can be duodenal, jejunoileal, ileocolic, or colic. Surgery is typically successful when the site of bleeding has been localized. In those that resolve without surgery, recurrent hemorrhage is not rare [31–33].

A patient with Crohn's disease presenting with acute gastrointestinal bleeding should be initially managed using the usual resuscitative algorithms for gastrointestinal bleeding, including nasogastric lavage to begin the process of source localization. In contrast to ulcerative colitis where bleeding is due to widespread mucosal ulceration, hemorrhage in the setting of Crohn's disease is more often due to a focal erosion into an intestinal vessel or occasionally an inflammatory pseudopolyp. Source localization therefore is extremely important to minimize unnecessary bowel resection should surgery be required. Up to 30% of patients with Crohn's disease and hemorrhage will have a bleeding duodenal ulcer and positive gastric lavage should trigger upper endoscopy [34]. Colonoscopy within 24 hours of bleeding can successfully locate the bleeding source 60–78% of the time [31, 32]; endoscopic control is not often successful, but will localize

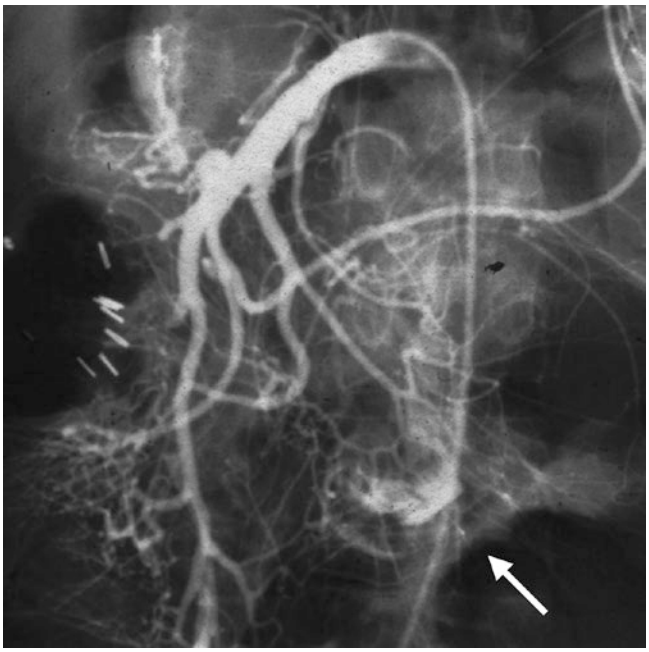

Fig. 48.4 Contrast extravasation (arrow) seen on angiography from an intestinal segment in a patient with Crohn's disease. (Reproduced with permission from F Michelassi, MD)

the site for guided resection. CT angiography and traditional mesenteric angiography have also been successfully utilized for source localization (Fig. 48.4). When mesenteric angiography localizes bleeding, methylene blue injection can be used to identify the segment of involved bowel so that it may be readily identified during operative exploration. This approach will typically stain a 10–40 cm segment of bowel for resection [35].

Surgical Considerations

Crohn's disease cannot be cured by surgical therapy, and thus surgery, like medical treatment, should be considered palliative. It is paramount to keep in mind the recurrent and chronic nature of the disease that is typically diagnosed in a young patient population with a long life expectancy. The pendulum has swung from an emphasis on margin-negative resection to bowel-sparing approaches largely based on a landmark paper from Fazio. The authors randomized 152 patients undergoing ileocolic resection to 2 groups in which the proximal line of resection was 2 cm (limited resection) or 12 cm (extended resection) from the macroscopically involved area. They showed that there was no difference in recurrence rates between the two groups; further, recurrence rates did not increase when microscopic disease was present at the resection margins [36]. Similar to medical treatment, the goal of surgical treatment of Crohn's disease is to provide long-lasting symptomatic relief while avoiding excessive morbidity. Complete extirpation of microscopic disease should not be the primary goal of surgery, as this does not produce cure and is frequently counterproductive. Rather, treatment of complications and relief of disease-related symptoms coupled with bowel preservation should be the main aims of surgical treatment.

To avoid excessive loss of small intestine, nonresectional techniques such as strictureplasty may be required. On the other hand, in patients with isolated Crohn's colitis, especially if multifocal and associated with perianal disease, a more aggressive approach is often indicated [37–39]. Understanding the natural history of different patient cohorts is key to optimal decision-making.

Nutritional Support and Total Parenteral Nutrition

Exclusive enteral nutrition has been shown to induce remission in the pediatric Crohn's population and to be as effective as systemic corticosteroids in inducting remission both in newly diagnosed and established patients. In fact, intestinal healing was significantly more likely among patients receiving exclusive enteral nutrition compared to corticosteroids (OR = 4.5 [95% CI 1.64,12.32]) in a recent meta-analysis [40]. In the adult patient population, exclusive enteral nutrition is not as effective in inducing remission, but it may be useful for maintaining remission in patients with quiescent Crohn's disease [41].

In the adult literature, nutritional support has been evaluated primarily for preoperative optimization. Crohn's patients are at increased risk for malnutrition, which can result in adverse clinical outcomes. In a recent study from China, 59.0% of screened patients were deemed to be at risk for malnutrition [42]. If we consider that surgical patients have failed medical management, that percentage is probably even higher in the operative cohort. Crohn's disease patients with serious nutritional deficits, based on weight loss >10% in the last 3–6 months, body mass index <18.5 kg/m, or albumin levels <30 g/L, have been shown to benefit from intensive enteral or parenteral nutritional support, thereby reducing the risk of surgical site infections and postoperative septic complications [43]. Malnutrition has been shown to be an independent risk factor for postoperative morbidity and mortality irrespective of immunosuppressive and biologic therapy [44]. The duration of preoperative nutritional support depends on the urgency of the operation and the suitability of the gastrointestinal tract for enteral administration [45, 46].

Overview of Operative Considerations

Minimally Invasive Surgery

Crohn's disease may present both real and perceived challenges to a minimally invasive surgical approach. A Crohn's-related inflammatory mass and secondary phlegmon can increase the risk of bowel injury during minimally invasive manipulation and dissection. Thick, inflamed mesentery may be difficult to divide with a vessel-sealing device. With limited tactile feedback, it may be difficult to determine whether a fistula requires resection versus debridement and repair. Despite these challenges, evidence has accumulated in favor of a tailored approach to minimally invasive surgery (MIS) in Crohn's disease.

Milsom and Maartense both conducted prospective randomized trials in selected Crohn's patients undergoing ileocecectomy, concluding that MIS patients enjoy improved postop pulmonary function, morbidity, and reduced length of stay [47, 48]. Analysis of long-term outcomes in these two trial populations supported improved body image perception and cosmesis, as well as a decreased risk of bowel obstruction and hernia [49, 50]. Evidence does not support the concern that diminished tactile feedback will lead to missed strictures or increased disease recurrence due to incomplete resection [51]. MIS approaches for complex Crohn's disease, defined as reoperative disease, presence of phlegmon, abscess and/or fistula, or immunosuppressed state, can be accomplished with acceptable outcomes, albeit with generally higher conversion rates [52–55].

Robotic MIS for Crohn's disease is technically feasible. Like the laparoscopic approach, morbidity and length of stay are reduced compared to open approach [56], but operative times are longer [57]. The conversion rate is lower than with laparoscopy in some series [58]. All in all, there is not yet a clear demonstrated advantage of robotic over laparoscopic MIS in Crohn's disease [59].

The general advantage of MIS versus open approach in Crohn's disease is no longer disputed. Widespread acceptance of MIS approach is cultivating advanced near-term technologies and techniques, such as single-incision surgery and intracorporeal anastomosis. Inability to deliver a foreshortened Crohn's mesentery through a small extraction site in order to perform an extracorporeal anastomosis makes intracorporeal anastomotic technique enticing and may reduce the surgical site infection rate [60]. Heimann demonstrated that it may be possible to decrease and possibly eliminate incisional hernia in Crohn's disease patients undergoing bowel resection using an intracorporeal anastomosis and small (<4 cm) transverse extraction incision [61]. Tou described a robotic-assisted strictureplasty, and Scaringi illustrated a robotic approach to stricturing disease that is in essence a nonresectional, intracorporeal, side-to-side isoperistaltic anastomosis [62, 63]. Further studies and long-term analysis are needed to understand how these techniques may influence disease recurrence.

Single-incision laparoscopic surgery utilizes only one abdominal incision and an incisional platform through which a 5-mm camera and two working instrument ports are inserted. A number of small studies support the safety of this approach in Crohn's disease, but there is no clear benefit over conventional laparoscopy [64].

IBD surgeons should tailor the approach to the individual patient and be willing to utilize a hybrid or open approach if there is a lack of progress in complex cases. The hybrid approach is attractive when circumstances prohibit a fully MIS procedure. If a Crohn's terminal ileal phlegmon is fixed to the retroperitoneum, the surgeon can mobilize the proximal bowel and distal colon in order to limit the incision required to complete the procedure. If the mesentery is noted to be too thick and unwieldy for laparoscopic vessel sealers, it may be possible to perform minimally invasive mobilization and then divide this mesentery extracorporeally using more traditional clamp and suture ligature technique [65].

Enhanced Recovery Pathways

Very little disease-specific data exists supporting the application of enhanced recovery pathways (ERPs) after colorectal resection in inflammatory bowel disease. A recent review identified only a dozen English-language studies on ERPs that included any proportion of patients with IBD in their analysis, and only 28.9% of the total number of patients within these studies had a stated surgical indication of IBD [66]. Most studies did not provide important IBD-specific demographic information such as biologic therapy, steroids, or immune modulations. Still, all available evidence to date suggests that application of ERPs to patients undergoing colorectal surgery for IBD is safe and likely leads to decreased length of stay without an increase in the rate of readmission or morbidity. Inflammatory bowel disease is a known risk factor for prolonged length of stay, and this should be taken into account when setting postoperative expectations for recovery [67].

Perioperative Medical Management

In steroid-treated and steroid-dependent patients, concern over postoperative adrenal insufficiency and adrenal crisis has traditionally led to the liberal utilization of stress-dose steroids in the perioperative setting. Truong noted that much of the evidence around dosing, duration, and indications for steroid supplementation is poorly supported and anecdotal [68]. The dose and duration of steroid therapy do not correlate with the degree and duration of hypothalamic-pituitary-

adrenal (HPA) axis suppression. Recovery of HPA axis function after cessation of steroid therapy can be as short as 2 days and as long as 1 year, which is the basis for recommending stress-dose steroids for a patient who has required steroid therapy within the past year [69].

As perioperative high-dose steroids are associated with impaired wound healing, reducing or omitting stress-dose steroids in Crohn's disease surgery is desirable. In a small pilot study, Zaghiyan did not administer any perioperative steroids to IBD patients who had received steroids within the year but were not on steroids at the time of surgery. All cases of hypotension, bradycardia, and tachycardia spontaneously resolved without the need for fluid bolus, vasopressor, or steroid administration [70]. Further studies support the notion that steroid-treated patients can be maintained on their usual preoperative steroid dose in the perioperative period. Patients who have been treated with steroids within the year probably do not need precautionary perioperative steroid supplementation at all. High "stress-dose" perioperative steroids are unnecessary and may increase perioperative risk [71, 72].

There is a dose-dependent relationship between steroid use and infectious complications. The highest risk of complications occurs in patients on >40 mg prednisolone or equivalent [73, 74]. If the surgery is elective or semi-elective, an attempt to wean steroids should be undertaken, with the goal to have patients off steroids for 1 week prior to surgery [75]. If complete cessation is not possible, an attempt to wean to their lowest possible dose, with a target of less than 20 mg prednisolone or equivalent, is recommended [6].

There have been few studies examining whether immunomodulator use leads to increased complications. Patients on 6-mercaptopurine/azathioprine (6-MP/AZA) alone do not have an increase in complication rates, and concurrent use of 6-MP/AZA and corticosteroids does not further elevate complication rates as compared to the known risk of corticosteroids alone [73]. In a recent review, Rosen did not find any literature suggesting an increased complication rate with methotrexate. Discontinuing immunomodulator therapy prior to surgery appears unnecessary. These medications are typically held on the morning of surgery and resumed as per the gastroenterologist treatment plan [76].

Since the approval of infliximab in 1998 for treatment of inflammatory bowel disease, biologic therapy has vastly advanced medical treatment options for Crohn's disease. The influence of biologic therapy on surgical timing, morbidity, and intraoperative surgical decision-making is a ripe area of clinical interest. Tumor necrosis factor-α (TNFα) is a central cytokine in the pathogenesis of IBD, and anti-TNFα therapies including infliximab, adalimumab, and certolizumab pegol are some of the most successful Crohn's therapies available.

Table 48.2 Risk factors for postoperative septic complications in patient with Crohn's disease undergoing surgical resection [79, 154, 155]

Corticosteroid use
Malnutrition/hypoalbuminemia
Anemia/acute blood loss
Emergency surgery
Anti-TNFα therapy
Vedolizumab therapy
Penetrating disease/fistula/intraoperative abscess
Recurrent disease Smoking

Several studies had sought to describe the relationship between anti-TNFα therapy and postoperative outcomes, with mixed results. Interpretation of the impact of biologics is complicated by drug pharmacokinetics and associated drug levels, as these medications are typically protein-bound and prone to be lost in the stool in patients with active disease. One study showed that 50% of patients on anti-TNFα at the time of surgery did not have detectable drug levels immediately preoperatively [77]. Complications do not appear to correlate with anti-TNFα serum trough levels [78]. There are several, heterogeneous, retrospective, and prospective studies that either support or refute the hypothesis that anti-TNFα therapy leads to a significant increase in postoperative complications. Thought leaders in this area recommend considering biologic therapy as one of the several risk factors (Table 48.2) that negatively influence postoperative complications.

A reasonable elective strategy is to delay surgery by 4 weeks (allowing for washout period of two half-lives) from the last anti-TNFα dose. If this is not possible due to the patient's clinical circumstances, temporary diversion may be considered if the patient has two or more risk factors [79].

Vedolizumab, a monoclonal antibody to α4β7 integrin, has been approved for medical treatment of Crohn's disease since 2015. Literature is also conflicted regarding the influence of postoperative septic complications in patients receiving vedolizumab therapy. Vedolizumab has been associated with an increased rate of postoperative surgical site infections [80]. A reasonable strategy is to delay surgery by 6 weeks (two half-lives) from the last vedolizumab dose and, if this is not possible, consider temporary diversion if the patient has additional risk factors for septic complications. Ustekinumab, a monoclonal antibody targeting interleukin-12 and interleukin-23, does not appear to increase the risk of postoperative septic complications [81].

Anastomotic Type

Different anastomotic techniques in Crohn's disease may be compared based on safety (i.e., anastomotic leak rates) and risk of recurrence. When looking at leak rates, one very

important component that is hard to factor in is the surgeon's experience with the applicable technique. With the advent and wide acceptance of the surgical staplers, many are less facile at sewing the anastomosis, and that may result in higher complication rates for the hand-sewn technique.

Despite anastomotic construction being a critical aspect of Crohn's disease management, there is limited level 1 evidence in the literature. Muñoz-Juárez [82] performed the first case-controlled comparative analysis of 138 patients divided evenly into wide-lumen stapled side-to-side anastomoses and hand-sewn end-to-end anastomoses. Clinical recurrence occurred in 16 (24%) of the side-to-side anastomosis group and in 39 (57%) of the end-to-end anastomosis. The cumulative surgical recurrence rates at 5 years were 11% after side-to-side anastomosis and 20% after conventional end-to-end anastomosis ($p = 0.017$). A 2007 meta-analysis [83] comprising only 8 studies with 661 patients who underwent 712 anastomoses compared the outcomes of end-to-end anastomoses (53.8%) and other types of anastomotic configurations (46.2%), including stapled side-to-side in the vast majority. There were no significant differences between the groups regarding overall complications, anastomotic recurrence, or surgical anastomotic recurrence. When comparing only side-to-side and end-to-end anastomosis, a lower leak rate as well as reduction in postoperative complications was demonstrated in the side-to-side anastomosis group. However, there was no difference in overall recurrence or surgical recurrence rates. These data were confirmed in a subsequent Cochrane review by Choy [84].

Two more recent systematic reviews [85, 86], however, demonstrated no difference in anastomotic leak rates between side-to-side and end-to-end anastomotic configurations. In terms of surgical recurrence, Guo [85] reported no differences between the two anastomoses, while Feng [86] reported superiority of the side-to-side anastomosis. The results from these reviews should be interpreted with caution given the retrospective nature of most studies included in each analysis.

In 2009, the first randomized study comparing anastomotic type, the CAST trial [87], was published. Patients were randomized to either side-to-side anastomosis or end-to-end anastomosis. A total of 139 patients were included, and after a mean follow-up of 11.9 months, the endoscopic recurrence rate was 37.9% in the side-to-side anastomosis group and 42.5% in the end-to-end anastomosis group ($p = 0.55$). The symptomatic recurrence rate was also similar between the two groups (22.7% and 21.9%, $p = 0.92$). In 2013, another prospective, randomized trial from Germany was planned with a primary endpoint to investigate whether stapled side-to-side anastomosis resulted in lower recurrence rates compared to hand-sewn end-to-end anastomosis. The secondary endpoint was early postoperative complications. The study was terminated early due to insufficient patient recruitment; while they did not have an adequate number of patients to draw conclusion for the primary endpoint, there was no difference in terms of postoperative complications, length of surgery, and length of hospital stay between the two techniques [88].

In 2011, Kono [89] developed a new hand-sewn antimesenteric functional end-to-end anastomosis with the intent of reducing surgical recurrence in CD. The rationale behind this anastomotic configuration is centered on preservation of the mesenteric vascularization and innervation and a posterior supporting column created by suturing the two staple lines together in order to maintain the three-dimensional structure. In the original paper, the authors performed Kono-S anastomosis in 69 CD patients and compared this group with a historical cohort of 73 CD patients. They found significantly lower endoscopic recurrence rates in the Kono group than in the conventional one, with a lower probability of anastomotic surgical recurrence in the Kono group at 5 years (0% vs 15%; $P < 0.0013$) [89].

In brief, a small window in the mesentery is created at the level of the proximal and distal resection margins. The mesentery is divided using a tissue -device close to the intestinal wall to preserve vascularization and innervation [89]. At this point, the bowel is divided transversely, placing the stapler perpendicular to the intestinal lumen and the mesentery, so that the mesentery is located in the middle of the staple lines. The corners of the two stapled lines are imbricated and reinforced with 4/0 silk Lembert sutures, and the two stumps are approximated by tying together the corresponding corner sutures. The two stapled lines are now sewn together with interrupted 4/0 silk sutures spaced apart, thus creating the so-called supporting column. At this point, an antimesenteric longitudinal enterotomy (or colotomy) is performed on each stump to allow a transverse lumen of 7 cm on the small bowel or closer to 8 cm on the colon, starting no more than 1 cm away from the staple line. The anastomosis is now completed by closing the longitudinal opening transversely in two layers (Fig. 48.5).

This anastomotic configuration has been evaluated in two large multicenter studies [90, 91] and more recently in a prospective randomized trial [92]. Kono reported only 2 surgical anastomotic recurrences in the Kono group with a follow-up of 65 months and a 5 and 10 years' surgical recurrence-free survival rate of 98.6% [90]. Shimada reported a surgical recurrence rate of 3.4% in the Kono-S group versus 24.4% in the end-to-end group, as well as an increased risk of anastomotic leak in the end-to-end group (17.3% vs 5.1%). Kono-S anastomosis had a significantly lower risk of anastomotic surgical recurrence at 1 year (OR 0.14). The 5-year surgery-free survival rate on the anastomosis site (95.0%) was significantly higher with the Kono-S than with the end-to-end anastomosis (95% vs 81.3%; $P < 0.001$) [91]. The first published randomized controlled trial (RCT) [92] confirmed the

early reports showing lower rates of endoscopic recurrence, reduced severity of endoscopic scores, and lower rate of clinical recurrence in favor of the Kono-S anastomosis.

The mesentery has been thought by some to be involved with the initiation and recurrence of the disease as early ulcers develop typically on the mesenteric side of the bowel with the corresponding "creeping fat." A recent report from Ireland [93] compared wide excision of the mesentery with the conventional closer division in 64 patients. They reported surgical recurrence rates of 40% and 2.9% in favor of the wide excision group ($p = 0.003$). This study has several limitations. The conventional group was a historical control with longer follow-up, postoperative medical prophylaxis of recurrence was not standardized, and there is no data on anastomotic technique. In summary, there is no definitive evidence supporting superior safety of one anastomotic technique over the other. In regard to the risk of recurrence, the role of radical mesenteric excision and the promising results reported with the Kono-S anastomosis will require further study.

Disease Recurrence Trends and Surveillance

After an ileocolic resection with an anastomosis, recurrent Crohn's disease at the anastomotic site is noted in 70–90% of patients within 1 year on endoscopy [94], and 20–30% of these patients will require additional operations within 5 years [95]. Many factors have been cited as potential culprits in the recurrence of the disease at the anastomotic site, including fecal stasis, alteration in the microbiome, and local ischemia, just to mention a few [96, 97].

Over the years, a number of strategies to prevent postoperative recurrence have been proposed. On the medical side, postoperative biologic therapy has been shown to be effective [98, 99]. Regueiro [100] in a small prospective randomized trial comparing early administration of infliximab (5 mg/kg), for 1 year versus placebo, showed that the rate of endoscopic recurrence at 1 year was significantly lower in the infliximab group (1 of 11 patients, 9.1%) compared with the placebo group (11 of 13 patients, 84.6%) ($P = 0.0006$). In a larger multicenter follow-up study, the PREVENT trial [101], the primary endpoint of lower clinical recurrence was not met, but patients on infliximab had lower endoscopic scores and recurrence. The questions of optimal patient selection and timing of administration for prophylaxis remain unanswered.

Attempts at risk stratification based on clinical disease-specific factors and early colonoscopy findings have been proposed to guide postoperative medical management. De Cruz [102] randomized 174 high-risk patients to early colonoscopy vs standard clinical observation and noted that treatment based on clinical risk of recurrence, including early colonoscopy and treatment step-up for recurrence, is better than conventional drug therapy alone for prevention of postoperative recurrence. Selective therapy, adjusted for risk of early recurrence rather than routine use, leads to disease control in most patients. The authors also noted that although clinical risk factors predicted recurrence, patients at low risk also should undergo monitoring and early remission did not preclude the need for ongoing surveillance.

Operative Considerations for Specific Locations

Gastroduodenal Disease

Clinically significant Crohn's disease of the foregut is rare, affecting 0.5–4% of patients [103]. Advances in digestive endoscopy have improved detection of this entity; 30–50% of patients with Crohn's disease have macroscopic UGI disease, and 40–70% have histologically visible UGI disease [104–106]. At least 2/3 of these patients are asymptomatic, and over 90% have coexisting Crohn's in the more distal GI tract [107, 108]. Patients may note insidious gastritis-like symptoms [109]. Early satiety, postprandial pain or emesis, and weight loss can indicate stricture, by far the most common pathology of gastroduodenal Crohn's disease. Fecal calprotectin is not a reliable indicator of gastroduodenal disease [105].

Aphthous erosions, longitudinal ulcers, and bamboo joint-like appearances in the cardia are characteristic of gastric Crohn's, while longitudinal and notch-like erosions of Kerckring folds characterize duodenal disease [106] (Fig. 48.6). Dynamic radiologic studies may reveal a rigid antrum or reduced duodenal peristalsis, while CT or MR enterography may demonstrate disease activity and stricturing (Fig. 48.7). Therapy for symptomatic gastroduodenal Crohn's mirrors that of more distal disease, with the addition of acid suppression [110].

Surgery for gastroduodenal Crohn's is uncommon and comprises <1% of surgery for Crohn's at tertiary centers [111]. Indications for surgery include obstruction and fistula. Almost all instances of gastroduodenal fistula result from penetration of the gastric or duodenal wall originating from another site, such as the terminal ileum or transverse colon. Fistula takedown requires thorough exposure, including Kocherization of the duodenum. The defect can be repaired primarily in one or two layers with low morbidity. A jejunal serosal patch is used for larger defects [112].

Strictures are the most common indication for intervention in gastroduodenal Crohn's disease. Successful endoscopic hydrostatic balloon dilation is feasible for short-segment strictures with a low rate of perforation. Patients are often able to avoid surgery, but multiple dilations are required, and

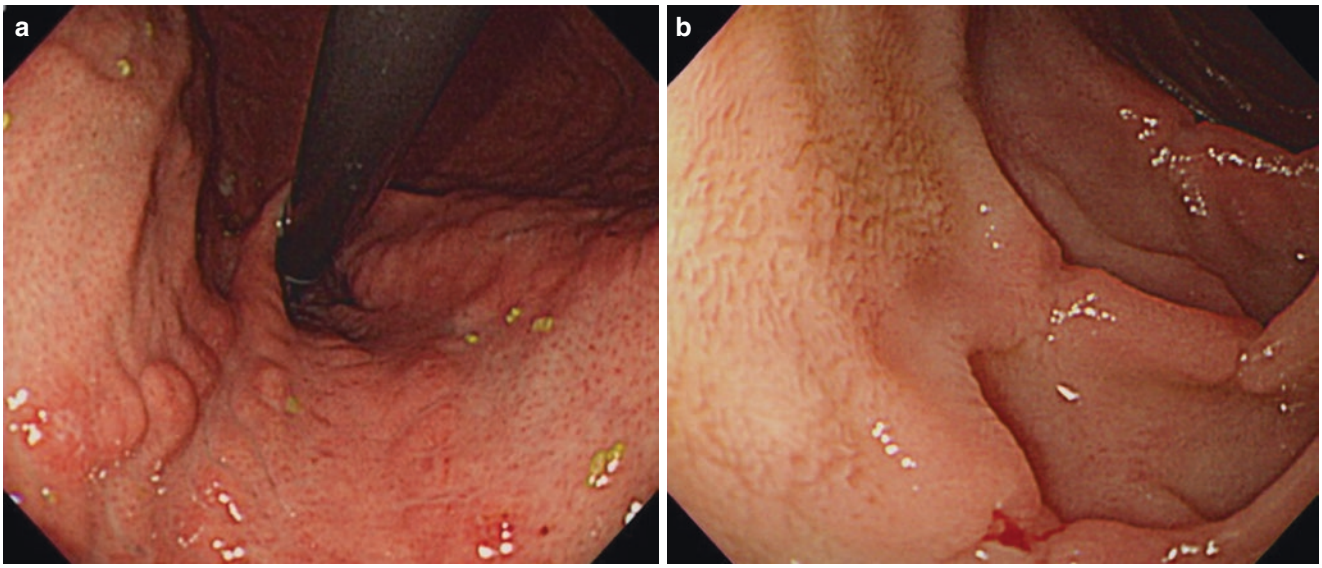

Fig. 48.6 Gastroduodenal disease. (**a**) Bamboo joint-like appearance in the gastric cardia. (**b**) Duodenal notching of Kerckring folds. (Courtesy of A. Sakuraba, MD)

recurrence is the rule. Surgical intervention for duodenal stricture includes strictureplasty and bypass. Both procedures are effective with low morbidity. Pancreaticoduodenectomy should be reserved only for instances of severe ampullary dysfunction and/or cholangitis.

Duodenal strictureplasty is a good option for short-segment strictures or if proximal jejunal inflammation prohibits consideration for gastrojejunostomy. After Kocherizing the duodenum, the stricture is assessed by visual inspection and palpation. A Heineke-Mikulicz or Finney strictureplasty is then performed in two layers. These techniques are described in the next section. A 20-mm Foley balloon may be floated in to trawl for more distal strictures. In instances of dense scarring around the stricture, stricturing in the first or fourth portion of the duodenum, or more than two strictures, bypass is preferred [111, 113].

Bypass procedures include gastroduodenostomy, gastrojejunostomy, and duodenojejunostomy predicated on the site of stricture. These procedures are safe with low morbidity. One-quarter to one-third of patients require reoperation for marginal ulceration or disease recurrence [114, 115]. Vagotomy does not decrease the rate of marginal ulceration in this population and need not be performed.

Upper Small Bowel Disease

The jejunum and ileum, not including the terminal ileum, are affected by Crohn's disease in 3–10% of patients [116, 117]. The two most common indications for surgical treatment of patients with disease in these locations are obstruction and sepsis; massive hemorrhage and carcinoma are much less common. The approach to small bowel Crohn's disease has shifted from extensive resections, with the intent to achieve negative microscopic surgical margin, to the resection of only the macroscopically diseased bowel segment [36], and/or to perform bowel-sparing strictureplasty to preserve intestinal length [6, 118, 119]. In the last decade, attention has been directed to the type of anastomosis as an important variable from the standpoint of endoscopic and surgical recurrence [120].

In very general terms, resection of grossly involved bowel segments remains the most common approach when dealing with an inflammatory or penetrating phenotype. On the other hand, strictureplasty is often preferred for quiescent stricturing disease and in patients at risk of developing short bowel syndrome. Patients with jejunoileitis typically have disease recurrence and a need for a second operation in as many as 30% of patients; short bowel syndrome has been reported in 8.5% of cases 20 years after the index surgery [121].

A significant proportion of small bowel strictures are not identified on preoperative workup, and the entire small bowel should be examined at exploration. When dealing with multifocal small bowel disease, assessment of bowel lumen can be done by running a calibration sphere through the bowel or, more simply, by inserting a cuffed catheter. Fibrostenotic strictures with a luminal diameter less than 20 mm are clear indications for strictureplasty or resection, although these cutoffs may vary depending on patient size and normal bowel diameter. Less critical strictures, especially in patients with previous resections and extensive disease, may not mandate operative treatment in an era of effective medical therapy. Strictures may be marked with metal clips for future reference; measurements of remaining intestinal length and location of the strictures in the operative report are important for long-term management.

In an attempt to preserve bowel length and function, Lee and Papaioannou in 1982 and, subsequently, Alexander Williams and Haynes in 1985 described the use of strictureplasty techniques, which had been previously described in India to correct tuberculous stricture of the terminal ileum and cecum [95, 122]. Currently, the most commonly performed strictureplasty techniques are the Heineke-Mikulicz, Finney, Jaboulay, and the side-to-side isoperistaltic strictureplasties. Strictureplasty procedures were adopted from the experience of treating peptic ulcer disease of the duodenum and were initially thought to be risky procedures for Crohn's patients.

However, after Lee [123] published their report proving the safety of strictureplasties, the Heineke-Mikulicz has become the most commonly performed strictureplasty performed in Crohn's patients. It is particularly suited for short-segment (<10 cm) chronic intestinal strictures [124]. A single longitudinal incision is made over the antimesenteric side of the affected small bowel, extending 2 cm beyond both proximal and distal thickened portions, and is closed transversely to create a wide lumen (Fig. 48.8). Finney strictureplasty is used for strictures that are longer than 10 cm but shorter than 25 cm (Fig. 48.9) [124]. Strictures longer than 25 cm if treated with this technique would result in a functional large blind loop leading to bacterial overgrowth and blind loop syndrome [124]. The segment of diseased is folded on itself, and a long, longitudinal enterotomy is made over the antimesenteric border. The anterior and posterior walls of the long enterotomy are sutured separately to create a wide lumen. The Jaboulay strictureplasty is also used for medium-sized (>10 and <25 cm) strictures. With this technique, bowel length is spared; however, there is the creation of a lateral diverticulum with resulting blind loop and potential for stasis in the strictured segment [124]. This short-segment "bypass" was also described in Lee's 1982 report [123], in which a shorter length of small bowel was involved. Both Jaboulay and Finney have the potential for stasis and bacterial overgrowth potentially resulting in a need for revision [125].

Michelassi proposed an isoperistaltic side-to-side strictureplasty for significantly long-segment strictures (>20 cm) or a long portion of bowel containing multiple short strictures in tandem, making the creation of multiple Heineke-Mikulicz strictureplasties unsafe [126]. The procedure involves dividing the bowel and its mesentery in the midpoint of the strictured bowel segment. The two loops are then approximated by a layer of interrupted seromuscular Lembert stitches, using nonabsorbable sutures. A longitudinal enterotomy is performed on both loops, with the intestinal ends tapered to avoid blind stumps. The outer suture line is reinforced with an internal row of running full-thickness 3–0 absorbable sutures, continued anteriorly as a running Connell suture; this layer is reinforced by an outer layer of interrupted seromuscular Lembert stitches using nonabsorbable 3–0 sutures (Fig. 48.10) [127]. This technique avoids sacrificing long segments of bowel and has achieved excellent long-term results [118, 119, 128]. With follow-up extending to 7.5 years in 20 patients, it has provided radiographic, endoscopic, and histopathologic evidence of regression of previously active Crohn's disease with restoration of intestinal function (Fig. 48.11) [129].

Several studies have confirmed the safety and efficacy of both short and longer strictureplasties [125, 128, 130–133]. Early postoperative complications, like bleeding and sepsis, have been reported in between 8% and 15% of cases [125]. Mucosal biopsies and marking the site with a metal clip should be considered, especially in long-standing disease, as cases of cancer at the strictureplasty site have been reported [125, 134, 135]. Reese [131] compared recurrence rates between patients undergoing strictureplasty or resection and found that surgical recurrence was more likely after strictureplasty ($p = 0.09$), and there was a significantly longer recurrence-free interval after resection ($p = 0.01$). Overall recurrence rates have been reported to be between 18% and 29% [130, 136, 137], but with only 4.6% of them at the previous strictureplasty site in one study [136].

Colonic and Rectal Disease

The operations used to treat Crohn's disease of the colon and rectum include total proctocolectomy, total abdominal colectomy with ileostomy or ileorectal anastomosis, and segmental resection. Patients who present with toxic colitis typically require total abdominal colectomy with end ileostomy irrespective of rectal involvement. If the rectum has significant inflammation, there are several options to mitigate against rectal stump leak. If the stump is left intraperitoneally, a rectal tube may be added for decompression. The rectal staple line can also be buried extraperitoneally in the left lower quadrant or fixed above the fascia in the lower midline; as such, the staple line leak will manifest as an abdominal wall, rather than pelvic abscess. The rectal stump may also be matured as a mucus fistula. A systematic review of rectal stump management, albeit in ulcerative colitis, reports that subcutaneous placement is associated with the lowest morbidity [138]. The decision to ultimately perform an ileorectal anastomosis or completion proctectomy can be determined at a later date.

The best operation to perform for a patient with medically refractory Crohn's colitis is less clear. Patients who present with rectal involvement in addition to their colitis are not good candidates for limited resection as there is no good distal target to establish an anastomosis; total proctocolectomy with end ileostomy is typically the indicated procedure. If the patient has poor nutritional status or is on high-dose steroids, a near-total proctocolectomy with an ultralow Hartmann pouch and end ileostomy may be performed to avoid the high risk of perineal wound sepsis. In this instance, the rectum is divided at the anorectal junction; a completion perineal proctectomy can be performed at a later date via perineal approach. Alternatively, a total abdominal colectomy with end ileostomy can be performed and the completion proctectomy accomplished at a later date.

For patients with short-segment Crohn's colitis and rectal-sparing, segmental resection is an option. Numerous retrospective studies have evaluated the outcomes of segmental resection for short-segment Crohn's colitis as compared to total colectomy or total proctocolectomy, reporting on recurrence rates, need for further surgery, and permanent stoma formation. The perioperative complication rate is similar, with no approach emerging with clear benefit. The range of recurrence rate, reoperation rates, and permanent stoma formation are shown in Table 48.3.

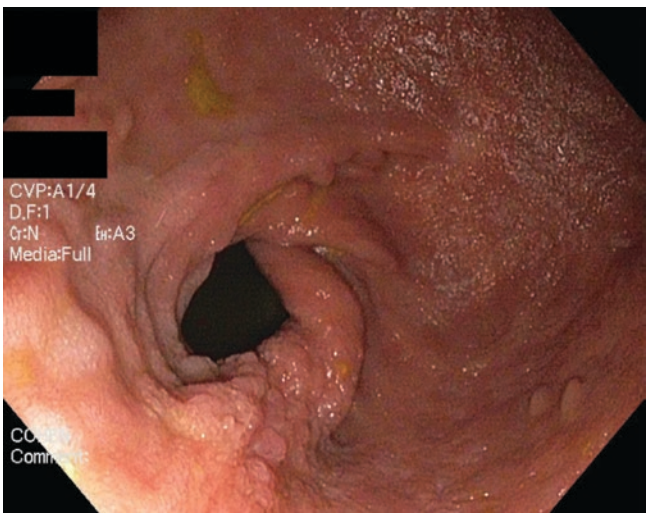

Fig. 48.11 Endoscopic evidence of regression of previously active Crohn's disease after Michelassi strictureplasty. (Courtesy of F. Michelassi, MD)

Patients undergoing segmental resection or total abdominal colectomy with anastomosis experience relatively high rates of colon or rectal recurrence. Up to half of patients will ultimately require a permanent stoma in the long term.

The correct operation for Crohn's colitis remains intrinsically dependent on the distribution of disease. The initial surgical approach should usually be to resect colonic segments that are grossly involved with disease. Patients with two contiguous intestinal segments with disease involvement should undergo resection of these segments in continuity, not two separate segmental resections.

Smoking appears to be associated with the need for further intestinal surgery and need for eventual proctectomy [38]. Patients with isolated distal disease are significantly more likely to require a permanent stoma than patients with isolated proximal disease. Perianal disease, young age, and female sex are independent risk factors for disease recurrence and eventual permanent stoma, and these may inform the consent process [139, 140].

Though it is true that some patients require completion proctectomy after a more limited colonic resection, for many, this can be deferred for several years [38]. The only operation that minimizes risk of disease recurrence is total proctocolectomy with end ileostomy. However, even after total proctocolectomy with end ileostomy, there is an up to 39% rate of recurrence in the small bowel, with up to 32% of patients requiring surgical intervention at 10 years [38, 139, 141–143].

It is important to again note that these recommendations are for Crohn's colitis with rectal-sparing, and not applicable to patients with dysplasia.

Ileal Pouch-Anal Anastomosis in Crohn's Disease

Because of the difficulty in distinguishing Crohn's disease from ulcerative colitis in various settings, some patients with

Table 48.3 Rates of disease recurrence, need for further intestinal surgery, and permanent stoma formation in patients with Crohn's colitis undergoing segmental resection, total abdominal colectomy, and total proctocolectomy

	Colon or rectal disease recurrence	Small bowel disease recurrence	Further intestinal surgery	Permanent stoma
Segmental resection [38, 156–160]	26–55%	4–14%	11–66%	5–44%
Total abdominal colectomy [38, 161–163]	24–66%	8–21%	30%	25–50%
Total proctocolectomy [38, 139, 141, 143]	n/a	Up to 39%	9–32%	Up to 100%

Crohn's disease inevitably undergo a restorative ileal pouch-anal anastomosis (IPAA). Older retrospective studies analyzing patients who were thought to have ulcerative colitis but were subsequently proven to have Crohn's disease demonstrated high complication and pouch failure rates; up to 56% required pouch excision, and a further proportion underwent indefinite diversion [144–146]. Patients with preoperative features suggestive of Crohn's, such as subtle perianal disease or discontinuous inflammation, do very poorly with no meaningful symptom-free intervals after ileal pouch formation. The authors of these studies did observe that a proportion of patients with Crohn's disease who underwent IPAA did well and enjoyed similar functional results as those patients with ulcerative colitis undergoing IPAA.

Two more recent studies suggest lower rates of pouch loss or indefinite diversion. A large prospective series of pouch patients from the Cleveland Clinic published in 2013 reported a 13.3% rate of pouch failure in Crohn's patients, versus only 5.1% in those with ulcerative colitis [147]. Li evaluated intentional IPAA and ileorectal anastomosis for Crohn's, noting that these two patient populations have distinctly different disease characteristics. They reported a 15.5% rate of indefinite diversion in the IPAA group [148]. Taking the above data into consideration, highly selected patients with Crohn's colitis with no perianal disease and no small bowel disease may consider restorative IPAA, provided the risk tolerance and shared decision-making priorities of both the patient and surgeon are aligned.

Special Considerations

Ileosigmoid Fistula

Ileosigmoid fistula is a common complication of perforating Crohn's disease of the terminal ileum. Typically, the inflamed terminal ileum adheres to the sigmoid colon that is otherwise normal and free of primary involvement with Crohn's disease. Most ileosigmoid fistulas are small, may be asymptomatic, and do not in and of themselves require operative management. On the other hand, large ileosigmoid fistulas can result in bypass of the intestinal contents from the terminal ileum to the distal colon and thus give rise to debilitating diarrhea. Such symptomatic fistulas often fail to respond to medical therapy and should be managed surgically.

More than half of the ileosigmoid fistulas from Crohn's disease are not recognized prior to surgery despite imaging and endoscopic evaluation [149]. For this reason, the surgeon should be prepared to deal with this complication in any case of Crohn's disease that involves the terminal ileum. Ileosigmoid fistulas can be managed by simple division of the fistulous adhesion and standard resection of the ileal disease [150]. The defect in the sigmoid colon is then debrided, and simple closure is undertaken; 75% of ileosigmoid fistulas can be thusly managed [149, 151]. The remainder requires resection of the sigmoid colon. Sigmoid colon resection is necessary when primary closure of the fistula is at risk for poor healing. This is the case either when the sigmoid is also involved with Crohn's disease, when the fistulous opening is particularly large, or when there is extensive fibrosis extending along the sigmoid colon. Also, fistulous tracts that enter the sigmoid colon in proximity to the mesentery may be difficult to close and often require resection and primary anastomosis.

Complex Perineal Wounds

Perianal Crohn's disease is common and occurs in one-third of the patients who suffer from intestinal Crohn's disease; this is covered in the chapter on perianal Crohn's disease. Complicated and active rectal disease significantly increases the need for proctectomy [152]; aggressive medical management with antibiotics and biologics [153] is a mainstay along with drainage of local sepsis when required in the attempt to avoid proctectomy.

Conclusion

Management of Crohn's disease is complex and requires a multidisciplinary team approach. Surgical intervention is reserved for refractory disease or complications of the disease. While significant progress has been made over the past 30 years and new medications are changing the course of treatment, much more work remains to be done including understanding how these medications will shift surgical treatment and whether specific surgical techniques lower the risk of recurrent disease.

Ulcerative Colitis: Surgical Management

49

Karen N. Zaghiyan and Phillip R. Fleshner

Key Concepts

- Multidisciplinary management and early surgical referral are crucial in the management of ulcerative colitis patients with moderate to severe colitis. While dysplasia screening and management is changing, surgical referral remains a cornerstone in the management of multifocal and high-grade dysplasia.
- Ileal pouch-anal anastomosis is the standard surgery for medically refractory disease, cancer, or dysplasia. One, two, or three-stage surgery may be chosen and tailored to various patient factors including preoperative nutritional status, corticosteroid use, and intraoperative factors.
- Alternative approaches such as total proctocolectomy with end ileostomy, continent ileostomy, and ileorectal anastomosis are options that may be considered in select patients.
- Long-term functional outcomes of patients undergoing surgery for ulcerative colitis including bowel, sexual, and urinary function, as well as fertility preservation, are important considerations and should be discussed preoperatively and monitored closely in the postoperative setting.

Introduction

Ulcerative colitis (UC) is a diffuse inflammatory disease of the mucosal lining of the colon extending from the rectum proximally and manifests clinically as diarrhea, abdominal pain, fever, weight loss, and rectal bleeding. While medical therapy is generally first-line, surgery is often required in patients with medically refractory disease, toxic colitis, dysplasia, or malignancy. This chapter summarizes the surgical options, decision-making, and techniques surrounding these operations.

Indications for Surgery

Approximately 30% of patients with UC will undergo surgery in their lifetime. In a majority of patients, surgery is recommended and scheduled electively, while 10% require emergent surgery due to various indications. The type of surgery is dependent on the indication for surgery and patient factors.

Elective Surgery

Elective indications for surgery include medically refractory colitis, complications, or side effects associated with medications, extraintestinal manifestations, growth retardation in children, as well as dysplasia or cancer.

Medically refractory colitis and its associated complications make up approximately 70% of the overall surgical cohort [1]. Since the United States Food and Drug Administration approval of infliximab for moderate to severe UC in 2005, several additional biologics have become available options for patients with medically refractory colitis. Medical decision-making has become more complex, and patients are frequently exposed to multiple biologics before proceeding to surgery. During this time, exposure to corticosteroids may increase surgical risk, and nutritional status may decline. An important role of the physician is to guide the patient during their medical journey while preventing them from experiencing complications that may occur as a result of prolonged intractable disease and steroid exposure. Timelines and goal setting can help patients feel in control of their health decisions when facing potential surgery. Shared decision-making may be facilitated through early surgical evaluation prior to exhaustion of all medical options. A survey of UC patients having surgery suggested that over 50% of patients felt that they should have undergone surgery at an earlier time-point [1]. Thus, it is the responsibility of physicians to provide patients with realistic expectations relating

S. R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, https://doi.org/10.1007/978-3-030-66049-9_49

to their disease treatment and status to allow patients to make appropriate and timely decisions when surgery is inevitable.

Colorectal cancer (CRC), high-grade dysplasia or multifocal low-grade dysplasia are additional indications for colectomy. The overall rate of colorectal cancer in patients with UC is 3.7%. However, this risk begins to increase with the duration of disease from 2% at 10 years after the onset of UC, to 8% at 20 years after disease onset and 18% at 30 years after disease onset [2]. Patients with a young age at diagnosis, pancolitis, moderate to severe UC, family history of CRC, and presence of primary sclerosing cholangitis are also at higher risk of CRC [3]. For patients with a UC diagnosis greater than 8 years, colonoscopy surveillance every 1–2 years has been recommended using chromoendoscopy or high-definition colonoscopy with random quadrant biopsies every 10 cm [4]. During colonoscopy, targeted biopsies of any raised lesions are also performed. In the past, any high-grade dysplasia in the setting of UC was an indication for colectomy. In addition, patients with multifocal low-grade dysplasia were also referred for colectomy. However, the recently published SCENIC guidelines have changed the management of endoscopically detected dysplasia in UC. The guidelines make an important distinction between visible and invisible (random) dysplasia as well as polypoid and non-polypoid lesions. The current consensus statement, albeit based on very low-quality evidence, recommends that endoscopically resected polypoid dysplastic lesions may undergo surveillance colonoscopy rather than colectomy. The SCENIC guidelines also recommend endoscopic surveillance of non-polypoid (flat) dysplasia; however, this recommendation remains conditional and controversial with other guidelines suggesting referral to surgery [4]. The SCENIC guidelines have also challenged the routine use of random quadrant biopsies in UC cancer surveillance [5].

The management of invisible dysplasia has also been challenged. Data with low-definition endoscopes showed that 22% (18 of 81) of patients with invisible low-grade dysplasia [5, 6] and 32–42% of patients with invisible high-grade dysplasia [7] who underwent a colectomy had colorectal cancer in the pathology specimen. These rates supported the recommendation for colectomy in patients with high-grade and even low-grade dysplasia. However, the SCENIC guidelines suggest that these high rates of CRC may be irrelevant in the current high-definition endoscope era. This rationale is supported by the much lower rate of invisible dysplasia (10%) among all biopsies showing dysplasia in the current era vs 87% of biopsies with dysplasia performed prior to high-definition endoscopy or chromoendoscopy [8]. This suggests that older studies reporting a high rate of CRC with invisible dysplasia may be a result of previously unrecognizable lesions prior to the routine availability of modern endoscopic techniques. Thus, the current SCENIC recommendation for invisible dysplasia, confirmed by a gastrointestinal pathologist, is referral to an inflammatory bowel disease (IBD) center with experience in chromoendoscopy and high-definition colonoscopy. If an endoscopically resectable visible lesion is identified and in the area of the previous invisible dysplasia, then the patient may be entered into an intensive screening program. If no visible lesion is identified, patients with high-grade dysplasia are referred for colectomy, whereas patients with low-grade dysplasia are frequently offered surveillance with a greater likelihood for surgical referral in the setting of multifocal low-grade dysplasia.

Elective surgical options include total proctocolectomy with an end or continent ileostomy; ileal pouch-anal anastomosis (IPAA) performed in one, two, or three stages; or total abdominal colectomy with an ileorectal anastomosis. The choice of elective procedure is individualized based on clinical and patient factors and is discussed later in this chapter.

Emergent Surgery

Emergent indications for surgery include acute severe ulcerative colitis (ASUC) not responding to medical therapy, sepsis, toxic megacolon, perforation, or severe bleeding. Perforation and severe bleeding occur less commonly but are emergent indications for surgery. ASUC may range in severity and its response to medical therapy. ASUC can quickly progress to sepsis or toxic megacolon requiring emergency surgery.

Toxic megacolon is a life-threatening condition, combining ASUC with radiologic dilation of the colon, either total or segmental. Whereas patients with a dilated colon without signs of toxicity can be offered an initial trial of conservative management with bowel rest and serial abdominal exams, signs of sepsis including fever, tachycardia, or progressive abdominal pain are indications for urgent colectomy.

Approximately 25% of patients with UC will develop ASUC requiring hospital admission [9]. ASUC is diagnosed according to the modified Truelove and Witts criteria, combining bloody stool frequency ≥6 per day with at least one systemic toxicity such as a heart rate >90 bpm, temperature >37.8 °C, hemoglobin level of <10.5 g/dL, or an erythrocyte sedimentation rate >30 mm/hr [10]. In these patients, initial treatment includes intravenous corticosteroids, along with supportive measures such as intravenous fluids and electrolyte replacement, thromboprophylaxis, and nutritional support. Concomitant infectious etiology, most importantly from *Clostridioides difficile* or cytomegalovirus (CMV), must be ruled out. Approximately 30–40% have a partial or no response to this initial treatment approach. In the prebiologic era, patients with steroid-refractory ASUC underwent urgent colectomy [11]. While the current standard of care for patients with steroid refractory ASUC includes inpatient inf-

liximab (IFX) or cyclosporin (Cys), colectomy rates remain high, ranging from 13% to 25% in-hospital and approach 50% at 1 year [12–14]. In a recent study of 270 patients hospitalized with ASUC between 2002 and 2017, a multivariable logistic regression model identified that previous treatment with thiopurines or anti-TNFs (hazard ratio [HR], 3.86; 95% CI, 1.82–8.18), *Clostridioides difficile* infection (HR, 3.73; 95% CI, 1.11–12.55), serum level of C-reactive protein above 30 mg/L (HR, 3.06; 95% CI, 1.11–8.43), and serum level of albumin below 3.0 g/dL (HR, 2.67; 95% CI, 1.20–5.92) were associated with increased risk of colectomy. A risk prediction score was developed, with each item assigned a score of 1. The cumulative risks of colectomy within 1 year in patients with scores of 0, 1, 2, 3, or 4 were 0%, 9%, 11%, 51%, and 100%, respectively [15]. Despite these statistics, the threshold for surgery remains high, with surgery being considered only when all medical options have been exhausted. Unfortunately, this approach results in an increased risk of surgical morbidity (over 50%) and in-hospital mortality (8%) [16]. We therefore advocate for early surgical evaluation in hospitalized patients with ASUC, with surgery being considered an alternative to medical management rather than a final resort after failure of medical therapy.

In the emergent setting, the preferred surgical approach is a total abdominal colectomy with end ileostomy. The rectum, even if diseased, can generally be left as a Hartmann's stump. When there are concerns about the integrity of the rectal staple or suture line, the rectum can be delivered to the skin as a mucous fistula or as a subcutaneous rectal stump, whereby the closed rectal stump is placed subcutaneously beneath the surgical wound to minimize intraabdominal complications of a stump blowout [17, 18]. The primary consideration when performing an urgent colectomy is to avoid a pelvic dissection as this may hinder future restoration of intestinal continuity and increase the risk of autonomic nerve injury and bleeding complications both in current and future operations. Removal of the diseased colon is generally sufficient to allow the patient to come off of immunosuppressive medications and regain nutritional status and overall health. Completion proctectomy with or without IPAA can be later performed in the elective setting.

Surgical Options and Postoperative Outcomes

Preoperative Planning

Once the decision for surgery is made, several steps should be taken in the preoperative period to optimize surgical outcomes. Preoperative consultation with an enterostomal therapist should be arranged to allow for ostomy site marking and preoperative counseling [19]. Preoperative small bowel evaluation, if one has not been performed in the recent past, is important to exclude small bowel inflammation and confirm the diagnosis of ulcerative colitis. A steroid taper should be considered as tolerated to minimize perioperative steroid dose. In preparing for surgery, the surgeon should also take the lead on perioperative corticosteroid dosing. With the exception of patients with documented adrenal insufficiency, a perioperative corticosteroid stress dose is not recommended and may in fact increase infectious complications. Rather, patients with prolonged steroid exposure should be maintained on their preoperative steroid dose in the perioperative period with a steroid taper on hospital discharge [20]. Preoperative nutritional optimization, and when available, referral to a dietician is important, especially in patients with preoperative weight loss or hypoalbuminemia. Prehabilitation consisting of preoperative oral nutritional supplementation alone or combined with an exercise program has been suggested to improve postoperative recovery and reduce postoperative hospital stay in patients undergoing colorectal surgery, although data specific to surgery for inflammatory bowel disease is limited [21, 22]. An oral antibiotic combined with mechanical bowel preparation should be ordered to minimize postoperative infectious complications [23].

Ileal Pouch-Anal Anastomosis

In 1978 Parks and Nichols described the ileal pouch-anal anastomosis (IPAA) [24], which has since become the standard operation in patients desiring restoration of intestinal continuity and may be performed in one, two, or three stages. In this operation, a near complete proctocolectomy is performed, and an ileal pouch is either stapled or hand-sewn to the anal canal. While the original operation described by Sir Alan Parks included a complete stripping of the rectal mucosa and creation of a triple-loop S-pouch, a majority of centers now preserve the anal transition zone and perform a stapled anastomosis between the ileal J-pouch and anal canal. When patients are considered appropriate candidates for upfront restorative proctocolectomy with IPAA, single stage (restorative proctocolectomy, ileal pouch-anal anastomosis without diverting ileostomy) or two-stage IPAA (restorative proctocolectomy, ileal pouch-anal anastomosis with diverting ileostomy) may be considered. While some centers have advocated for a single-stage approach, a staged IPAA is a far more common and prudent approach. Creation of a diverting ileostomy at the time of IPAA prevents catastrophic septic complications in the event of an anastomotic leak. The ileostomy can later be reversed in 2–3 months. Alternatively, total abdominal colectomy with end ileostomy may be performed first, allowing the patient to recover and

regain nutritional health and later return for completion proctectomy and IPAA.

Prior to embarking on this operation, the integrity of the anal sphincter mechanism must be assessed. Patients should be motivated and willing to cope with potential postoperative complications as the surgical approach may result in impaired function, especially in patients with preexisting fecal incontinence. Ileal pouch-anal anastomosis may be performed using laparoscopic or open technique. In the elective setting, a laparoscopic approach is preferred and offers short-term benefits such as reduced minor complications and shorter hospital stay [25]. Over the long-term, a laparoscopic IPAA may reduce postoperative adhesions and offer female patients improved fertility [26]. In this chapter, a laparoscopic IPAA is described; however the nuances and key technical steps are similar irrespective of open, straight laparoscopic, hand-assisted laparoscopic or robotic approach. The surgeon is advised to use the approach that is safest in their hands, based not only on the patient's clinical condition but also surgeon experience and skill level.

Operative Technique

The patient is brought to the operating room and placed in the modified lithotomy position [27]. An orogastric tube is inserted to decompress the stomach. Trocars are placed in three positions: 11 mm umbilical port for the camera, 5 mm suprapubic port, and a 12 mm port at the future ileostomy site (Fig. 49.1). This allows adequate visualization while at the same time maximizing cosmesis in these often young patients. After creation of pneumoperitoneum, the small bowel is evaluated for Crohn's disease and the abdomen explored for any evidence of bowel perforation (purulent drainage or abscess). Abdominal colectomy is performed in a standard fashion, with close to bowel mesenteric dissection, preservation of the ileocolic artery, and avoiding injury to the duodenum, stomach, small bowel loops, spleen, and pancreas. A 10 mm laparoscopic vessel sealer is used for the majority of the dissection. Colectomy is performed from right to left. The lateral attachments are taken down, and the hepatic flexure is mobilized (Fig. 49.2a). The ileocolic pedicle is identified and preserved. The mesenteric window distal to the ileocolic artery is incised, and the transverse mesocolon and gastrocolic ligament are divided (Fig. 49.2b). The lesser sac is entered (Fig. 49.2c), small bowel loops are swept to the right, and the ligament of Treiz is identified and protected. Care is taken to avoid injury to the stomach, pancreas, and spleen as the splenic flexure is taken down (Fig. 49.2d). The remaining mesentery is divided close to the colon, and the dissection is carried down to the pelvic brim. At this point, decision must be made to proceed with or abort proctectomy and IPAA. Assessment of small bowel mesenteric length for pouch reach at this point is critical. If the mesentery is foreshortened or thick due to fat infiltration, the upper rectum should be cleared of its mesentery with superior rectal artery preservation, stapled closed with an endo-GIA stapler (Fig. 49.2e) and the ileal pouch aborted. It is our approach to extract the specimen through the future ileostomy site. The 12-mm trocar is removed, and the fascial opening is enlarged in a cruciate fashion and rectus muscle split to accommodate two fingers. A wound protector is inserted, and the rectosigmoid colon is delivered through this incision. The ileum is left attached and transected flush with the cecum extracorporeally with a GIA stapler to prevent staple line blowout during extraction. The remaining mesentery is divided with the vessel sealer, close to the bowel in order to preserve the ileocolic pedicle and future perfusion to the ileal pouch. In the event that the colon or mesentery is too thick to safely deliver the intact specimen through the ileostomy site, a small Pfannenstiel incision can be made for extraction. The end ileostomy is then matured and a transanal drain placed to decompress the rectal staple line. In severely malnourished patients when there is concern over the integrity of the rectal staple line, an alternative approach to the abdominal stump is to create a subcutaneous stump or mucous fistula.

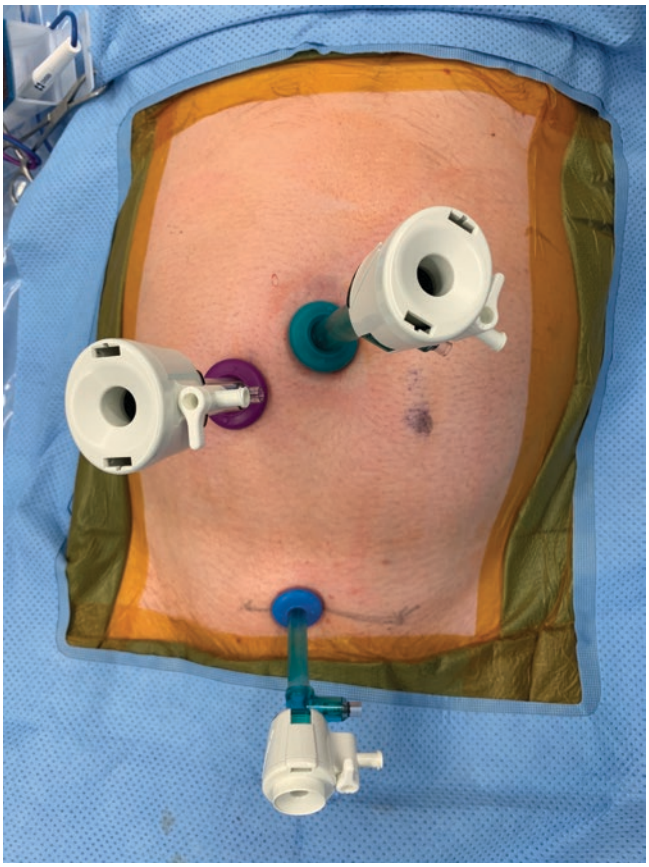

Fig. 49.1 Trocars placement for laparoscopic colectomy. A 12 mm trocar at the future ileostomy site may be used for insertion of Endo-GIA stapler. This site can be later enlarged to create the ileostomy aperture and for specimen extraction

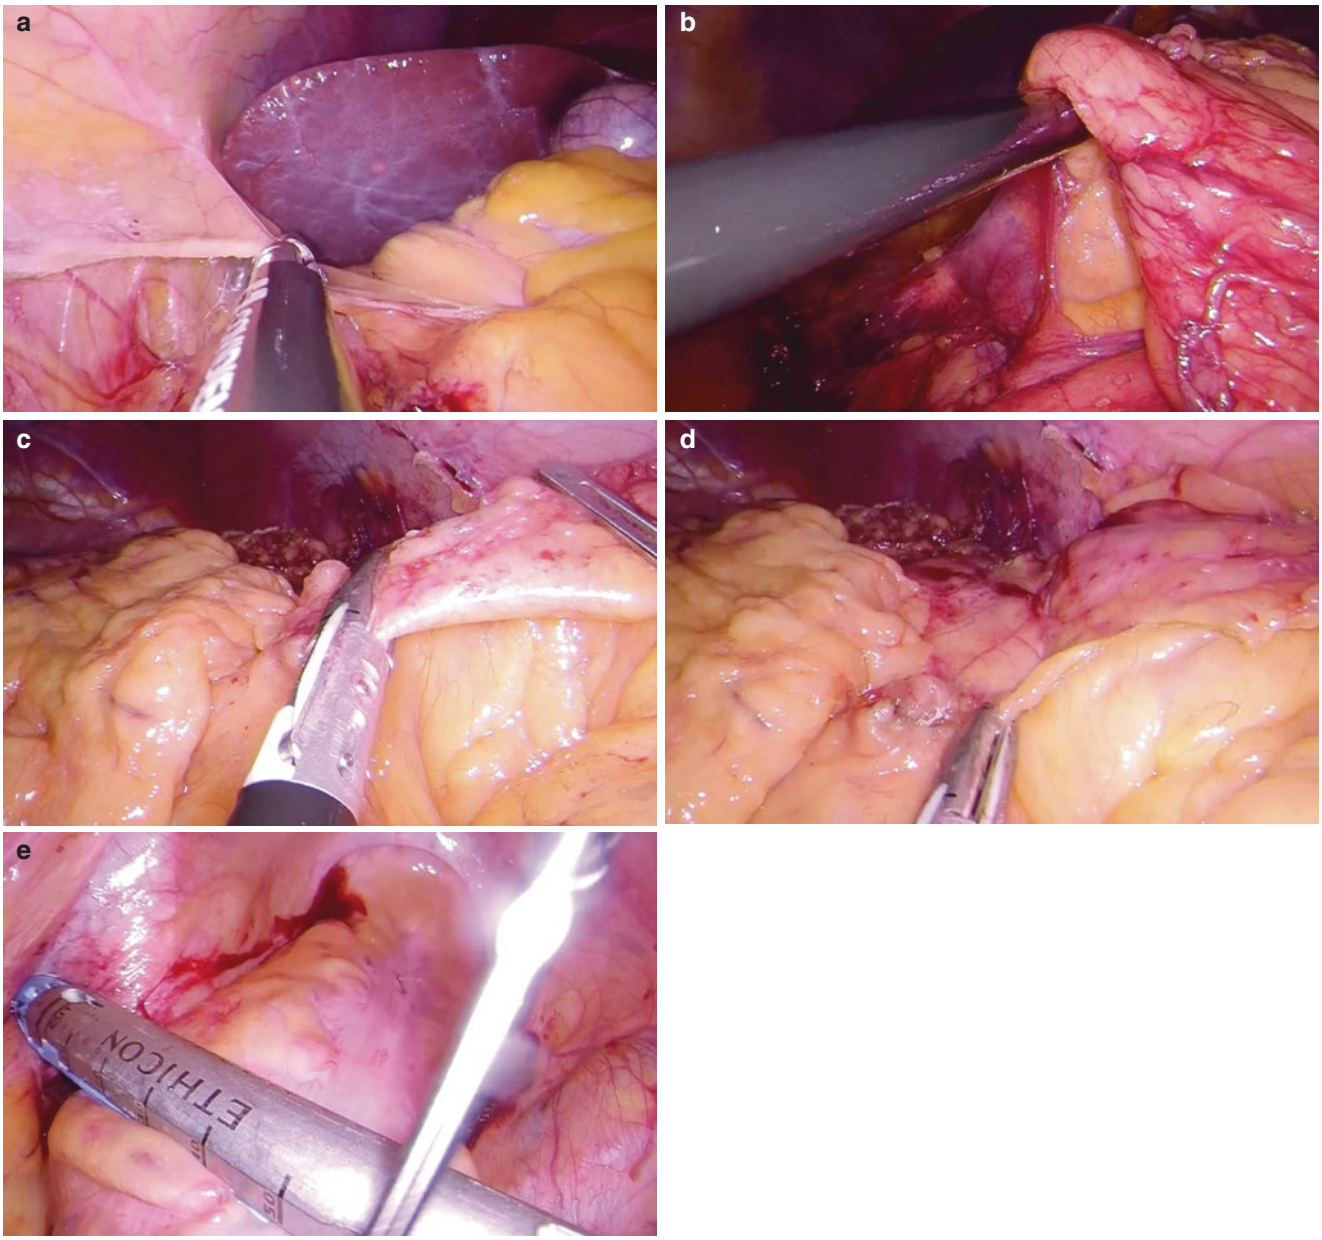

Fig. 49.2 Technical steps of laparoscopic abdominal colectomy. (**a**) The right colon is mobilized in a lateral to medial fashion toward the hepatic flexure, (**b**) the mesenteric window distal to the ileocolic artery is opened, and the mesenteric dissection is taken toward the transverse mesocolon, (**c**) the greater omentum and transverse mesocolon may be divided together or separated to gain entry into the lesser sac, (**d**) the splenic flexure is taken down working form right to left, and (**e**) the rectum is divided intracorporeally using one or two firings of a 60 mm endo-GIA stapler

If there is adequate pouch reach and the patient's clinical condition is conducive to IPAA, then the rectal dissection is carried to the pelvic floor. This dissection may be continued laparoscopically, or, alternatively, a Pfannenstiel incision can facilitate open proctectomy, while still maintaining cosmesis and minimizing incision size and associated complications. The superior rectal artery is divided with the vessel sealer, and entry is gained into the presacral space. It is our practice to perform the posterior dissection in the relatively bloodless total mesorectal excision plane. However, an alternative option, popularized by increased availability and comfort with the use of vessel sealers, is the intramesorectal or close rectal dissection to further reduce the risks of autonomic nerve injury [28]. Anterior dissection is carried close to the rectum preserving the rectoprostatic fascia in men and rectovaginal septum in women, and the lateral stalks are divided close to the rectum, again to minimize injury to autonomic nerves in the setting of benign disease. Anteriorly, the dissec-

tion is carried to the level of the prostate in men and the mid-portion of the vagina in women. Posteriorly, the dissection is carried past the end of the coccyx. When a double stapled anastomosis is planned, the rectum may be stapled closed and transected at the level of the puborectalis muscle using an articulating endo-GIA stapler or right-angle linear stapler leaving a 1–2 cm cuff of rectal mucosa.

Next the ileal reservoir is created (Fig. 49.3). The terminal ileum is aligned in a J configuration, and the pouch constructed with either a continuous absorbable suture or stapling device. Both limbs of the J should measure approximately 15–25 cm in length, the exact length guided by where the pouch reaches deepest into the pelvis. The prospective apex of the pouch must reach beyond the symphysis

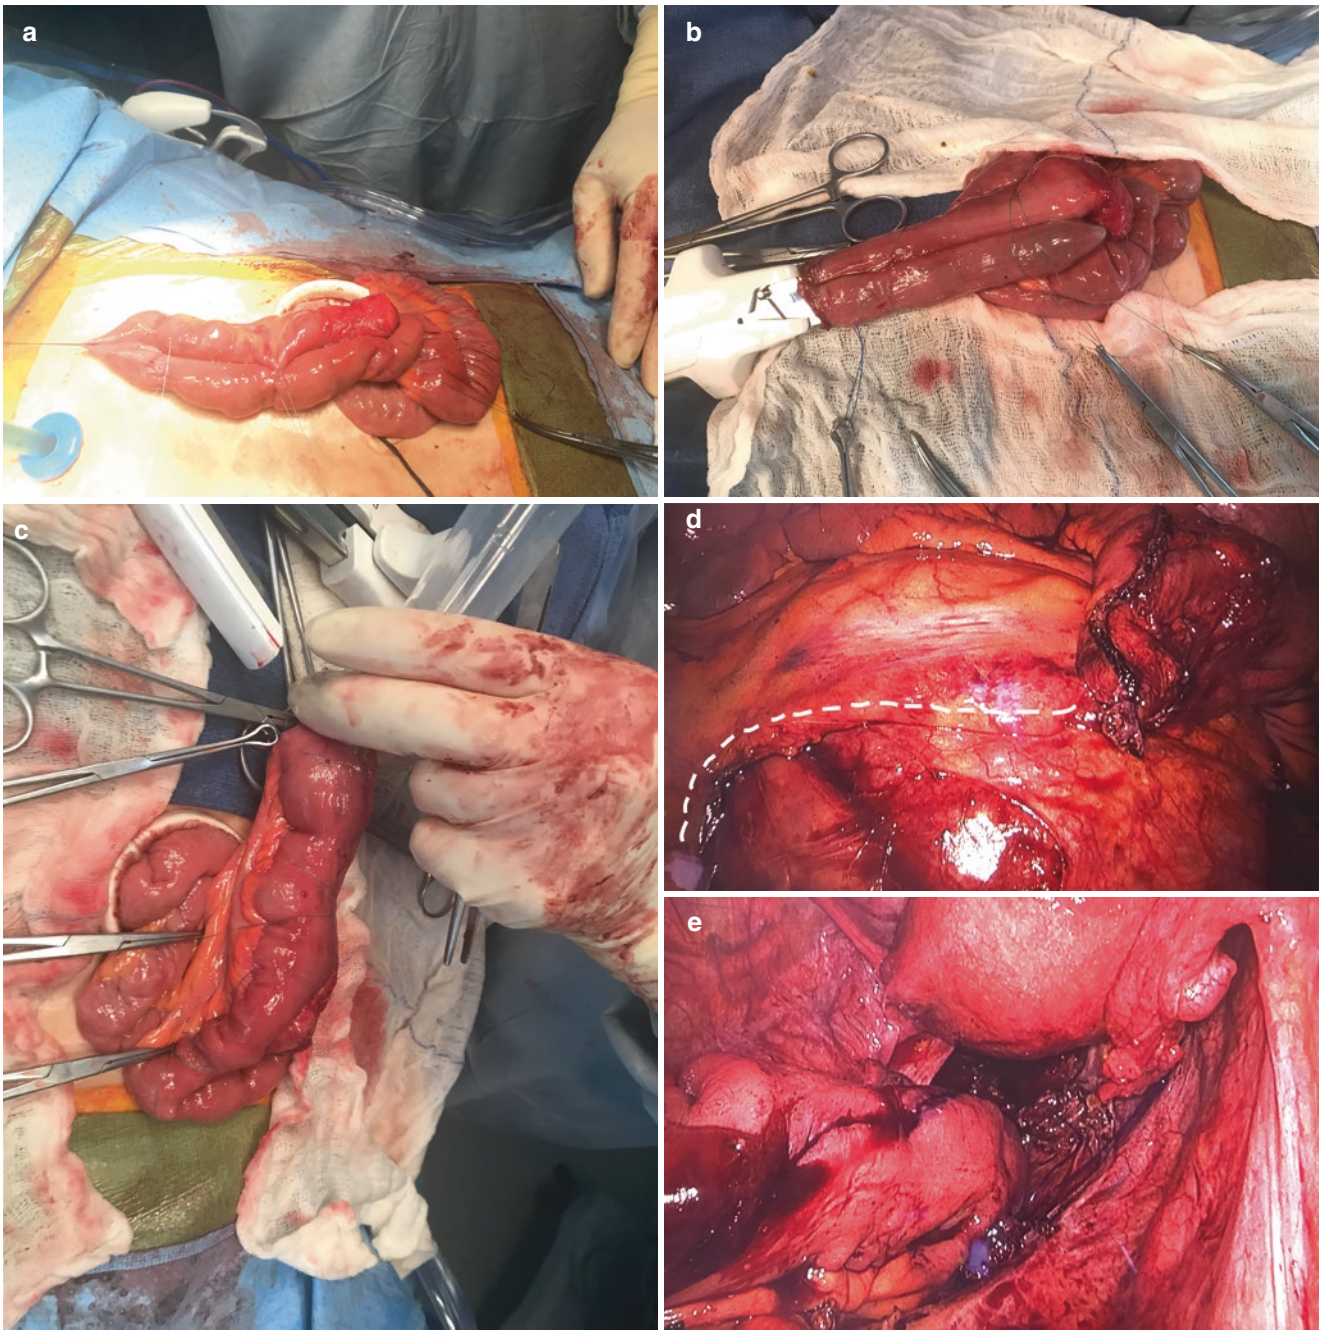

Fig. 49.3 Technical steps of ileal J pouch creation. (**a**) Pouch reach is assessed, and the apex of the pouch is chosen at the point of maximal reach beyond the pubic symphysis. An apical suture and additional aligning sutures are placed, (**b**) enterotomy is created at the apex of the pouch and linear cutting staplers are used to create the reservoir, (**c**) the pouch is air tested to assure absence of leaks, (**d**) the pouch is delivered back into the peritoneal cavity and oriented so that the mesentery is straight along the retroperitoneum (dotted line) to the duodenal sweep and proximal bowel loops are not tethered caudal to the pouch mesentery, and (**e**) the pouch is delivered to the pelvis for anastomosis

pubis in order to accomplish a tension-free ileoanal anastomosis. Selective division of mesenteric vessels to the apex of a proposed J-pouch will allow for more length. Superficial incision on the anterior and posterior aspects of the small bowel mesentery along the course of the superior mesenteric artery and mobilization of the small bowel mesentery up to and anterior to the duodenum are two additional important lengthening maneuvers.

In the case of a double-stapled anastomosis, after transection of the rectum at the level of the puborectalis muscle (Fig. 49.4a), the anvil of the midsized circular stapler device is inserted into the apex of the ileal pouch and secured in place using a running purse-string suture. Before proceeding with the anastomosis, integrity of the rectal staple line is tested using air insufflation. The stapler is placed transanally (Fig. 49.4b) and the trocar advanced through the transverse staple line and connected to the anvil (Fig. 49.4c) assisted by the abdominal operator, who ensures that no adjacent tissues are trapped within the stapling device as it is closed and fired (Fig. 49.4d). The integrity of the staple line may be checked digitally and confirmed using transanal air insufflation.

Alternatively, distal mucosal stripping may be performed with a hand-sewn ileal pouch anal anastomosis [29]. The use of a Lone Star™ retractor facilitates exposure and minimizes damage to the sphincter mechanism (Fig. 49.5a). A solution of dilute epinephrine (Fig. 49.5b) is injected into the submucosal plane to facilitate mucosectomy and minimize bleeding (Fig. 49.5c). The excised mucosa and remaining proximal rectum are removed, leaving a short cuff of denuded rectal muscle distally above the dentate line. The pouch is then pulled into the pelvis and the anastomosis carried out between the apex of the pouch and the dentate line, approximating full thickness of the pouch wall to the internal sphincter and anal mucosa (Fig. 49.5d). A proximal defunctioning loop ileostomy is created. One or two suction drains are placed in the presacral space and brought out through the lower abdominal quadrant. In the case of open proctectomy, placement of an anti-adhesion barrier around the stoma and underneath the incision should be considered to reduce the incidence and severity of postoperative abdominal adhesions [30]. Postoperative management is similar to that in patients who have had a low anterior resection. Ileostomy output can be quite high, since the stoma is more proximal than a traditional terminal ileostomy. Patients should be encouraged to keep themselves well hydrated. In some instances, antidiarrheal medication is prescribed. Enhanced recovery pathways including early diet advancement [31, 32], ambulation [33], and early urinary catheter removal [34] are safe in this patient population and have been shown to improve postoperative outcomes and hospital stay. Patients are discharged when tol-

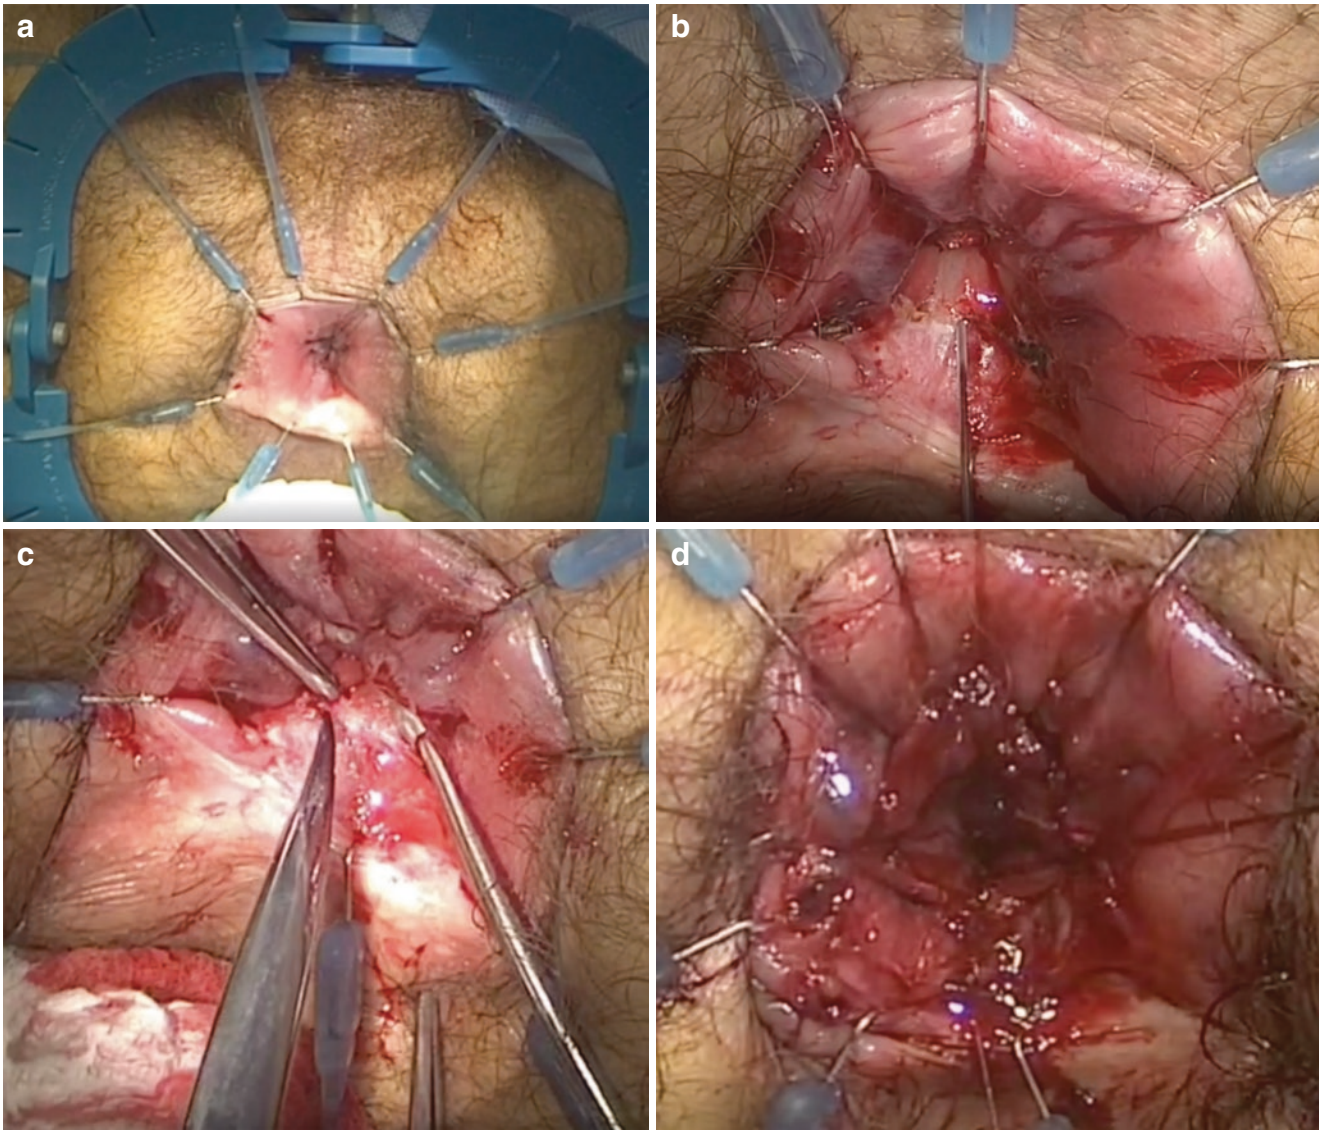

Fig. 49.5 Technical steps of mucosectomy with hand sewn ileal pouch-anal anastomosis. (**a**) Lone Star™ retractor facilitates anal retraction, (**b**) solution of dilute epinephrine is injected submucosally to help develop the dissection plane and minimize bleeding, (**c**) mucosectomy carried upward toward the distal aspect of the abdominal dissection at which point the mucosa is pushed upward and rectum transected, and (**d**) pouch is delivered to the pelvis and hand-sewn to the dentate line

erating a solid diet with adequate ileostomy output and free of signs of infection. Ileostomy may be closed approximately 6–8 weeks later. Before closure however the pouch is thoroughly investigated. Digital rectal examination is used to assess anal sphincter tone and detect anastomotic strictures or defects. The pouch is examined endoscopically to ensure that the suture lines are healed, and a contrast study is performed to detect pouch leaks, fistulas, and sinus tracts. Only after confirmation that pouch abnormalities are not present is the ileostomy closed.

Controversies

One-, Two-, or Three-Stage IPAA

In well-nourished patients undergoing an uncomplicated IPAA and tension-free anastomosis, a single-stage IPAA and omission of a diverting ileostomy have been considered. Proponents of a single-stage IPAA cite the high rate of ileostomy-related complications (43%) including obstruction (23%) and dehydration (25%) in addition to complications related to the ileostomy closure operation (29%) [35].

While level 1 evidence supporting or refuting a single-stage IPAA with omission of an ileostomy is lacking, retrospective reports of selective ileostomy omission suggest similar complication rates and overall long-term function as patients with a diverting ileostomy [36]. In a recent study of 317 diverted and 670 undiverted pouches, pouch leaks occurred in 13.7% ($n = 92$) of patients without diversion and 13.6% ($n = 43$) of patients with diversion. Five diverted patients (12%) developing a pouch leak and 41 (45%) undiverted patients with a pouch leak underwent unplanned trips to the operating room ($p < 0.01$). Ten out of 43 (27%) diverted patients with a pouch leak, and 53 of 92 (60%) of undiverted patients with a pouch leak underwent an unplanned ostomy within 200 weeks of surgery ($p < 0.01$). The rate of pouch salvage operations over total follow-up was similar between the two groups, 74% and 78% of patients with a pouch leak [37]. In another retrospective evaluation of 4031 IPAA patients, of whom 357 developed pelvic sepsis with a diverting ileostomy and 31 without, there was a higher rate of reoperation for diverting ileostomy (48%) in patients without diverting ileostomy at time of IPAA compared with patients with diverting ileostomy (12%); $p < 0.0001$. Five-year and 10-year follow-up however demonstrated no difference in pouch survival between groups, 99% vs 97%, and 88% vs 87%, respectively [38]. These studies are biased, as omission of a diverting ileostomy would only be considered in the most healthy patients having a straightforward operation. Considering the sequelae of a pelvic anastomotic leak and potential long-term effects on pouch function, it is the practice of the authors to perform routine diverting ileostomy in patients undergoing IPAA.

Many patients with UC are not appropriate candidates for upfront IPAA. In these patients, a three-stage IPAA may be offered. This approach involves initial total abdominal colectomy with end ileostomy. After several months of recovery, the patient may undergo completion proctectomy with ileal pouch-anal anastomosis and diverting loop ileostomy followed by ileostomy closure several months later. Patients best suited for a three-stage IPAA include not only hospitalized patients having urgent colectomy but also patients with preoperative malnutrition, high-dose steroids, obesity, cancer, female patients desiring pregnancy, or patients in whom there is diagnostic uncertainty (inflammatory bowel disease-unclassified).

Preoperative corticosteroids more than 20 mg/day and preoperative hypoalbuminemia (serum albumin <3 g/dL) are two factors that carry a significantly higher risk of postoperative pouch-related infectious complications [39, 40] and in the opinion of the authors are indications for initial total abdominal colectomy with staged IPAA. The implications of preoperative biologics have also been debated extensively. While several studies have suggested a higher rate of infectious complications in patients exposed to preoperative biologics, concerns over the retrospective nature of these studies and multiple confounders including concomitant treatment with corticosteroids have resulted in significant debate over this topic [41–44]. However, the recent PUCCINI study, a prospective, multicenter evaluation of 955 patients with inflammatory bowel disease undergoing abdominal surgery found that any infection (19% vs 20%) and surgical site infections (12% vs 13%) were similar in patients treated with or without anti-TNFs in the preoperative period [45]. While the effect of more recently available biologic drugs such as vedolizumab and ustekinumab are yet to be determined, there does not appear to be any robust data suggesting an independent impact on surgical morbidity in patients treated with these agents [46, 47]. Thus, preoperative treatment with biologic drugs does not appear to be an independent factor requiring initial colectomy with staged completion proctectomy and IPAA.

Obesity is an independent predictor of pouch abandonment [48] after IPAA. This is largely related to visceral fat deposition within the ileal mesentery limiting pelvic pouch reach. In addition, obese patients carry a higher risk of overall complications [49] as well as anastomotic leak [50] after IPAA. Patients having elective IPAA should therefore be counseled on preoperative weight loss when possible, and patients having a staged approach should be offered nutritional and weight loss counseling to achieve a BMI <30 kg/m^2 prior to IPAA. Patients with colon cancer in the setting of UC may be better served by a staged approach whereby the proctectomy and IPAA are performed at a later time after systemic chemotherapy in order to avoid a situation where pelvic infectious complications prohibit or delay timely chemotherapy.

Patients desiring pregnancy in the short-term after colectomy may also prefer a staged operation. In these patients, the risk of infertility related to pelvic dissection and IPAA surgery may be minimized by allowing the patient to attempt child bearing after total abdominal colectomy and end ileostomy. The patient may pursue completion proctectomy and restoration of bowel continuity when they have finished child-bearing. Lastly, in patients with inflammatory bowel disease unclassified, a staged approach can allow for pathologic evaluation of the colectomy specimen to guide surgical decision-making. Patients with Crohn's-like features may choose to delay IPAA to allow better diagnostic workup or avoid it all together.

While a three-stage IPAA is the common approach for patients initially undergoing total abdominal colectomy with end ileostomy, a modified two-stage IPAA has recently been described. In this approach, after initial total abdominal colectomy and end ileostomy, the patient returns for the second and final stage several months later (completion proctectomy, ileal pouch-anal anastomosis without diverting ileostomy). Proponents of this approach argue that patients

undergoing total abdominal colectomy and returning for surgery in overall good health and nutrition may be offered IPAA without diversion. In this approach, complications of ileostomy such as dehydration, electrolyte derangements, and the need for a third operation can be omitted. An initial report of this approach compared 23 patients who had a modified two-stage IPAA vs 31 patients who underwent a three-stage IPAA [51]. No patients having a modified two-stage IPAA had pouch-related complications requiring stoma creation. Total hospital cost and hospital stay were also lower in the modified two-stage group. In a more recent cohort comparing 223 patients who had a traditional two-stage IPAA (restorative proctocolectomy with ileal-pouch anal anastomosis and diverting loop ileostomy followed by ileostomy closure several months later) with 237 who had a modified two-stage IPAA, patients having a modified two-stage IPAA had a 4.7% rate of anastomotic leak versus 15.7% of patients having a traditional two-stage IPAA; $p < 0.01$ [52]. While these results appear promising, concerns over patient selection and the overall generalizability of this approach have limited widespread application. Prospective randomized studies may help shed more light on the overall applicability of the modified two-stage IPAA.

Optimal Pouch Design

In their initial description of the IPAA, Parks and Nichols constructed a three-limb "S" pouch with a hand-sewn pouch-anal anastomosis [24]. Several years later, Utsunomiya et al. reported on a two-limb "J" pouch, which, with the advent of the surgical stapler, became the procedure of choice due to its ease of construction [53]. As practice patterns have changed over time, a number of studies have compared both postoperative complications and functional outcomes between the different pouch designs (Fig. 49.6). The majority of these studies are limited to retrospective, single-center series of patients undergoing IPAA for either ulcerative colitis or familial adenomatous polyposis. With regard to short-term outcomes, a meta-analysis performed in 2007 of 23 studies found no difference in rates of anastomotic leak, pelvic sepsis, or pouch failure [54]. Long-term outcomes have been looked at in two large meta-analyses [54, 55] comparing pouch designs. Both studies concluded that J-pouches were subject to increased stool frequency with an average of one more bowel movement over 24 hours. All other functional outcomes however were equivalent between pouch designs.

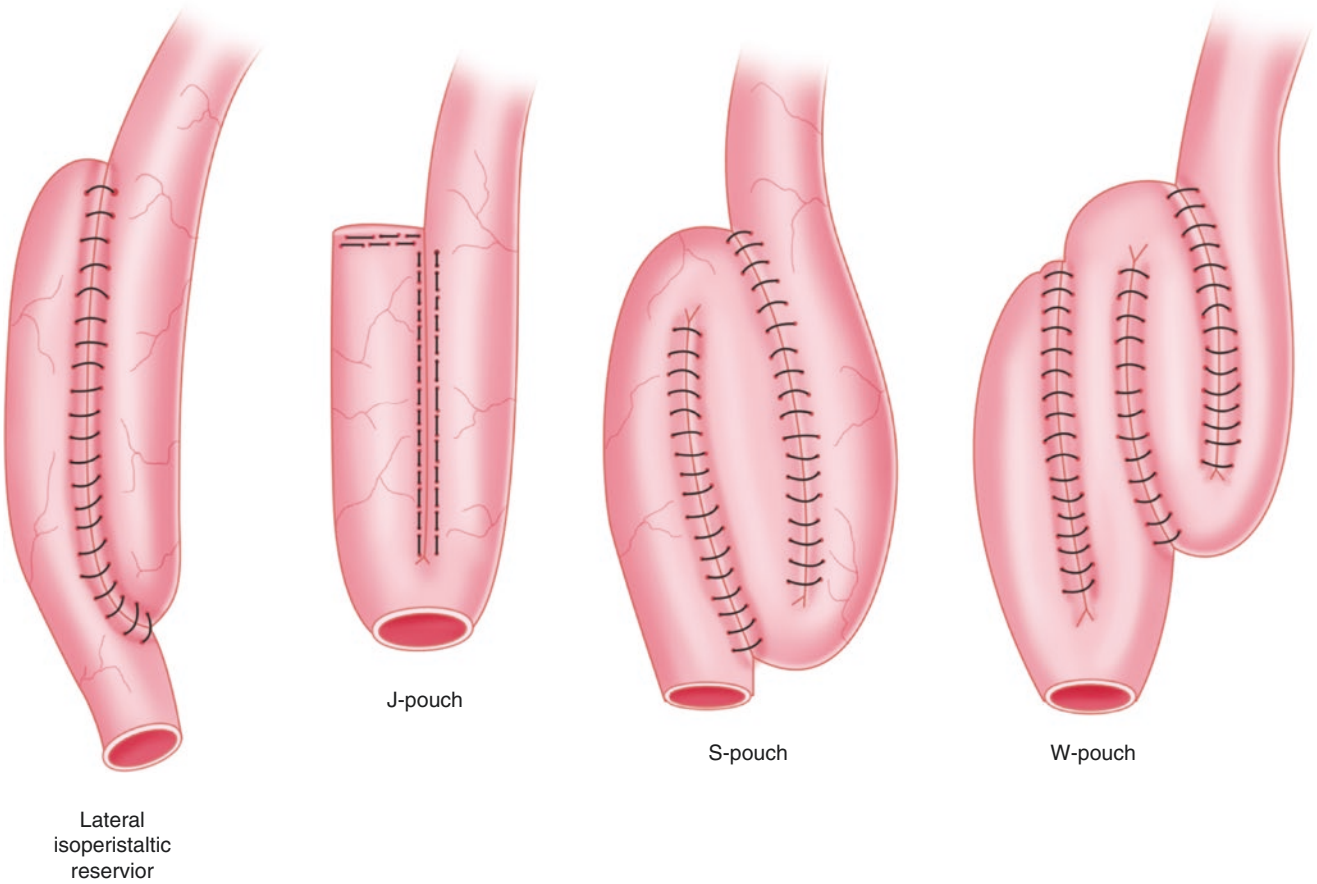

Fig. 49.6 Different ileal pouch configurations

Type of Anastomosis: Hand-Sewn or Stapled

While the original description by Parks and Nicholls in 1978 [24] suggested complete mucosectomy to the dentate line and hand-sewn anastomosis, stapling devices over the last three decades have become the default practice [56]. Several historical randomized trials [57, 58] compared mucosectomy and stapled IPAA in the 1990s, but none demonstrated the superiority of either technique. Small sample size and single institutional methods may account for such findings. Recent evidence has revealed equal long-term functional results comparing both anastomotic techniques [59], while short-term morbidity was consistently lower after stapled IPAA [60]. Regarding the risk of disease relapse or malignancy, the largest published series [61] did not find a higher rate of neoplasia in either the ATZ or pouch after a stapled procedure, while dysplasia or malignancy at the time of IPAA remain independent risk factors [62]. Thus, in patients presenting with colitis and rectal high-grade dysplasia or adenocarcinoma by the time of surgery, mucosectomy and hand-sewn IPAA should be strongly considered. Stapled anastomosis can be considered as the first choice in all other circumstances.

Transanal Pouch

An important yet technically demanding step in laparoscopic ileal pouch surgery is assuring the distal rectal transection is perpendicular to the pelvic floor. Often the angle for transection is oblique, resulting in the need for multiple stapler firings and an increased risk of anastomotic leak [63]. In addition, inadequate transection of the distal rectum may risk leaving a long rectal cuff behind resulting in an increased occurrence of cuffitis and/or pouch evacuation problems. The transanal J-pouch (ta-J-pouch) was developed in an effort to address technical shortfalls of the laparoscopic ileoanal pouch. Another advantage of this approach is the design of the ileoanal anastomosis, changing from a double staple with the potential creation of "dog ears" at the sides to a single stapled which can be easily reinforced transanally. Finally, the transanal platform allows an ergonomic dissection in a horizontal plane of the most distal and curved part of the rectum. Although short-term [64, 65] and long-term functional data [66] appear to support the role of a transanal approach to ileal pouch surgery, more robust data with increased surgical experience is eagerly awaited.

Ileorectal Anastomosis

While IPAA remains the gold standard surgical approach for ulcerative colitis, recent series of ileorectal anastomosis (IRA) for UC have suggested similar long-term functional results and quality of life. Proponents of IRA report advantages including the lower technical demand compared with IPAA, the ability to perform a single stage operation and elimination of a pelvic dissection, and the potential associated complications such as pelvic sepsis, poor function, pouchitis, sexual and urinary dysfunction, and female infertility.

Technical aspects of the operation are similar to the colectomy portion of IPAA. The ileocolic pedicle and superior rectal arteries are preserved. The ileum is transected flush with the cecum and rectum transected where the taenia coli splay. A 29 mm EEA stapler is used to provide a wide lumen and minimize stenosis. After extracorporeal transection of the ileum, the anvil is placed inside and secured with a 2–0 polypropylene purse-string suture. The bowel is re-delivered into the peritoneal cavity, pneumoperitoneum re-achieved, the ileal mesentery laid straight and flush with the retroperitoneum, and EEA anastomosis created and tested under water using flexible sigmoidoscopy. Fluorescence angiography can be used to assure perfusion to the anastomosis. In healthy, well-nourished patients with a tension-free and intact anastomosis, diverting ileostomy is generally not required.

Several studies have shown safety of IRA for UC with overall complications ranging from 24% to 28% and anastomotic leak rate of 3–4% [67–69]. Long-term failure rate is the most important concern and ranges from 18% to 49% [67, 69–71]. In a recent multicenter retrospective study of 343 patients undergoing IRA in France, multivariable analysis identified treatment with both immunosuppressants and anti-TNF before colectomy as independent predictors of IRA failure, whereas colectomy for severe acute colitis was associated with a decreased risk of IRA failure [72].

Another concern with IRA is development of dysplasia or cancer in the retained rectum. In a study published in 1981, overall cancer rate in 89 patients undergoing IRA for UC was 4.8%. This risk ranged from 0% in patients with disease less than 10 years to 13% after 25 years of disease. Patients with cancer or dysplasia in the colon at the time of colectomy had a higher risk of later developing cancer or precancer of the rectum. In patients with mild colonic dysplasia, the risk of rectal cancer or precancer was 22% (2 out of 9 patients), and in surviving patients with colon cancer or precancer, the risk of later developing rectal cancer or precancer was 71% (5 out of 7 patients) [73]. In a meta-analysis of patients with UC undergoing surgery, the risk of subsequent colorectal cancer in patients with a rectal stump, IRA or IPAA, was 2.1%, 2.4%, and 0.5%, respectively. While having an IRA or rectal stump compared with IPAA increased the risk of subsequent colorectal cancer (OR 6.4; 95% CI, 4.3–9.5), a history of colorectal cancer was the most important risk factor for development of CRC after both IRA (OR 12.8; 95% CI, 3.31–49.2) and IPAA (OR 15.0; 95% CI 6.6–34.5) [74].

While a history of colorectal cancer or high-grade dysplasia may portend an unnecessarily high risk of subsequent

dysplasia or rectal cancer after IRA, certain populations such as patients with acute severe colitis requiring urgent colectomy who are relatively naïve to biologics or immunomodulators, those with indeterminate colitis with relative rectal sparing, and patients possibly young female patients desiring to maximize fertility may be candidates for selective IRA. One important factor to consider when choosing to proceed with IRA is the functional capacity of the rectum as chronic UC may impede rectal compliance. Most importantly, the decision for IRA or IPAA should be made under the guidance of a skilled surgeon capable of performing both operations.

Continent Ileostomy

Although continent ileostomy is not primarily advised in patients needing a permanent fecal diversion, it may be a viable option in patients who have failed Brooke ileostomy or those who are candidates for an IPAA but cannot have a pouch because of rectal cancer, perianal fistulas, poor anal sphincter function, or occupations that may preclude frequent visits to the toilet. Suspicion of Crohn's disease contraindicates construction of a continent ileostomy, since the risk of recurrent disease in the pouch is increased which may necessitate resection of the entire pouch encompassing approximately 45 cm of viable small bowel and render the patient unable to maintain nutrition. Obesity and age over 40 years are associated with an increased risk of pouch dysfunction and represent relative contraindications to the continent ileostomy [75]. For patients considering continent ileostomy, an open discussion with the patient is important, stressing that although continence is likely, major complications often occur. These setbacks generally must be corrected surgically, sometimes leading to pouch excision and creation of a standard Brooke ileostomy. Only highly motivated, emotionally stable individuals should consider this procedure.

Operative Technique

After mobilization of the existing ileostomy from the abdominal wall, the reservoir is constructed. The continent ileostomy is created by using the terminal 45–50 cm of the ileum to create an aperistaltic reservoir as initially described by Kock [75] or as an S pouch. The outlet is constructed from the distal 3–5 cm of this segment, the nipple valve is created from the next 18 cm of bowel, and the remaining 30 cm is used for the pouch (Fig. 49.7a). Peritonectomy is performed overlying the mesentery supplying the nipple valve on both sides (Fig. 49.7b). This is performed to increase adhesion formation during intussusception of the nipple valve and prevent slippage. The pouch is oriented in the form of an S, and a posterior row of sutures is placed between each limb and an enterotomy made along the S-shape (Fig. 49.7b). A second posterior row of sutures is created to re-approximate the cut edges (Fig. 49.7c). The nipple valve is then created with three firings of the GIA stapler without the knife (Fig. 49.7d). A two-layer closure of the anterior portion of the pouch is then performed (Fig. 49.7e). A circumferential row of interrupted sutures are placed between the outlet and the pouch to help maintain the position of the nipple valve. The end of the ileum is then brought through the abdominal wall at the preoperatively identified site just above the escutcheon. The stoma is sutured flush with the skin and the pouch firmly anchored to the posterior rectus sheath (Fig. 49.7f). A wide plastic tube with large openings is placed into the pouch to allow gravity drainage of the pouch in the early postoperative period. This tube is occluded for progressively longer periods beginning 10 days after surgery until it can be removed for 8 hours without distress. At this point, the pouch is significantly expanded, the tube is removed, and drainage is achieved by intubating the pouch three times a day.

Postoperative Complications

Postoperative complications that occur with sufficient frequency are nipple valve slippage, pouchitis, intestinal obstruction, and fistula. Nipple valve slippage [76, 77] occurs because of the tendency of the intussuscepted segment to slide and extrude on its mesenteric aspect. Difficult pouch catheterization, chronic outflow tract obstruction, and incontinence ensue. Because of the frequency of this problem, many techniques other than simple surgical stapling have been described to stabilize the valve. Wrapping the valve with prosthetic materials does prevent valve slippage but also is accompanied by a potentially unacceptably high incidence of parastomal abscess and fistula formation [78]. Despite these technical modifications, nipple valve slippage remains the most common complication after continent ileostomy, occurring in almost 30% of patients [76–78]. Although nonoperative approaches have been attempted to correct this problem, surgical correction is virtually inevitable. The repair of the existing malfunctioning valve or creation of a new valve from the afferent ileal limb is performed.

Pouchitis is recognized in 25% of patients, making this the second most common postoperative complication after continent ileostomy [76–78]. Pouchitis refers to nonspecific inflammation that develops in the reservoir and is thought to result from stasis and overgrowth of anaerobic bacteria. Patients present with a combination of increased ileostomy output, fever, weight loss, and stomal bleeding. The diagnosis is made by history and confirmed by pouch endoscopy.

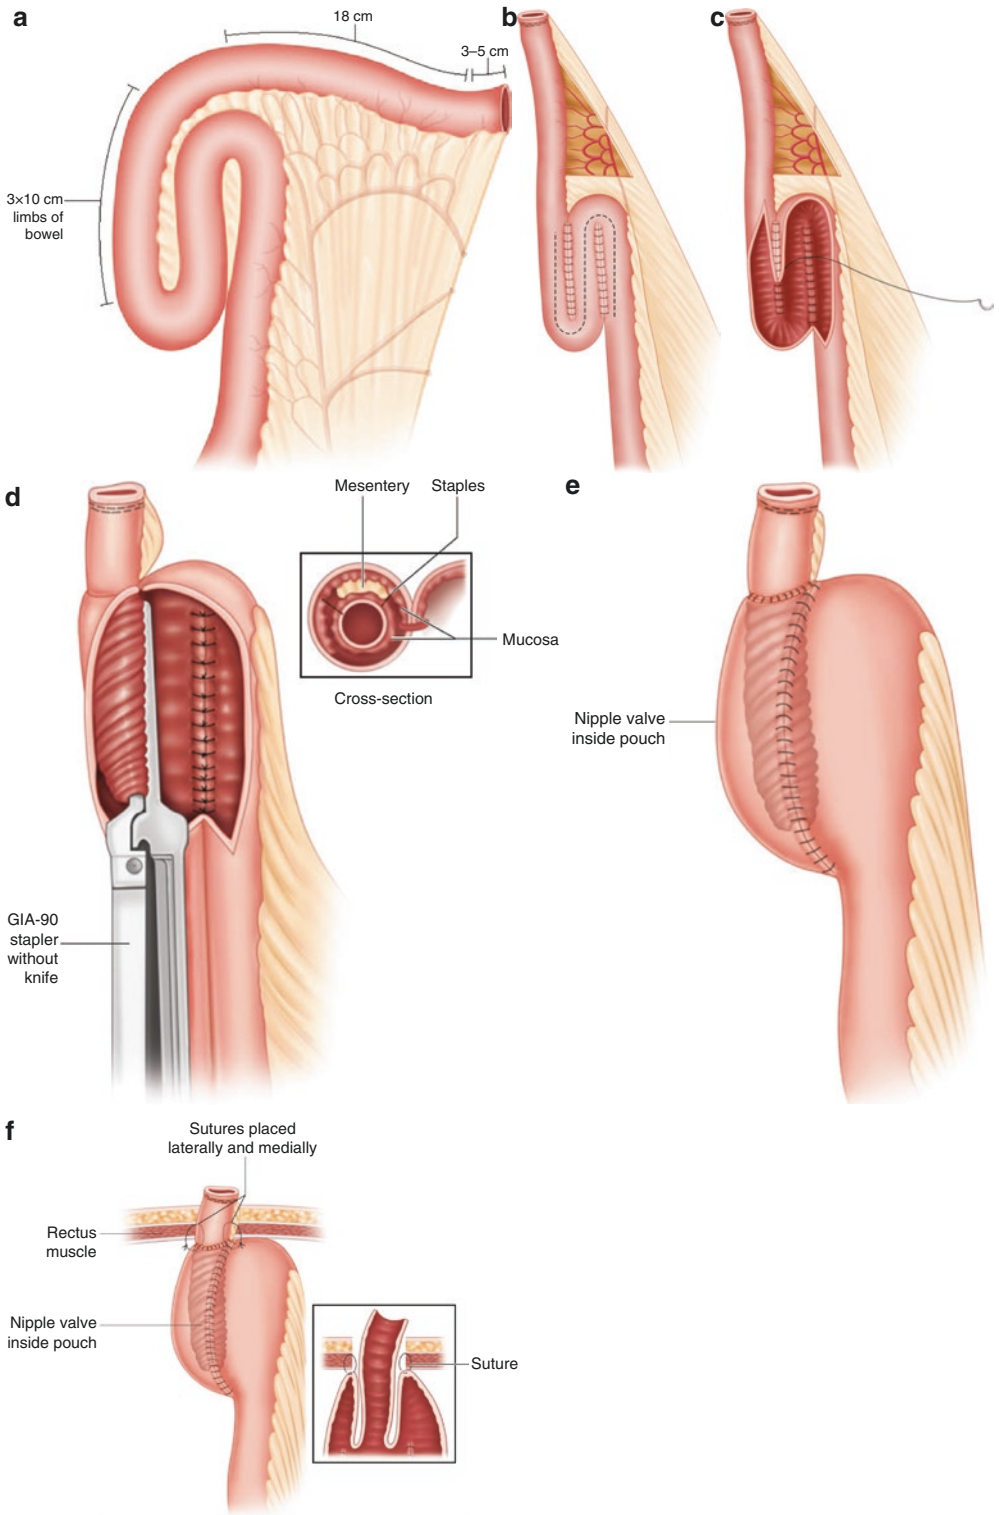

Fig. 49.7 Construction of a Kock Pouch. (**a**) About 45–50 cm of small bowel is used to create the Kock pouch. The distal 3–5 cm is used for the outlet, the middle 18 cm is used to construct the nipple valve, and the proximal 30 cm is utilized in creation of the pouch (**b**) The peritoneum overlying the mesentery to the nipple valve is excised. The S-shaped pouch is constructed by folding the proximal 30 cm of bowel into three 10 cm limbs with sutures placed between the limbs. An enterotomy is made (dotted line) starting at the distal aspect. (**c**) The posterior layer is created, (**d**) the nipple valve is created with three firings of a stapler without the knife, and (**e**) the anterior aspect of the valve is then completed with an inner and outer layer of sutures. To help maintain the nipple valve position, a row of interrupted sutures is placed between the pouch and the outlet. (**f**) After the stoma is delivered through the skin, sutures are placed between the pouch outlet and the posterior sheath of the abdominal wall on the lateral and medial aspects

Pouchitis usually responds to a course of antibiotics and continuous pouch drainage. Other complications include an incidence of intestinal obstruction after continent ileostomy of about 5%. Surgical intervention is mandatory when nonoperative therapy has been unsuccessful. The incidence of fistulas after creation of a continent ileostomy is approximately 10%. Fistulas most commonly originate in the pouch itself or at the base of the nipple valve. Pouch fistulas results from dehiscence of suture lines or rarely ileostomy tube erosion. These tracts may close with bowel rest, parenteral nutrition, and continuous pouch drainage. Fistulas from the base of the valve lead to incontinence, since ileal contents bypass the high-pressure zone of the nipple valve. These fistulas commonly arise with tearing of the sutures anchoring the pouch to the anterior abdominal wall. Valve fistulas rarely heal without operation. At laparotomy, the valve is excised, the pouch rotated, and a new continent valve constructed from the afferent tract.

Patient satisfaction with a continent ileostomy has been reported by some authors as being very high [79, 80]. Most patients note a marked improvement in their lifestyle, and almost all patients work and participate in social and recreational activities without restriction [76, 80]. These observations are understandable in that 90% of patients eventually have total continence after one or more procedures. On the other hand, their enthusiasm is surprising considering that complications are quite frequent and often require major surgical intervention [79, 80]. The often-advertised Barnett modification of the Kock pouch uses the afferent limb of small bowel to construct the nipple valve and wraps a portion of the residual efferent limb around the nipple valve [81]. Although designed to reduce the incidence of valve slippage and fistula formation, there are no controlled data to suggest that this modification is any better than the standard procedure most centers are using.

Complications of the Pelvic Pouch

50

Jean H. Ashburn and David W. Dietz

Key Concepts

- Pelvic sepsis is the most common cause of pouch loss.
- Patients with IPAA dysfunction should undergo a structured assessment.
- Pouch dysfunction is often inappropriately ascribed to a diagnosis of Crohn's disease.
- Fecal diversion may palliate disabling symptoms from pouch dysfunction.
- Pouchitis is the most common complication of IPAA.

Introduction

The ileoanal pouch reservoir (IPAA) made stoma-free living a reality in patients, who desire to maintain bowel continuity, requiring the removal of the colorectum [1, 2]. This operation was specifically created with a vision to achieve a higher quality of life after proctocolectomy, providing the patient with an alternative to a permanent lifelong stoma and restoring the natural route of defecation. Contemporary improvements have enhanced the operation since its popularization in the 1980s, but the goals of surgery remain the same: to cure disease while providing the highest possible quality of life (QOL) for the patient.

Failure of the IPAA is an uncommon but devastating situation for patients undergoing restorative proctocolectomy [3]. Patients with IPAA dysfunction, in whom local corrective measures fail, have traditionally been managed with permanent fecal diversion, with or without excision of the failed pelvic pouch [4]. However, advancements in the understanding of pouch failure have opened the door for surgical revision; selected patients who are decidedly motivated to avoid permanent conventional ileostomy may be considered for surgical pouch salvage with a reasonable expectation of good results [5–8]. Critical to the success of pouch revision is the understanding of why pouches fail, which is an evolving topic, as the treatment of pouch complications varies greatly depending on etiology. The management of pouch-related complications, including pouch salvage surgery, is challenging and is best approached in a multidisciplinary, patient-centered fashion with input from both the patient and experienced IPAA clinicians for best results.

Risk Factors for Pouch Dysfunction

The success of an IPAA procedure and its long-term functional outcomes are very much dependent upon adequate healing and maintenance of integrity of the many staple or suture lines required. Anastomotic disruption, with the resultant development of peri-pouch sepsis, is a dreaded complication of staple or suture line failure and typically has marked detrimental effects on long-term functional outcomes [9, 10]. Pelvic sepsis is reported to occur in up to 25% of IPAA patients and is due primarily to the disruption of the pouch-anal anastomosis or, less frequently, the staple line at the tip of the J-pouch [11]. Thirty percent of these patients will experience pouch failure, making it the most common cause of pouch loss [1, 12].

Much emphasis has been placed on avoidance of anastomotic complications by identification of adverse risk factors. Strategies of avoiding or delaying pouch creation in patients taking higher doses of corticosteroid and/or biologic therapy and performing this restorative procedure using a staged approach have been recommended for this reason [13]. Despite patient optimization and technical perfection, anastomotic leak is a known consequence of IPAA surgery, and strategies for management are necessary. The ramifications

of a leak are great in terms of long-term function; equally concerning and burdensome are the associated financial strains on the patient and healthcare system as these complications often lead to a delay in ileostomy closure and a need for additional radiographic intervention, pouch revision or excision, and prolonged hospital convalescence [14, 15].

Pouch failure due to structural non-septic complications or functional issues is a less studied cause of IPAA dysfunction. One source of these complications may be due to technical missteps performed at the index pouch surgery. Examples include inappropriate rotation or twisting of the small bowel mesentery as it runs into the pelvis (180° or 360° rotation) that causes obstruction or ischemia or an elongated rectal cuff (or S-pouch outlet) causing outlet obstruction and pouch emptying issues. An emphasis on proper technique of IPAA surgery and a vigilance during these challenging cases can prevent these complications from occurring or identify them early so they may be corrected.

Finally, patient selection is crucial to achieving success after pouch surgery. Those patients who have pelvic floor or anal sphincter compromise may not fare well in terms of pouch function and quality of life, and one should be realistic when discussing outcomes when these issues are present. Additionally, a diagnosis of Crohn's disease should generate a thoughtful, individualized assessment of the risk prior to pouch surgery.

Approach to the Patient with a Dysfunctional Pouch

Initial Evaluation

First and foremost, patients referred with a diagnosis of IPAA dysfunction should undergo a comprehensive and standardized evaluation, understanding that the previous diagnosis may be incorrect. Commonly, a patient with non-specific pouch issues is labelled as having chronic pouchitis or Crohn's disease and undergoes a long-term treatment on this basis, without significant improvement in symptoms. Other causes of pouch dysfunction such as chronic pelvic sepsis may be easily missed.

A complete history should be obtained including a full review of the patient's symptoms, treatments that have been attempted prior to the present evaluation, and response to each treatment. Operative reports should be obtained and reviewed, with specifics of surgery and convalescence noted. Any indication of technical difficulty must be thoroughly explored, as a technical complication of the initial pouch surgery may be mistaken for pouchitis. One should pay particular attention to the condition of the patient at the time of pouch creation and the use of covering ileostomy, as large doses of immunosuppression negatively affect pouch healing; anastomotic complications may result in occult sinus tracts or chronic anastomotic leaks with symptoms mimicking pouchitis.

It is not unusual for an empiric diagnosis of "Crohn's disease" or "chronic pouchitis" to be given to patients with symptoms of pouch dysfunction, with limited or no support from endoscopy or other imaging studies. One drawback of this approach is that patients may be given a presumptive diagnosis of Crohn's disease that is never confirmed and medical therapy considered unsuccessful. Therefore, it is important to establish the etiology of compromised pouch function when it begins, even if the symptoms have been longstanding. The correct diagnosis accounting for pouch dysfunction is crucial as treatment options are at times vastly different for each complication [16].

Endoscopic evaluation is performed to look for key identifiers of pouch dysfunction. One must approach pouchoscopy in a standardized fashion, so as to carefully examine the rectal cuff, pouch body, and afferent limb to identify both mucosal changes as well as clues to structural abnormalities such as an elongated rectal cuff, a strictured or twisted afferent limb, or a prolapsing anterior body wall. Pouch endoscopy is very helpful when done in conjunction with an anoperineal exam under anesthesia to identify fistulae, abscesses, or other anal pathology not as easily seen in the endoscopy suite. Contrast enemas and pelvic MRI may reveal or rule out anastomotic complications, fistulae, sinuses, or chronic leaks that may be the source of symptoms.

Next, the surgeon must assess the patient's health status and quality of life during the initial patient encounter, even if the etiology of pouch dysfunction is still unclear. Patients are often referred to the surgeon after years of medical treatments that have left the patient malnourished, decompensated, and mentally exhausted. These individuals may benefit from surgical intervention such as fecal diversion sooner rather than later.

Finally, it is important to have an honest and straightforward discussion with the patient regarding expectations. It must be emphasized that surgical outcomes depend on many factors, especially the etiology of pouch failure. Expectations must be discussed and agreed upon prior to embarking on surgical correction.

Multidisciplinary Approach to Diagnosis

When a patient presents with IPAA dysfunction and the etiology of failure is in question, a multidisciplinary approach is in order. After preoperative evaluation with history, physical, and radiographic testing as outlined above, an evaluation with an anoperineal exam under anesthesia and pouchoscopy

is performed as a team including a colorectal surgeon and gastroenterologist. The anoperineum, pouch-anal anastomosis, pouch body, and afferent limb (complete to the ileostomy closure site) may be examined with members of both specialties in the operating room, enabling both perspectives and respective expertise to be utilized. Any clinical signs of pouchitis or any other IPAA complications are noted (anastomotic sinus or fistula, stricture, pouch prolapse, Crohn's disease, etc.), many of which may cause similar symptoms. Biopsies are obtained for pathologic review. At the completion of the exam, the findings are discussed with the patient and family member, and a patient-centered treatment strategy begins to develop. This multidisciplinary team approach is ideal for the patient as he/she is often presented an immediate plan for treatment, with opportunity for discussion with members of both specialties. The strategy can always be tailored at a later time as pathology results and/or recommendations from a multidisciplinary case conference are made.

The Case for the "Thoughtful" Ileostomy

Fecal diversion is an effective way of alleviating symptoms in patients suffering from a failing IPAA and buying time while investigation continues and decisions are made regarding pouch salvage. Any patient suffering significant health consequences or with poor quality of life is a candidate for ileostomy during any part of the pouch dysfunction evaluation. This approach may provide symptomatic relief as mucosal inflammation is lessened by diversion of the fecal stream and anoperineal excoriation as a result of frequency of bowel motions that may be controlled. The pouch is left in place, allowing for relief of symptoms without committing to a major pelvic operation. This approach can also be useful in patients with little chance of pouch salvage who are not initially accepting of a permanent stoma. A loop ileostomy without "burning the bridge" may convince the patient that fecal diversion will dramatically improve their life as compared to a dysfunctional IPAA and ease the psychological transition to ultimate pouch excision [17].

Loop ileostomy provides many benefits. First, it allows for relief of symptoms related to a dysfunctional pouch in a manner that can be temporary and somewhat easily reversed if the patient is not pleased. In many cases, it may be completed with a laparoscopic approach, even if open IPAA had previously been performed; this will usually shorten convalescence and minimize adhesion formation in case repeat laparotomy for pouch revision or excision is desired. Second, patients are able to experience or have a reminder of what life is like with an ileostomy and may choose to keep the ileostomy on a more permanent basis.

Exploration at the time of ileostomy allows for a thorough exam of the abdomen and small bowel to identify any pathology missed on prior imaging that may be the source of the patient's symptoms. Possible sources are mesenteric twists, afferent limb adhesions, abdominal wall or pelvic mesh adherent to the ileal pouch, or large ovarian cysts thought to be part of the ileal pouch on preoperative imaging. In each of these situations, the pathology can be operatively addressed.

When creating an ileostomy in this setting, it is important to consider the next potential surgical steps in the patient's future. The site of the ileostomy should be made with the most dependent portion of the small bowel and at least 15 cm proximal to the pouch, such that this enterotomy could be used for a new pouch-anal anastomosis in those who may be candidates for pouch revision or recreation in the future.

Etiology and Management of Pouch Complications

Structural Complications of the Pouch

Afferent Limb (AF) Complications

Complications involving the pre-pouch ileum, or the afferent limb (AL) of the pouch, have historically been termed afferent limb syndrome (ALS). ALS is becoming a more recognized and diverse group of findings after pouch surgery in which patients present with symptoms of bowel obstruction, abdominal pain and cramping, and dyschezia but have an otherwise normal pouch body and outlet on endoscopy or distal contrast study. The causes of ALS were initially thought to include only a displacement of the pre-pouch ileum posterior to the pouch causing obstructive symptoms; but a more contemporary understanding of ALS has shown a growing number of potential abnormalities of this portion of the bowel, many of which can be difficult to identify on initial evaluation. For example, a fibrotic stricture causing ALS may be easily seen during pouchoscopy, but angulation of the afferent limb due to adhesions or an inappropriate rotation of the small bowel mesentery is sometimes only identified at laparotomy with findings of partial or complete obstruction [18].

There are several important discussion points regarding ALS that should be highlighted. First, although CD occurring in the pre-pouch ileum can cause fibrostenotic or inflammatory changes of the AL, many of these changes may NOT be due to CD. Chronic nonsteroidal anti-inflammatory medications and Crohn's disease-like conditions (CDLC) can cause similar radiographic and endoscopic findings; clinicians should be careful not to label a patient as having CD of the pouch unless there is reasonable certainty in the diagnosis (Fig. 50.1). Many patients given a label of "CD of the pouch" are branded with this negative stigma and are only offered pouch excision, when in actuality, they may be candidates for salvage procedures.

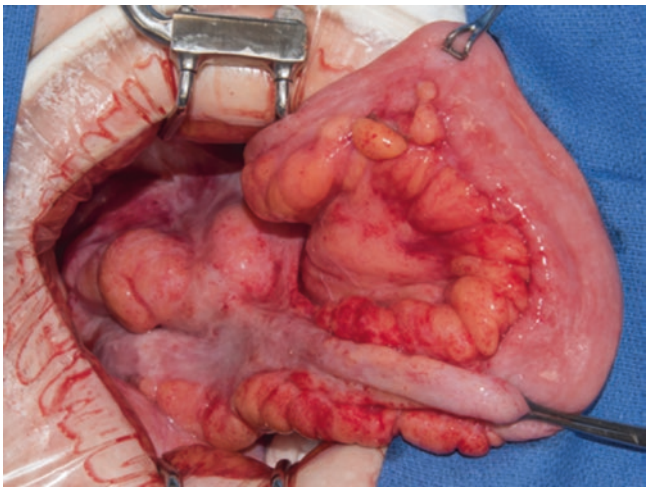

Fig. 50.1 Chronic inflammation of the afferent limb of the ileal pouch forming a strictured segment and causing obstructive symptoms

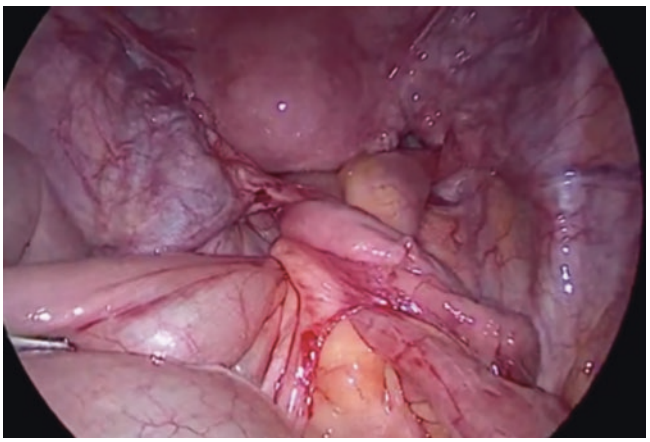

Fig. 50.2 Adhesive bands causing volvulus of the afferent limb of the J-pouch. Note the dilated upstream small bowel (left) due to obstruction of the distal small bowel. A laparoscopic lysis of adhesions with reduction of volvulus was successfully performed

Dysfunction of the AL may also be caused by factors external to the bowel wall (Fig. 50.2). Volvulus or trapping of a redundant AL underneath the small bowel mesentery may result in acute ischemia of the limb or a more chronic intermittent obstructive pattern; patients may be intolerant of large meals, but the pouch is typically normal on radiographic imaging and/or pouchoscopy [19].

Another variant of this is a 180° or 360° rotation of the small bowel mesentery at the time of pouch creation. This incorrect rotation can cause external compression of the mesenteric edge of the AL, often in an intermittent fashion, which makes diagnosis difficult unless the patient is having overt obstructive symptoms. At endoscopy, insufflation of the AL may overcome the external compression and a patent; otherwise normal appearance is suggested. Acute angulation of the AL without mesenteric rotation, "accordioning" of a floppy or redundant pouch, or a rotation of the anterior wall of the pouch can cause obstructive symptoms. Pouch-pexy with creation of a temporary diverting ileostomy to pull the pouch upright "on stretch" helps to secure the pouch in a proper orientation [20–22].

Many patients who suffer from ALS are candidates for endoscopic and/or surgical correction and will not require pouch excision. AL strictures may be assessed for endoscopic balloon dilation, although many strictures persist and require surgical correction. Such strictures are amenable to either surgical resection with primary anastomosis of the pre-pouch ileum, stricture plasty, or a bypass to the pouch inlet. Those with a diagnosis of CD may benefit from ongoing, postoperative medical therapy to prevent inflammatory recurrence. In this way, pre-pouch strictures are dealt with similarly to fibrostenotic CD in other locations [23, 24].

Issues of the Pouch Body

Pouch-Anal Anastomotic (PAA) Defect

One of the most common and devastating complications of IPAA surgery is a leak of the pouch-anal anastomosis. When this occurs in the acute setting (immediate postoperative period), patients may present with fever, leukocytosis, pelvic pain, or other signs/symptoms of sepsis (chills/night sweats), often prompting CT imaging which reveals a pelvic abscess and/or staple line leak. Soluble contrast enema of the pouch, pelvic magnetic resonance imaging (MRI), or examination under anesthesia (EUA) are also helpful to better characterize an anastomotic leak if one is suspected in the early postoperative period [25]. The presentation may be more indolent in some cases, with patients exhibiting indirect symptoms of pelvic sepsis, such as prolonged ileus or urinary retention. Upper pelvic or abdominal abscesses may be percutaneously drained with a CT or ultrasound-guided percutaneous technique; surgical drainage may be required for those not amenable to image-guided measures.

For lower pelvic abscesses or collections obviously associated with an anastomotic disruption, EUA with gentle anoscopy and placement of a flexible mushroom drain through the anastomotic defect is strongly recommended. Care must be taken to avoid drainage approaches that would lead to complex fistula formation; the transanal approach is preferred over percutaneous measures for lower pelvic abscesses for this reason. In patients exhibiting peritonitis or hemodynamic instability, exploration in the operating room with pelvic washout and wide drainage is indicated. This approach, when necessary, is associated with poor pouch outcomes; the rate of pouch excision exceeds 40% with an associated low likelihood of ileostomy reversal [26].

Swift recognition and treatment of anastomotic disruption are paramount to preserve optimal IPAA function and avoid the known long-term sequelae of pelvic sepsis. In cases

where local sepsis is quickly controlled, pouch function is typically preserved, whereas a delay in management risks chronic inflammation with peri-pouch fibrosis and poor compliance of the pouch [11].

When an anastomotic disruption does not heal with the conservative measures described above, patients may develop pouch sinuses, fistulae, strictures, or a number of other pouch-related complications that require further management. Anoperineal fistulae may present as chronic pelvic or anoperineal sepsis which usually require source control with mushroom or draining setons. This presentation is often very similar to CD, but there are subtle and critically important differences. In a patient with AL, sepsis originates from the pouch-anal anastomosis, with the majority of the fibrosis or chronic inflammation at the anastomosis itself; the distal pouch and anal canal are otherwise soft and supple. The anoperineum may be excoriated similar to CD, but without a bluish hue, and there is lack of other CD findings such as waxy skin tags. There is typically (but not always) more fixed fibrosis of the distal pelvis in patients with complications truly attributable to CD.

These subtle clues may help distinguish between CD and sepsis due to AL; but in many cases, these two conditions are indistinguishable, leading to management conundrums. Patients are best evaluated and managed using a multidisciplinary approach involving experienced pouch surgeons and gastroenterologists. Studies have shown that up the three quarters of IPAA patients diagnosed as CD of the pouch were reclassified as having AL after secondary evaluation at a specialty IPAA center and underwent pouch salvage with good results.

Less commonly described, but equally challenging to manage, is the anastomotic sinus-a blind-ending track resulting from an anastomotic dehiscence (Fig. 50.3). It typically presents months to years after IPAA surgery that was complicated by an anastomotic leak, even if the initial leak was not appreciated or documented. It is reported to occur in 2.8–8% of patients undergoing a pelvic pouch procedure, may threaten the integrity of the pouch-anal anastomosis, and is an important predictor of pouch failure [14, 27]. The most common location of a pouch sinus is the posterior portion of the pouch-anal anastomosis and is often associated with presacral inflammation or fibrosis. Pouch sinuses may present as asymptomatic findings on imaging obtained for other indications (e.g., routine evaluation prior to stoma closure) or may exhibit a wide range of symptoms including pelvic or tailbone pain, fecal urgency, night fevers, and other symptoms of pouch dysfunction or failure.

Asymptomatic sinuses require differing management strategies depending on the circumstances of the patient. Sinuses detected in patients without symptoms may be left alone without any intervention, assuming they are not diverted. Those discovered during preoperative evaluation prior to closure of a covering ileostomy will likely heal with a conservative approach; a delay in ileostomy closure of 3–6 months and a repeat pouchogram prior to closure are advised [14, 27, 28].

Sinuses that persist despite these measures can be very difficult to manage for the surgeon and both morbid and frustrating for the patient. Contrast studies of the pouch, pelvic MRI, and EUA are helpful for further delineation of the tract [29]. Treatment begins with periodic incision and drainage of the sinus with healing by secondary intention over a course of usually 6–9 months. Some sinuses may be amenable to endoscopic debridement with sinusotomy (needle-knife therapy) with or without fecal diversion [27, 30]. Revisional or redo pouch surgery via a transabdominal/transanal approach may be considered for refractory cases.

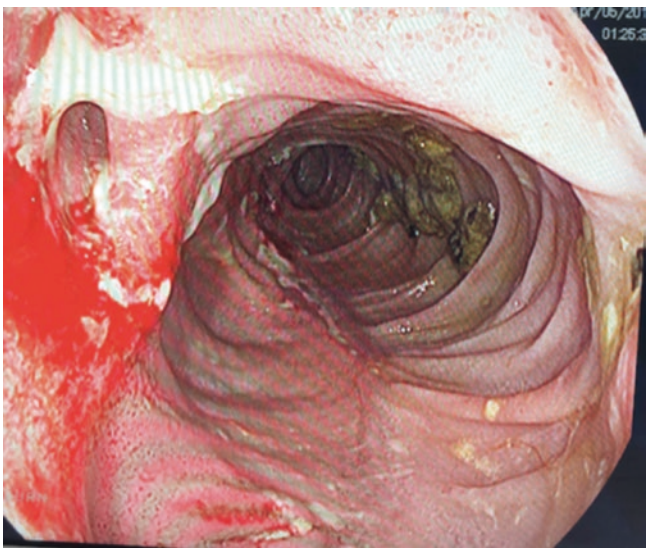

Fig. 50.3 A sinus tract of the pouch-anal anastomosis

"Tip of J" Pouch Leak

The tip of the J-pouch is the anatomic end of the small bowel and may be at risk for ischemic injury or staple line dehiscence, which can lead to sinus formation or persistent staple link leak. If these occur, patients often present with an abscess in the upper pelvis adjacent to the tip of J or with a persistently draining lower midline abdominal wound associated with a low-volume enterocutaneous fistula. These leaks typically do not heal without intervention; although there are reports of endoscopic repair, most will require surgical revision and (much less commonly) full recreation of the pelvic pouch [31, 32].

Incomplete healing of the anterior (or common channel) suture or staple line is a less commonly noted complication of the pelvic pouch. These present as a pelvic abscess, often in the mid-pelvis, that persists despite drainage and without an obvious defect at the pouch-anal anastomosis. Imaging studies may show a connection to the midportion of the

pouch body or even, more rarely, a fistulous connection to other staple lines of the pouch including the tip of J. A full surgical repair of the pouch is usually required, as these also typically do not resolve without intervention. One must be prepared to fully revise or redo the pouch body when embarking on corrective surgery for this complication.

Failure of Pouch "Scaffolding"

The anterior portion of the pouch will usually have more redundancy than the posterior portion, as the shorter, "limiting" axis is typically the posterior aspect of the pouch/small bowel mesentery. Because of this, the anterior portion of the pouch is "floppier" and may become tethered to the presacral fascia, which can limit capacity, or produce internal anterior wall prolapse and cause outlet obstruction. The pouch may also exhibit full thickness external prolapse and protrude from the anus similar to that observed in rectal prolapse [33, 34].

Patients may present with a wide range of symptoms including inability to fill or empty the pouch, pelvic pain, and obstructive symptoms. These patients are often diagnosed with chronic pouchitis. A comprehensive evaluation as described above may identify the abnormal configuration, but sometimes the clues are limited, and this is found only on abdominal exploration. Pouch-pexy techniques (sometimes with an "ileostomy on tension" as described above) is helpful to maintain the appropriate pouch "scaffold." Reports describing mesh or other matrix fixation of the pouch have been published; larger studies with longer follow-up are needed to assess the success and safety of this corrective approach [33, 35].

180°/360° Mesenteric Rotation

Incorrect orientation of the pouch and small bowel mesentery as it descends into the pelvis may cause external compression of the AL or compression/limitation of the volume of the pouch body, resulting in either frequent pouch emptying and/or obstructive symptoms with difficult filling of the pouch. This complication is thought to occur at the time of pouch-anal anastomotic creation, if the pouch inadvertently is allowed to rotate posteriorly (180° defect) or with complete revolution (360°). Patients may be at increased risk for pouch ischemia if the mesenteric blood flow is compromised and may have undue tension on the posterior portion of the anastomosis, a location already prone to anastomotic dehiscence [36, 37].

This complication, as is the case with most others, is better prevented than remediated; appropriate orientation of the mesentery should be assured at the time of anastomotic creation, especially during a laparoscopic or robotic approach, since the abdominal portion of the mesentery is often out of view. To correct this complication, a complete detachment and recreation of the pouch-anal anastomosis is required.

Efferent Limb (EL) Problems

Complications involving the pouch outlet, or efferent limb complications (EL), are likely to present as inability or difficulty emptying the pelvic pouch, with obstructive symptoms, straining with bowel motions, and feelings of incomplete emptying.

Efferent Stricture

Pouch-anal anastomotic strictures usually develop within the first 9 months after surgery. They are more commonly noted after mucosectomy with creation of hand-sewn pouch-anal anastomosis but can be seen in up to 17% of all pouch patients [38, 39]. Development of stricture after IPAA is similar among the commonly used stapler sizes (28/29 mm vs 31/33 mm) used to create the pouch-anal anastomosis [40]. Soft, weblike strictures are often seen after a diverted stapled anastomosis and are amenable to gentle digital dilation. They generally do not recur after restoration of intestinal continuity or are responsive to daily self-dilation [41]. Long, fibrotic strictures commonly result from perioperative pelvic sepsis or pouch ischemia. These generally do not respond to repetitive dilation in the long term, and surgical options are often considered and include (transanal or transabdominal) pouch advancement or pouch revision. Pouch excision with permanent ileostomy may be considered if patient factors are not favorable or if the patient desires this option [42].

Elongated S-Pouch Outlet/Elongated Rectal Cuff (Pouch-Rectal Anastomosis)

At times, efferent limb issues may be caused by technical errors made at the time of pouch creation. These are most commonly in the form of an S-pouch outlet that is made too long or a rectal cuff that is left too long (pouch-rectal anastomosis; Fig. 50.4). Again, meticulous surgical technique dur-

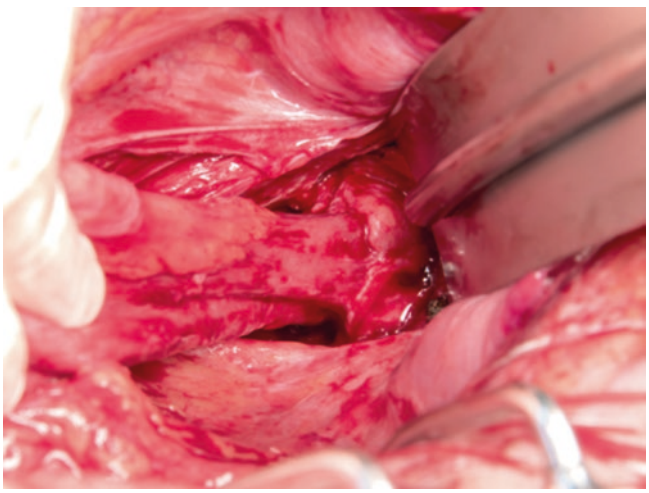

Fig. 50.4 Efferent limb syndrome caused by an elongated rectal cuff (pouch-rectal anastomosis)

ing the de novo pouch operation is critical and can help to avoid these difficult to manage complications. When they do occur, nonoperative maneuvers such as transanal intubation to evacuate the pouch may be offered for amelioration of symptoms but are not likely acceptable as a long-term option to patients and can cause tissue trauma with repetitive use over the years.

Transabdominal/transanal pouch revision is typically employed to shorten the elongated segment. In the setting of an elongated rectal cuff, the surgeon may have the option to restaple a very long cuff with a 30 mm linear stapler and maintain the anal transition zone. If so, a redo double-stapled pouch-anal anastomosis is achievable, and a transanal approach (and mucosectomy) avoided [43].

A situation becoming more commonly seen (and debated) is creation of a pelvic pouch after a proctectomy that preserves the mesorectum and leaves it in place. Although some surgeons argue that this serve as a space filler so that the pouch does not rotate and is "protective" of the retroperitoneal or presacral structures, in actual practice, the residual mesorectum may act as a "collar" around the distal pouch and can contribute to evacuation issues. The correction of this requires transabdominal completion mesorectal excision with a recreation of a new pouch-anal anastomosis.

Inflammatory Complications of the Pouch

Pouchitis

Pouchitis is the most common long-term complication of IPAA surgery. Despite the absence of a surgical "cure" for refractory or chronic pouchitis, the surgeon's role in the multidisciplinary management of pouchitis is crucial to aid with diagnosis and offer options for symptom management.

Although the etiology and pathogenesis of pouchitis are not entirely clear, pouch creation may provide an "inflammation-prone" environment as the distal ileum is converted to storage reservoir. About half of patients who undergo IPAA surgery for UC will develop at least one episode of pouchitis in their lifetime. Approximately 40% of patients experience a single episode (increased frequency of loose bowel movements, tenesmus, rectal bleeding, lower abdominal cramping, and malaise) and respond to a 2–4-week course of oral antibiotics. The remaining 60% will follow a relapsing course; half of these patients will suffer from refractory pouchitis and require treatment with second-line therapies such as chronic antibiotics, steroids, or biologic agents.

A small minority of patients with treatment-resistant pouchitis does not find relief with medical therapy and may desire surgical options for treatment and alleviation of symptoms. These patients should undergo a comprehensive pouch failure evaluation to rule out diseases with similar presentations as outlines earlier in the chapter and be offered the appropriate treatment options depending on the most likely etiology of failure. If refractory pouchitis is suspected, patients may be considered for fecal diversion as a means of alleviating symptoms from mucosal inflammation and perianal excoriation from frequent bowel motions. These patients may also be considered for pouch excision or a loop ileostomy with the pouch left in situ, depending on individualized risk factors for either pouch neoplasia (pouch in situ) and wound healing (pouch excision) [44]. One should be hesitant to offer a redo pouch surgery in this setting without a clear reason to hope for a different outcome with a second pouch.

Pouchitis may be divided into three categories that consider the presumed etiological and pathogenic factors of the condition. Classic pouchitis occurs from dysbiosis of commensal bacteria or infection from bacterial, viral, or fungal pathogens. Patients in this category present with homogeneous, diffuse inflammation of the pouch with or without ulcers. Immune-mediated pouchitis is typically found in the setting of primary sclerosing cholangitis or concomitantly with other autoimmune conditions. Inflammation in this category is found both within the pouch body and afferent limb, with some cases exhibiting concurrent cuffitis [45, 46]. Ischemia-associated pouchitis is thought to occur when undue mesenteric tension on the pouch causes a chronically ischemic environment in the pouch and is characterized by inflammatory changes of only one limb of the pouch in a vascular distribution. Alternatively, one may note ulcerations along the common channel staple line. The typical patient in this category is an obese male with excessive visceral adiposity [47].

A helpful algorithm to treat patients suffering from pouchitis is to initiate a 2-week course of oral ciprofloxacin and Flagyl. Those who are antibiotic-responsive and have resolution of symptoms may undergo additional antibiotic treatment as symptoms recur. Those who respond but are dependent on medications for remission should continue a monitored maintenance antibiotic/probiotic regimen. Patients who continue to have symptoms despite antibiotic therapy should be evaluated for pathogen-induced pouchitis (CMV/C difficile infection) or immune-mediated pouchitis and undergo the appropriate treatment depending on presumed etiology [45]. When ischemic pouchitis is suspected, the patient should be encouraged to pursue loss of visceral adiposity [48].

Cuffitis

Cuffitis is the symptomatic inflammation of the remnant rectal cuff that remains in UC patients after they undergo stapled IPAA. Symptoms can occur in up to 6% of patients with a double-stapled anastomosis and are at times confused with those caused by pouchitis. In these cases, patients may be inappropriately diagnosed and treated for refractory pou-

chitis, when better medical and surgical treatments are available for cuffitis. Medical options of topical steroid enemas, suppositories, or aminosalicylate (5-ASA) drugs are effective. In rare cases when symptoms are not responsive, surgical intervention is warranted. The residual rectal mucosa can be removed with a transanal mucosectomy, followed by ileal pouch advancement with pouch-anal handsewn anastomosis or by transabdominal/transanal pouch redo with anal canal mucosectomy. The success of surgery is increased if the initial stapled anastomosis is no more than 3–4 cm above the dentate line [27] and a tension free anastomosis is fashioned [49].

Crohn's Disease of the Pouch

A diagnosis of CD of the pouch does not necessarily require one to pursue pouch removal with permanent conventional ileostomy as a first step. Disease phenotype heavily influences degree of pouch retention. A study of 65 patients with de novo CD of the pouch reported that 57% were able to maintain their pouch with acceptable function despite this diagnosis. However, the presence of fistulae at the time of diagnosis of CD of the pouch and early diagnosis of Crohn's disease after initial pouch surgery were independent risk factors for pouch failure [50].

Surgical therapies for CD of the pouch may be employed independently or in combination with medical and endoscopic treatments. Regardless of approach, it is most important to consider the desires of the patient and his or her individualized definition of quality of life, as this should be the ultimate measure of treatment success. Many patients diagnosed with CD of the pouch desire pouch preservation and should be offered an evaluation in an IBD center with surgeons experienced in treating this challenging scenario. Those who are not interested in pouch preservation and choose to pursue a permanent conventional ileostomy should be equally supported in this endeavor as well. In either case, the majority of patients with CD of the pouch benefit from both medical and surgical therapy in parallel.

Diagnosis with Exam Under Anesthesia

Making an accurate diagnosis of CD of the pelvic pouch is the cornerstone of success in these challenging patients. An examination under anesthesia (EUA) is often the best first operative option in these patients, allowing the surgeon to establish the correct diagnosis, control sepsis control, and obtain biopsies. Fistulae from a CD pouch are easily confused with pelvic sepsis from a chronic pouch-anal anastomotic leak, and distinguishing between these is critical as the treatment and prognosis are vastly different. It is generally accepted that pelvic sepsis within 3–6 months following ileostomy closure after IPAA is likely a postoperative complication rather than a sequela of CD of the pouch, which is more likely to manifest more than 12 months after IPAA [16, 51].

Control of Sepsis

An initial EUA allows the surgeon to carry out the next critical step of managing CD-related pouch fistulae, which is the control of sepsis. This can be performed using carefully placed mushroom drains in abscess cavities and non-cutting silastic setons to manage fistula tracts (Fig. 50.5). Indiscriminate injury or division of the anal sphincter complex should be avoided, as the risk for fecal incontinence is high. Cautious and gentle completion of these local procedures may control symptoms, improve quality of life, and help to maintain the best chance for pouch preservation for the future [51].

Fecal Diversion

As mentioned previously, a diverting loop ileostomy with pouch in situ is an effective method of controlling symptoms

Fig. 50.5 Anoperineal sepsis in a patient with Crohn's disease of the pouch. Control of sepsis is achieved with thoughtfully placed drains and setons

from fistulizing CD of the pouch when the patient has failed medical/endoscopic therapy and/or is not ready to commit to pouch excision or pouch revision (if an option). It is important to emphasize that fecal diversion *improves* but does not necessarily *resolves* anorectal symptoms, as patients may experience ongoing mucous drainage and untoward symptoms from diversion pouchitis [52].

Pouch Excision

Pouch excision is, at times, a necessary surgical option when medical, endoscopic, and local surgical therapies fail but comes with a high morbidity rate. Pathologic confirmation of CD of the pouch is not always confirmed after pouch excision, as shown in a series of 35 such patients, with only 7 cases achieving pathologic diagnosis of CD [53]. A morbid complication of pouch excision is the nonhealing perineal wound and subsequent development of perineal sinus, which can be more difficult to manage than a pouch left in situ. This occurs in up to 40% of patients, and the risk for this troublesome complication should be considered when developing a surgical strategy (Fig. 50.6) [54]. Fecal diversion with staged pouch excision may help reduce the risk for nonhealing.

Pouch Revision in the Setting of CD

Carefully selected patients suffering from fistulizing CD of the pouch may be candidates for pouch revision, either with perineal/perianal repair of the existing pouch or major corrective surgery with recreation of a new pouch-anal anastomosis and/or new pouch.

Any surgical repair of a pouch fistula first requires control of sepsis to normalize tissue quality, followed by medical therapy to reduce inflammation and promote healing. During this time, response to therapy is monitored and assessed, and discussions regarding the next steps must establish reasonable patient expectations and the goals of surgery in these very challenging cases.

Local procedures such as seton placement, mucosal advancement, and fistulotomy have been studied as a means to mitigate symptoms of CD-related pouch fistulas. Although there is evidence to support the use of local procedures for CD-related complications of the pouch, the presence of a fistula at the time of CD diagnosis was an independent risk factor associated with pouch failure [50].

Data regarding pouch revision for CD pathology of the pouch are very limited. Unpublished data regarding patients undergoing redo IPAA for CD revealed pouch retention rates were lower than index pouches (<60% vs 79% at 5 years) but perioperative complications and functional outcomes were comparable. This highlights the critical importance of proper patient selection for this process. Additionally, acceptable outcomes of revisional IPAA surgery for CD of the pouch can be achieved in very carefully selected patients who present for surgery with no active anoperineal disease, limited small bowel disease, and an uncompromised anal sphincter.

Fig. 50.6 A nonhealing perineal wound (left) and persistent sinus tract (right) after pouch excision for Crohn's disease

Above all, any patient undergoing pouch revision for fistulizing CD must have insight as to the complexity and limitations of redo surgery in this setting and accept the increased risk for postoperative complications, eventual pouch loss, or need for long-term medical therapy.

When considering surgical options for CD of the pouch, it is important to re-emphasize that many patients are misdiagnosed with CD, when failure is actually due to technical complications at the pouch-anal anastomosis. These patients are commonly good candidates for a redo pouch but were not considered owing to an incorrect diagnosis of CD.

Functional Complications of the Pouch

Irritable pouch syndrome is a clinical scenario in which a pouch patient suffers from symptoms of diarrhea, urgency, pelvic pain, and cramping in the absence of endoscopic or histologic findings of mucosal inflammation. It is thought to be related to visceral hypersensitivity and hypermotility of the pouch, but the true etiology is poorly understood. In one study of 61 patients after RP IPAA, 43% exhibited the clinical symptoms described above, with postoperative complications, pouchitis, and CD ruled out. Although an effective treatment strategy is still being elucidated, patients often benefit from a combination of systemic and topical antidiarrheal, antispasmodic, and anticholinergic therapies, in addition to cognitive behavioral therapy [55, 56].

Dyssynergic defecation (DD) or nonrelaxing pelvic floor dysfunction, in which the puborectalis muscle fails to relax during defecation, can cause dyschezia and straining in pouch patients. DD can occur as a primary disorder (idiopathic) or secondary disorder (associated with inflammatory pouch conditions like pouchitis or cuffitis). Anal manometry commonly shows paradoxical contractions of the muscle and failure of the balloon expulsion test. Pelvic floor physical therapy (biofeedback) is helpful in many cases of both primary and secondary DD, along with the treatment of underlying inflammatory conditions that may coexist [57–59].

Neoplasia of the Pouch

Cancers of the pelvic pouch are poorly understood, difficult to detect even with routine endoscopic surveillance, and have a poor prognosis. Studies on the topic are sparse and primarily consist of case reports and small series. One of the largest studies of over 3000 pouch patients reported a cumulative incidence for pouch dysplasia of 0.8% at 5 years and 2.2% at 20 years after pouch construction [60]. Pouch dysplasia is primarily noted at the anal transition zone or rectal cuff and is more likely to occur in IBD patients whose original indication for proctocolectomy was dysplasia or cancer.

Less than 50 cases of pouch cancer have been reported in the literature, with the majority being adenocarcinoma located in the ATZ (64%) or pouch body (19%). Cumulative incidence for pouch cancer has been reported as 0.2%, 0.4%, and 2.4% at 5, 10, and 20 years in one large study of over 3000 UC patients [60], with similar results in other studies [61].

Outcomes of Surgical Management of Pouch Complications

The decision regarding what surgical options to offer a patient with a failed IPAA is extremely complex with life-altering consequences for the patient. On the one hand, pouch excision offers the hope of a better quality of life (QOL) but requires the acceptance of a permanent conventional ileostomy and risk for wound healing issues. Conversely, pouch repair and revision maintain continuity of the intestine but sometimes require a commitment to undergo multiple major operations over an extended period of time. The literature informing the optimal approach to pouch failure with regard to pouch excision vs pouch redo is limited. There are no randomized trials available or studies that directly compare the two approaches. The large majority of available studies are retrospective and descriptive experiences of specialized, high-volume IPAA centers.

The traditional approach to pouch failure has been to offer the patient pouch excision with a permanent conventional ileostomy, often in one operative setting. However, several studies on the topic have reported significant postoperative morbidity after this operation. A retrospective review from the Mayo clinic of 147 patients undergoing pouch excision reported short- and long-term complication rates of 57% and 37%, respectively, with 11% requiring a return to the operating room due to complications within the immediate postoperative period [4]. This is consistent with a prior study from St Mark's Hospital reporting a 25% and 53.7% early and late postoperative complication rate, respectively. Over half of the patients required readmission, with greater than 50% of

these patients requiring reoperation. Persistent perineal wounds were reported in 40% and 10% at 6 and 12 months, respectively [54]. Another retrospective report highlighted the difficult challenge of postoperative perineal wound healing in their study of 47 patients undergoing pouch excision. Of these, nearly 30% suffered from perineal wound complications, including perineal wound infections (100%), perineal sinus tracts (28%), and perineal hernia (7%) [62].

The significant morbidity and need for permanent conventional ileostomy are major drawbacks of pouch excision for pouch failure [63], thus making pouch redo an attractive alternative in highly selected patients. Remzi reported the largest experience describing outcomes of redo pouch surgery performed in over 500 patients spanning three decades. The large majority suffered from sepsis-related pouch dysfunction. Postoperative complications occurred in 53%, with pelvic sepsis the most common. Ileus/bowel obstruction (16%), anastomotic leak (8%), and wound infection (8%) were the most common short-term complications (along with pelvic sepsis). A total of 20% of patients had redo IPAA failure, but 83% of patients had a functional IPAA at most recent follow-up, with 5- and 10-year pouch survival noted to be 90% and 82%, respectively. This report is one of few that examined QOL and functional outcomes and reported that more than 90% of patients recommended surgery to others and would undergo the surgery again if needed [5]. Overall, these results support the important role of pouch revision surgery in carefully selected patients. Many patients with IPAA failure may have a second chance to achieve stoma-free living with acceptable bowel function and quality of life with the redo pouch.

Other series report similar positive results, albeit with smaller number of patients and more limited follow-up. One recent study of 81 patients undergoing pouch revision reported a predicted 5- and 10-year pouch survival of 85% and 65%, respectively, and pouch loss of 23%. The overall (early and late) complication rate was 35.6%, with most the common complications being ileus/bowel obstruction and recurrent fistula [6]. Another study described the outcomes of 51 patients undergoing pouch salvage, 23 of these undergoing transabdominal redo. Of these, 69% were reported to have acceptable functional results, with septic events described as the most notable and morbid postoperative complication [8]. Others have also reported successful redo IPAA with good functional outcomes and patient satisfaction with acceptable rates of complications [64–67].

Patients with IPAA dysfunction should be offered the opportunity to undergo comprehensive evaluation in an IPAA center (experienced in revisionary pouch surgery), with discussion of multidisciplinary management options. A patient's decision to pursue an improved QOL by accepting pouch excision with a permanent lifelong ileostomy should be honored without exception and without persuasion otherwise. For appropriately selected patients desiring an attempt at pouch salvage, pouch revision and redo are good options with a high likelihood of success and require a thoughtful and honest discussion between patient and clinicians to set shared goals and expectations for care.

One additional tool in the toolbox of the reoperative pouch surgeon is the continent ileostomy (CI). CI is an intra-abdominal ileal reservoir made with a continent nipple valve that allows for patient control of stool evacuation (Fig. 50.7a–c). A catheter is inserted into the pouch several times daily by the patient to empty the pouch, at private and convenient times. In this way, patients are able to maintain continence with improved lifestyle and body image as compared to a permanent ileostomy [68–71]. Although less commonly created in contemporary times than the J-pouch, it remains a good option for selected patients desiring a control of bowel habits but who are not candidates for a pelvic pouch.

Despite its many benefits over conventional ileostomy, CI is a complex procedure that carries significant risk of postoperative complications as well as a long-term need for reoperation to repair nipple valve slippage, the commonest complication and indication for reoperation in these patients [70–72]. Patients must undergo extensive preoperative counseling to confer understanding of the associated risks and accept a realistic vision of life with CI. In carefully selected and motivated patients, CI continues to be a durable option, with long-term pouch survival rates approaching 80% [73]. CI patients enjoy greater QOL than others with a conventional ileostomy and that 95% would choose to undergo the procedure again and recommend it to others [74, 75].

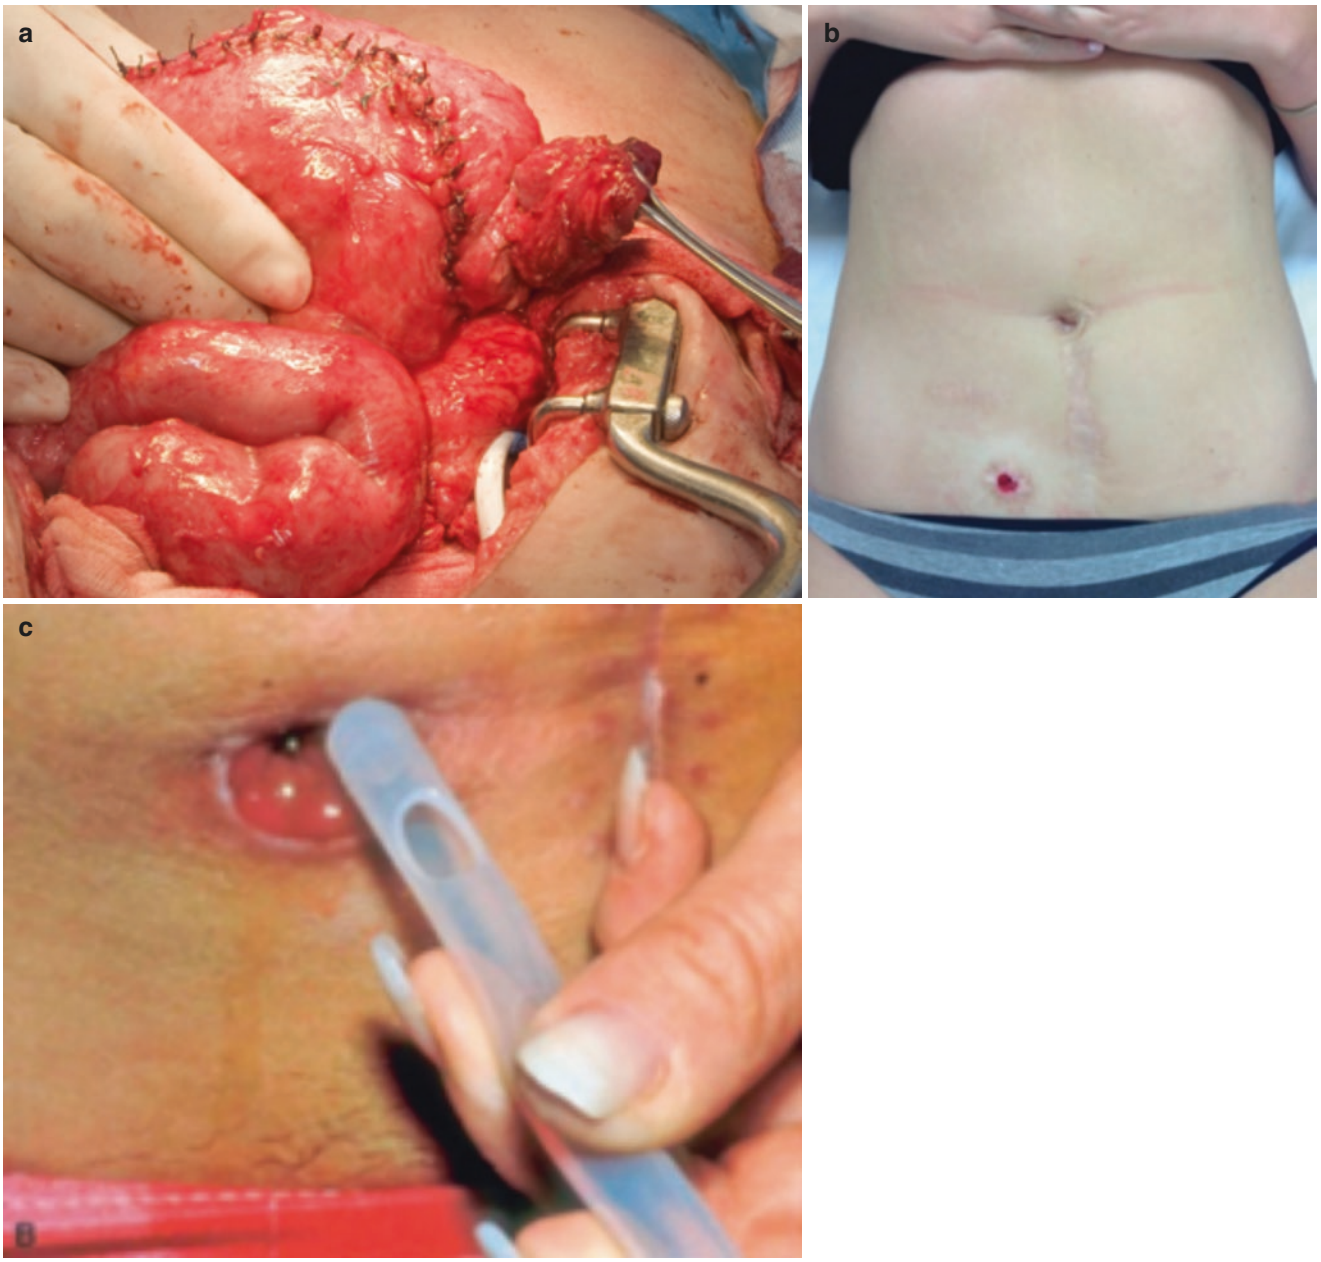

Fig. 50.7 A continent ileostomy created in a patient not suitable for a pelvic pouch (**a**). The inconspicuous stoma (**b**) gives patient control of continence with intermittent intubation and improved quality of life (**c**)

Conclusion

The debate as to how best to approach IPAA failure is multifaceted and ongoing, with limited comparative studies on which to base important decisions. One of the major barriers to mastering this topic is the remarkable uniqueness of every IPAA failure patient. Each patient is different with a distinctive etiology of pouch dysfunction coupled with personal desires and QOL aspirations. Further studies are necessary to continue to learn how to approach the patient with a failed or failing pouch; an individualized plan of care is necessary to achieve the best outcomes.

Infectious Colitis

51

Craig A. Reickert and Maher A. Abbas

Key Concepts

- Campylobacter is the most common cause of bacterial colitis worldwide.
- Yersinia may cause a mesenteric adenitis and ileitis resembling Crohn's disease.
- Amebic colitis causes flask-like ulcers.
- The diagnosis of CMV may be made by identification of viral inclusion bodies on mucosal biopsies.

Bacterial Colitidies

Campylobacter

The symptoms of campylobacter infection are usually diarrhea (often bloody diarrhea), fever, and abdominal pain. In the United States (US), the Centers for Disease Control and Prevention (CDC) has identified an incidence of 19.6 cases per 100,000 people making campylobacter the most common bacterial colitis. Worldwide, the incidence is 25–30 cases per 100,000 population [1]. Most cases are related to ingestion of contaminated food or water. Poultry is a common, but not exclusive, source of infection. Definitive diagnosis is confirmed by stool culture or polymerase chain reaction (PCR) testing of the stool in the setting of symptoms of infectious diarrhea. Endoscopic findings may reveal mild inflammatory changes but without pathognomonic findings.

Campylobacter infection is usually self-limited and does not require specific treatment other than supportive care for the diarrhea. Campylobacter infection has a median incubation period of 2–4 days. The bacteria multiply in the bile and invade the gastrointestinal mucosa to the depth of the lamina propria. The infection causes edematous enteritis with bloody diarrhea. The infection can inflame the terminal ileum and cecum and create a clinical picture similar to appendicitis. Campylobacter infection usually resolves in 7 days without significant sequelae. However, up to 16% may have persistent colonization for up to 10 weeks. In addition, severe complications from campylobacter include clinically significant lower gastrointestinal (GI) bleeding, toxic colitis, pancreatitis, Reiter's syndrome, and Guillain-Barre syndrome [2].

Treatment with antibiotics is not usually required, but may be indicated for severe disease. Drug-resistant forms of the bacteria are common in some areas with high disease incidence [3]. Fluoroquinolone antibiotics are highly effective but have a high rate of drug resistance (>25% in the USA and up to 80% in some areas of the world). Treatment with azithromycin is almost as effective as a fluoroquinolone with lower rates of drug resistance [4]. Most studies advise up to 3 days of antibiotic therapy, but severely compromised patients may benefit from longer courses, parenteral medications, and/or multi-drug treatment [5]. Patients with campylobacter infection do not require specific isolation precautions.

Salmonella

Infection with salmonella has two types of clinical presentations. Non-typhoid salmonella infections are characterized with diarrhea (usually self-limited) with gastrointestinal symptoms such as nausea, vomiting, and cramping. The incubation period is between 8 and 48 hours after the ingestion of contaminated food. Typhoid fever describes the presence of salmonella infection with symptoms of fever, delirium, pain, and skin rash. Typhoid fever is related to bacteremia from the GI tract infection. The typhoid fever presentation is associated with salmonella typhi and salmonella

paratyphi. Salmonella enteritidis and salmonella typhimurium are most common in the US population [1]. Routes of transmission include food, feces, fingers, fomites, and flies (the 5 Fs). Many infections are related to contaminated meat and poultry products [2].

Diagnosis with stool culture or PCR or a positive blood culture with the organism is confirmatory. Endoscopic findings are non-specific and do not confirm the diagnosis. Most infections do not require treatment and are self-limited. Treatment with antibiotics for patients with bacteremia is reasonable and should be considered in immunocompromised or frail patients. Fluoroquinolones are the treatment of choice, although azithromycin is a reasonable alternative, particularly in developing nations or in patients with exposure during travel to those endemic areas [5].

Shigella

Infection with shigella is more common in young children but can affect all individuals. In the USA, *Shigella sonnei* is the most common [1]. Transmission via contaminated water and from contaminated or infected individuals is the most common routes of spread. Infection is associated with diarrhea, usually non-bloody, but colitis, tenesmus, and bloody stools may develop 3–5 days after onset of symptoms. Children frequently recover in 3–4 days, while adults may need 3–4 weeks to fully recover from the infection. Complications include perforation, toxic colitis, hemolytic-uremic syndrome, and dehydration/electrolytes abnormalities [2].

Diagnosis requires stool culture or PCR for confirmation. Endoscopic findings are non-specific and non-diagnostic. Symptoms usually resolve without antibiotic therapy, but patients may continue to shed the organism for up to 6 weeks without symptoms. Antibiotic resistance is becoming more common and empiric/universal treatment for patients is not advisable. In patients with more systemic signs of infection, complications, or immunosuppression, as well as patients who have public health consequences due to the prolonged shedding (such as food handlers, child-care providers, nursing home residents), treatment based on culture/sensitivity results is recommended, with fluoroquinolones, azithromycin, or a third-generation cephalosporin [6]. Treatment should be limited to between 3 and 5 days for most patients.

Escherichia coli

Escherichia coli (*E. coli*) bacteria are among the most populous species of bacteria in the normal human colon. Most are harmless and even beneficial. There are five pathotypes or groups of *E. coli* conclusively associated with diarrhea: shiga toxin-producing *E. coli* (STEC) (also known as verocytotoxin-producing *E. coli* (VTEC) or enterohemorrhagic *E. coli* (EHEC)), enterotoxigenic *E. coli* (ETEC), enteropathogenic *E. coli* (EPEC), enteroaggregative *E. coli* (EAEC), and enteroinvasive *E. coli* (EIEC). Both EPEC and EIEC are non-toxin producers. An additional pathotype, diffusely adherent *E. coli* (DAEC), has been described but has not been conclusively linked to pathologic manifestations and diarrheal illness [2].

Infections from EPEC frequently affect infants, while EAEC affects children with more persistent diarrhea. ETEC and EAEC are often associated with traveler's diarrhea. EIEC is endemic in South America and parts of Europe, and it is associated with dysentery in these areas. All pathotypes have caused disease in the USA and around the world. Collectively non-STEC infections have lower incidence in the USA, Canada, Australia, New Zealand, Japan, and countries in Northern and Western Europe. Non-STEC infections have highest incidence in most of Asia, the Middle East, Africa, Mexico, and Central and South America.

STEC (including groups known as VTEC and EHEC) is associated with a hemorrhagic colitis presenting with diarrhea that may be bloody. It is often implicated in food-borne outbreaks in the USA and globally more common in industrialized nations. A well-described strain of *E. coli* O157:H7 was identified in 1982 [7]. The reservoir for this bacterium is cows, and transmission of this strain is associated with food transmission (undercooked beef or milk). Both EHEC serotypes O157:H7 and non-O157:H7 produce shiga-like toxins similar to *Shigella dysenteriae*. Outbreaks have been associated more often with the *E. coli* O157:H7 subtype. Most infections are not severe and are self-limited. However, some patients progress to bloody diarrhea, and a subgroup of these patients may develop hemolytic uremic syndrome (HUS) and life-threatening complications. STEC infections with non-O157 strains are important causes of diarrheal outbreaks, accounting for 75% of STEC infections [8]. Stool analysis for pathogens and shiga toxin can help confirm non-O157 STEC [9].

Stool cultures or the rapid multiplex GI panel PCR test for STEC should be considered for all patients with bloody diarrhea. Endoscopic findings of colitis and focal ulcerations may be seen but are not diagnostic [10]. Clinical treatment of most patients with diarrhea from *E. coli* is supportive with early hydration and correction of electrolytes. Avoidance of anti-motility agents is critical in STEC infection as increased toxin production and exposure can exacerbate the risk of HUS.

There are no antibiotic regimens for *E. coli* infection, and treatment with antibiotics is not recommended in most cases. Several antibiotics have actually been found to increase the risk of HUS in STEC. EAEC in children may be treated with rifaximin for protracted cases. There are no current vaccines or prophylactic regimens to reduce the risk of traveler's diarrhea associated with *E. coli*.

Yersinia

Transmission of yersinia occurs via the handling of contaminated animals as well as ingestion of contaminated food (often infection is related to undercooked pork or contaminated milk products). Diarrhea with fever and abdominal pain may last up to 21 days. The clinical findings of mesenteric adenitis or ileitis could be confused with Crohn's disease. Further systemic complications of a migratory arthritis, Reiter's syndrome, and findings of erythema nodosum are sometimes noted and further complicate the diagnostic dilemma. Colonoscopy findings can also mimic Crohn's disease with erosions in the right colon [10].

Diagnostic testing with stool culture may not be able to identify yersinia by isolation methods. Hemagglutinin testing for titers in a ratio of 1:128 is indirect confirmation of infection. More recently PCR-based assays were developed for the detection of plasmid- and chromosome-borne virulence genes in *Yersinia enterocolitica* and *Yersinia pseudotuberculosis* [11]. In most cases the disease resolves without treatment. Supportive care for the diarrhea may be required. In patients with systemic manifestations, antibiotic coverage with aminoglycosides, trimethoprim/sulfamethoxazole (TMP-SMX), doxycycline, and fluoroquinolones have all been effective [2].

Vibrio

Vibrio infection is associated with both non-cholerae and cholerae presentations. Vibrio contaminates shellfish, so consumption of raw and undercooked shellfish is the main route of transmission. The development of diarrhea and abdominal cramping within 48 hours of ingesting raw shellfish is consistent with acute vibrio infection. Routine stool cultures do not often include vibrio species, so a special request may be made based on history of exposure [12]. PCR stool testing can be helpful. *Vibrio parahaemolyticus* causes diarrhea and cramping but is self-limited and not associated with massive diarrhea. Tetracycline, fluoroquinolones, aminoglycosides, and third-generation cephalosporins for treatment of severe infection are all effective. Vibrio cholerae species are associated with invasive infection with severe, voluminous (up to 1 liter per hour) diarrhea which can lead to dehydration, hypovolemic shock, and death within hours of the development of symptoms [13]. Vibrio cholerae strains O1 and O319 are the most commonly associated with outbreaks [14]. Treatment of cholerae symptoms requires high-volume crystalloids resuscitation with the addition of ciprofloxacin or doxycycline (treatment is a single dose) to control the active bacteria.

Other Bacterial Colitidies

Infection with other bacteria associated with colitis includes *Mycobacterium tuberculosis*, *Aeromonas* species, *Bacteroides*, *Listeria*, as well as *Clostridium difficile* (covered in a separate chapter). Bacterial sexually transmitted diseases (STDs) such as gonorrhea, chlamydia, or syphilis predominantly affect the anorectal region through direct transmission (covered under a separate chapter).

Tuberculosis infection is carried from the primary pulmonary site via swallowed sputum. *Mycobacterium tuberculosis* infection of the GI tract is associated with abdominal pain, fever, and weight loss. Inflammation of the ileocolic region can be mistaken for new-onset Crohn's disease or complicated appendicitis [15]. Endoscopic findings and biopsy are not pathognomonic and radiology findings are variable in reliability. Computer tomography findings are non-specific in most cases (Fig. 51.1). Surgical intervention is reserved for diagnostic purposes in undiagnosed cases or in the setting of an established diagnosis when there is perforation or obstruction [16].

Aeromonas colitis is most often associated with diarrhea. Symptoms can persist for 2 weeks or longer and must be suspected in cases of exposure based on travel to endemic areas. Stool cultures can be diagnostic but require specific request in non-endemic areas. While symptoms may persist, they are often self-limited. Treatment in immunocompromised patients includes fluoroquinolones or azithromycin [17].

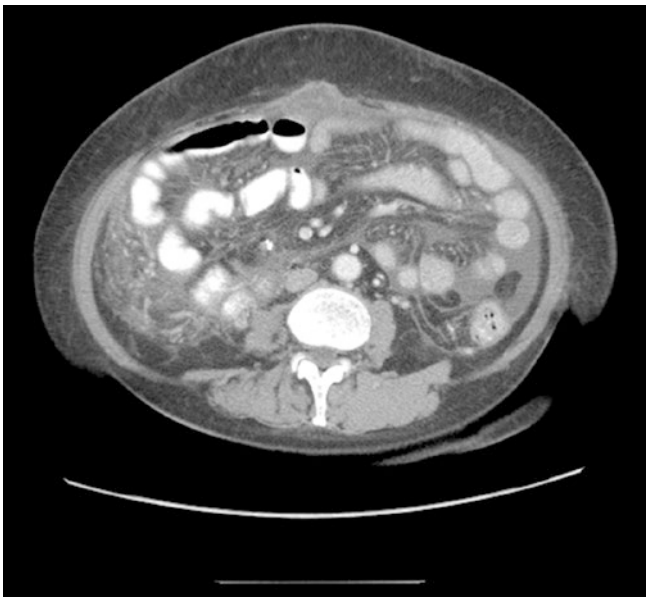

Fig. 51.1 Computed tomography of tuberculous colitis with dissemination into the peritoneal cavity with ascites and omental infiltration (axial view)

Bacteroides fragilis colitis is associated with infection by a subclass of organisms with a secreted toxin [18]. The symptoms of acute diarrhea are self-limited. *Listeria monocytogenes* is associated with acute colitis in immunocompromised individuals [19]. Treatment in immune compromised patients would include TMP-SMX but is not required in most otherwise healthy patients.

Parasitic Colitidies

Amebic Colitis

Amebiasis is caused by *Entamoeba histolytica*. It is prevalent in areas of the world with limited sanitation capabilities such as tropical central/southern America, Africa, and Asia [20, 21]. Travel exposure is the most common finding in patients diagnosed in the USA. Transmission between humans is most often via fecal/oral contamination. The amebic cysts can persevere in the soil for up to a month. The cycle of transmission includes ingestion of mature cysts which replicate inside the gastrointestinal tract through a process of excystation, resulting in active trophozoites (non-encysted amebae) which can invade the colonic wall. Incubation times after exposure can be from 2 to 4 weeks before the development of symptoms. While the majority of patients are asymptomatic or have mild symptoms, individuals can develop a wide spectrum of symptoms including poor appetite, weight loss, fever, nausea, vomiting, lower abdominal pain, diarrhea (including bloody diarrhea in some cases), and anemia due to colonic inflammation and ulceration [20, 21]. The parasite can cause deep ulcerations in the colon leading to full-thickness perforation [22, 23]. Extraintestinal complications of amebiasis due to bloodstream infection can involve the liver, brain, and lung [24–26]. Hepatic abscess can develop in absence of colonic symptoms and can rupture into the abdomen or the chest cavity leading to lung abscess or empyema [21, 27, 28]. Amebiasis can lead to death when there is colonic perforation or systemic extraintestinal disease with a reported mortality rate up to 50% [29]. Approximately 55,000 amebiasis-related deaths were reported globally in 2010 [30].

The diagnosis of amebiasis can be confirmed by stool tests including microscopy, increased white blood cell (non-specific), and PCR antigen testing which is highly sensitive and specific [31, 32]. More than one stool sample (up to three on different days) is needed in some patients to make the diagnosis. Serologic testing to detect antibodies can be helpful and usually becomes positive after a period of 2 weeks. Higher level of antibodies is noted in patients with extraintestinal disease such as hepatic abscess. The antibody level can remain positive for a long period of time after treatment. Therefore, a positive test may not necessarily represent active disease. Endoscopic findings usually include ulcerations of various depths and widths from a few millimeters to centimeters (Fig. 51.2). While the right colon is most often affected, ulcerations can occur on the left side as well.

Histopathologic assessment of the specimen usually demonstrates flask-shaped ulcers (Fig. 51.3). In some cases, the trophozoites are noted at the periphery of the ulcer using

Fig. 51.2 Colonoscopy findings of amebic ulcer

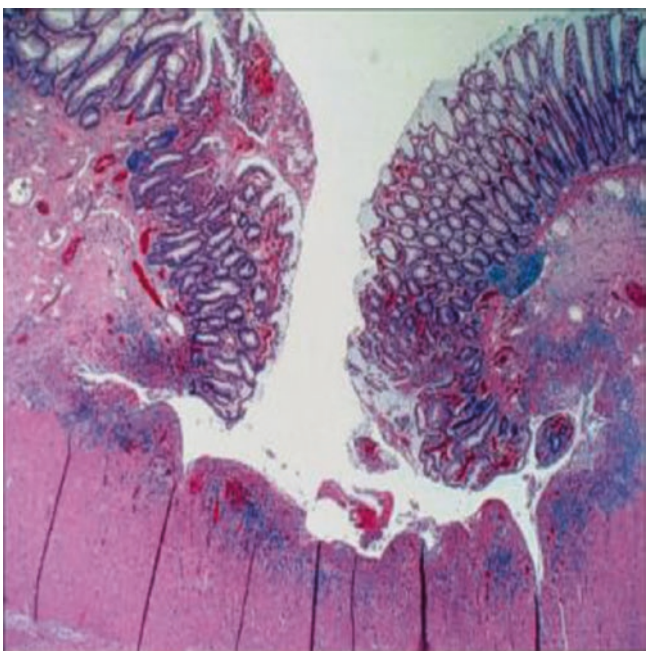

Fig. 51.3 Histopathologic examination of an amebic ulcer. Note the flask-shaped ulcer

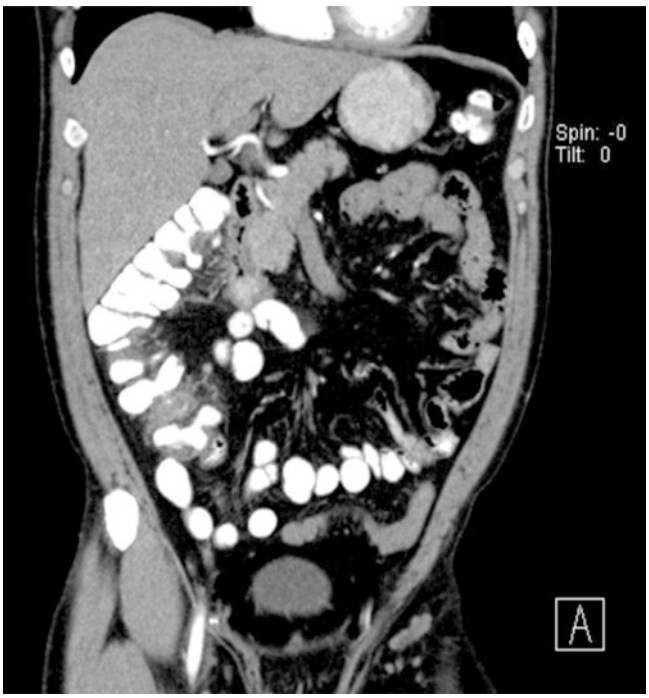

Fig. 51.4 Computed tomography of amebic colitis involving the ascending colon (coronal view)

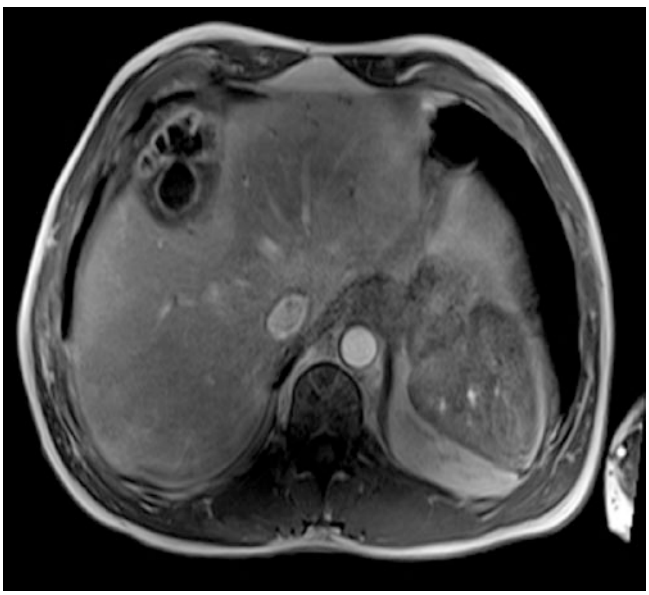

Fig. 51.5 Magnetic resonance scan of amebic hepatic abscess (axial view, T1 sequence post-contrast)

immunohistochemical stains specific to antibodies against the *Entamoeba histolytica*. While computed tomography can be helpful in delineating areas of inflammation, the presence of hepatic abscess or perforation is not specific for amebic colitis (Fig. 51.4). Hepatic abscess can be assessed by ultrasound examination, computed tomography, or magnetic resonance imaging (Fig. 51.5). An uncommon presentation of amebiasis is ameboma which is a granulomatous mass in the wall of the colon. It can present with obstructive symptoms and can be confused for a malignancy [33, 34].

Asymptomatic patients can be treated with a luminal agent directed at the cysts to prevent transmission to other humans. Luminal agents include paromomycin, diloxanide furoate, or iodoquinoline. Management of confirmed active disease of amebic colitis needs a combination therapy initially with amebicidal agent followed by a luminal medication. A 10-day course of metronidazole is considered as first-line therapy for patients with active colitis [35, 36]. Other medication options include tinidazole, nitazoxanide, dehydroemetine, and chloroquine. Amebic hepatic abscess is treated with medical therapy; patients with a large abscess or those who fail to respond to medical therapy can benefit from imaging-guided aspiration or drainage [25, 26, 37]. Surgical intervention is reserved for the rare complications of perforation or toxic colitis.

A group from Mexico City reported their 30-year experience with patients who suffered perforations from amebic colitis [23]. During the study period, 112 cases of colonic perforation related to amebiasis were identified (0.6% of all emergency abdominal operations). The right colon was the most common location of disease (90.5%), and multiple colon perforations were noted in 74% of patients. A segmental colectomy was performed in 53.3% of the patients, subtotal colectomy with end ileostomy in 35.3%, exteriorization of the colon in 10.7%, and primary repair in 0.8%. A mortality rate of 40% was noted.

Anisakidosis

Infections caused by *Anisakis simplex* and *Pseudoterranova decipiens* are associated with gastritis; >90% of the infections have been reported from Japan. Consumption of contaminated raw fish allows the larvae to attach to the GI tract (4% involving colon). Symptoms of lower abdominal pain, fever, and diarrhea are common [38]. The larvae burrow into the muscular wall and cause a hypersensitivity reaction with granulomas and eosinophils. Symptoms and signs can be confused with appendicitis, ileitis, diverticulitis, and acute abdomen [39]. Surgery for complications of perforation and obstruction can be required and is often the means of diagnosis. Treatment with albendazole for 7–21 days can be effective [40].

Ascaris

Ascaris lumbricoides infection is prevalent in tropical and subtropical climates. It is a major world health issue with up to 1.2 billion infected persons at this time. A human host

consumes ascaris eggs; the larvae hatch in the small intestine and migrate via venous return to the lungs. The larvae are able to enter the airway and can be returned to the GI tract by being swallowed in the sputum from the airway. Larvae in the intestine grow into adults and begin to produce eggs. Adult ascaris worms can live for up to 2 years and can produce thousands of eggs each day. Eggs are passed in the stool and can live for years in the environment [41].

Most patients with infection are asymptomatic. Patients with very high worm burden may have symptoms of abdominal pain or bowel obstruction. Treatment of obstructing worm masses can include milking the mass into the more distal bowel; resection may be required even in the absence of bowel compromise from the obstructive process [42].

Diagnosis can be confirmed with stool microscopy. The eggs and larvae are well described and easy to identify. Retrograde GI contrast studies can identify the curvilinear densities or obstruction from the parasites. Treatment with mebendazole or albendazole is highly effective [43].

Infection with *Ascaris suum*, a similar infection in pigs, has also been found in humans and can be an important alternate source of infection in areas where the use of pig manure as fertilizer is common [44].

Strongyloides

The intestinal nematode *Strongyloides stercoralis* is prevalent in tropical climates but also has a notable incidence in the Appalachian areas of the USA. Larvae shed from infected hosts can penetrate the skin of a new host to cause infection. The larvae travel to the lungs and are swallowed in sputum to allow adults to grow in the GI tract. Strongyloides can autoinfect their host [45].

Patients demonstrate acute infection with skin changes from the burrowing larvae – larvae currens. Chronic states with auto-infection can present with diarrhea, pain, and wasting [46]. The infection can sometimes present with findings of pancolitis, potentially mimicking ulcerative colitis. Endoscopy cannot easily distinguish it from other forms of colitis [47]. Stool detection of larvae confirms the diagnosis. However, repeated testing, duodenal biopsy, enzyme-linked immunosorbent assay (ELISA) testing, or bronchial washings may be required for confirmation.

Ivermectin for 2 days is the first-line treatment. Albendazole and mebendazole are alternate medications for treatment [48].

Trichuris

Trichuris trichiura, or whipworm, infection affects almost 800 million people around the world, mostly in tropical and subtropical climates. Ingestion of contaminated soil/food allows the larvae to grow in the colon. Adult worms can secrete thousands of eggs per day. Most infected humans have minimal or no symptoms. Advanced infection can create symptoms of diarrhea, bleeding, and tenesmus with stool having a characteristic odor [49].

Symptomatic rectal prolapse can occur with the ability to observe the worms on the mucosa. Additional symptoms of anemia from bleeding and growth retardation in children are noted. Confirmation of the diagnosis with stool microscopy, the barrel-shaped eggs and worms are easily identified. Colonoscopy can visually identify the worms. Treatment with mebendazole or albendazole is effective [50]. Surgical repair of prolapse can be required but is otherwise not typically part of the treatment of trichuris infection.

Enterobius

Pinworm infection by *Enterobius vermicularis* is common in all areas of the world. Most of the infected humans are children. Spread is by ingestion of eggs. The adult worms grow in the cecum for 10–12 weeks. Female pinworms migrate to the perianal skin and deposit up to 10,000 eggs in the perianal skin folds. The larvae hatch and create an intense pruritus. Scratching of the skin can allow larvae to travel on the fingers to auto-infect or infect others through oral ingestion [51]. Diagnostic testing with the tape test – pressing a strip of adhesive tape against the perianal skin to pull eggs onto the tape and allow microscopic detection – is easy and diagnostic. Treatment with mebendazole or albendazole is effective. Care is taken to treat all family members; environmental cleaning to prevent reinfection is usually required for proper eradication.

Cryptosporidium

Infection by cryptosporidium, an intracellular protozoan parasite, was first described in humans in 1976 [52]. Ingestion of oocysts from contaminated food or water allows growth in the small bowel and shedding of oocysts in the stool. The oocysts are small, making filtration challenging, and are resistant to chlorination. Heating, freezing, and ozonation can destroy the oocysts. The oocysts are able to create infection with exposure to only a few oocysts.

Cryptosporidiosis typically presents in one of four clinical scenarios: pediatric diarrhea in developing areas, traveler's diarrhea, diarrhea in immunocompromised conditions, and water-borne outbreaks in developed areas. Diarrhea in immunocompetent patients is usually self-limited. The explosive diarrhea can present with fever, abdominal pain, and nausea. In immunocompromised patients, the symptoms are pro-

tracted, and biliary symptoms of acalculous cholecystitis and cholangitis have been described. Cholecystectomy can be helpful in these severe cases along with supportive care. Detection of the oocysts in the stool by PCR or ELISA test is diagnostic. No medication has been found effective to control infection with cryptosporidium. In patients with the human immunodeficiency virus (HIV), treatment with highly active antiretroviral therapy (HAART) can help shorten the disease course [53]. Nitazoxanide is shown to help shorten disease in immunocompetent patients. Cure rates of 60–75% are described [54]. Avoiding swimming for 2 weeks after resolution of symptoms is advisable to reduce spread of the disease.

Balantidium

The major source for *Balantidium coli* infection is pigs [55]. Ingestion of contaminated food and water allows spread of the only ciliated protozoan that infects humans. The ingested parasite cysts lodge in the colon and create ulceration and inflammation with both bloody and non-bloody diarrhea. Stool study can identify the trophozoites. Treatment with tetracycline is effective. Alternate treatment with metronidazole and doxycycline are also effective.

Giardia

Giardia lamblia is a common parasitic infection in the USA and around the world. Transmission is through water, fecal contamination, and fecal-oral spread. Consumption of untreated water in rural areas or fecal contamination of water and swimming pools leads to disease transmission. Ingestion of oocysts allows the giardia trophozoites to attach to the small bowel mucosa. The development of diarrhea usually occurs within 1–2 weeks of infection. The stool appears greasy and has a foul odor. Stool examination is able to confirm the diagnosis. ELISA or immunofluorescence antigen detection or PCR stool test is useful. Metronidazole is the first line of therapy [56].

Schistosomiasis

Trematode infection by *Schistosoma haematobium*, *S. mansoni*, and *S. japonicum* affects around 250 million people each year around the world. Most infections occur in tropical regions. It is most common in Africa. The parasite eggs are shed in urine and stool from infected hosts. Snails are intermediate hosts and the mobile cercariae are released into water. The cercariae can attach and invade the skin of a new host. They migrate to the heart and lungs, and then the liver, while continuing to mature. *S. haematobium* affects the urinary bladder, while *S. mansoni* and *S. japonicum* affect the mesentery of the small bowel and colon. The eggs are deposited in the tissues and the immune response creates significant damage to the local organs [57]. Symptoms of pain and diarrhea are common. Additional organ damage with urinary obstruction, mass, enteric fistulas, and hepatic, pulmonary, and neurologic impairment are all described. Stool evaluation commonly identifies the eggs and confirms the diagnosis. Treatment with praziquantel is effective [58]. Surgical intervention for complications of perforation and obstruction may be required but is uncommon.

Tapeworms

Parasitic flatworm infections from *Taenia solium*, *T. saginata*, *Diphyllobothrium latum*, *Hymenolepis nana*, and *Dipylidium caninum* allow growth of the worm in the GI tract of the host. Most infections are asymptomatic. *T. solium* is spread by consumption of contaminated pork. *T. saginata* is associated with contaminated beef. *T. solium* ingestion can be associated with the development of cysticercosis, associated with progressive neurologic symptoms. *D. latum* is associated with consumption of raw fish; the adult worm attaches to the terminal ileum and may be associated with megaloblastic anemia. The actual worm may be identified in the feces; ELISA and PCR stool test can help make the diagnosis. All infections respond to treatment with praziquantel. In some cases, a bowel preparation to clear the GI tract shortly after treatment can be helpful [59].

Trypanosoma

Chagas disease is caused by infection with *Trypanosoma cruzi*. Infection is endemic in Central and South America. Clinical findings are grouped into acute and chronic phases. Immediately after an acute infection, patients may manifest fever, malaise, edema, lymphadenopathy, and hepatosplenomegaly. These symptoms resolve and are followed by a latent period. Up to 30% of patients may develop chronic symptoms, while the remainder may stay asymptomatic for life. Chronic symptoms relate to end-organ damage, cardiomyopathy, megaesophagus, and megacolon [60]. The parasite is associated with damage to the GI neurons resulting in dilation and impaired function. Symptoms are related to the organ dysfunction and may include constipation, abdominal pain, dysphagia, and volvulus. Surgical intervention for complications from symptoms may be required, but is not curative. All patients with diagnosed trypanosome infection benefit from treatment [61]. Benznidazole and nifurtimox are indicated but can have significant GI and neurological side effects.

Fungal Colidities

Histoplasma

Infection with *Histoplasma capsulatum* can be associated with GI involvement. The fungal disease is endemic in the USA in the Ohio and Mississippi river valley regions. Pulmonary infection may be commonly seen. A subgroup of patients can develop progressive disseminated histoplasmosis (PDH). Patients with PDH can develop GI ulcerations, sometimes severe, deep ulcers, and pseudopolyps which can be confused with inflammatory bowel disease (IBD) or malignancy. Confirmation of the diagnosis is made with tissue culture [62]. Surgical intervention for cases of perforation or obstruction may be required. Treatment is intravenous (IV) amphotericin B. Itraconazole is an alternative but not first-line therapy.

Candida

Candida is a common organism in humans. Candida colitis is rare and it presents with diarrhea and abdominal pain. It is associated with severe systemic illness and immune compromise. Diagnosis by microscopic confirmation of budding yeast with hyphae or culture can be confirmatory. Endoscopic examination reveals white plaque-like lesions [63]. Treatment with fluconazole, with dosage based on severity of illness, can be helpful. Mortality is high in immunocompromised patients. Colectomy may be performed for perforation or peritonitis but is associated with a very high risk of death.

Other Fungal Colitidies

Colitis associated with advanced disseminated *Aspergillus* presents with fever, pain, GI bleeding, and tenderness. Complications of perforation or ischemia may require surgery. Pathology evaluation can confirm the presence of the characteristic hyphae, and culture can confirm the diagnosis. Treatment of disseminated aspergillosis is voriconazole. Amphotericin B is a second-line medication [64].

Cryptococcal infection by *C. neoformans* and *C. gattii* can affect the GI tract in severe cases. Patients are usually immunocompromised or immunosuppressed. Colitis with spontaneous perforation has been described in these patients [65]. Surgical intervention can be required to control the abdominal emergency. GI nodules from disseminated infection can mimic IBD. Biopsy with histology or culture may confirm the diagnosis. Treatment for disseminated cryptococcal infection is IV amphotericin B [66].

Viral Colitidies

Cytomegalovirus

Cytomegalovirus (CMV), a double-stranded DNA virus, is a member of the herpesvirus family. It is an extremely common pathogen with an estimated prevalence between 31% and 70% in children of various ethnicities in the USA [67]. At a global level, the seroprevalence of CMV has been estimated as high as 83% in the general population [68]. Transmission of CMV occurs through various routes including perinatal, breast milk, viral shedding in close-contact settings including sexual transmission, and blood products during transfusion and/or organ transplantation. In the immunocompetent patient, primary CMV infection is often asymptomatic. Patients at highest risk for symptomatic CMV infection are immunocompromised and immunosuppressed individuals such as those with HIV or IBD or transplant recipients. However, symptomatic CMV infection can occur in immunocompetent individuals and has been reported in elderly patients with significant medical comorbidities or critically ill individuals [69, 70].

CMV can affect various parts of the body including the brain and central nervous system, the eyes, the lungs, the heart, the kidneys, the esophagus, the liver, the pancreas, the small bowel, and the colon. It is speculated that when CMV colitis occurs, it is due to a reactivation of a latent infection secondary to an alteration in immune competence of the patient's T lymphocytes. This secondary infection is believed to be the most common cause of CMV colitis. Primary infection can occur in immunocompromised patient if not previously exposed to CMV. Symptoms of CMV colitis include fever, malaise, abdominal pain, diarrhea, rectal bleeding, and weight loss.

Endoscopic findings typically consist of mucosal friability and ulcerations of the colon. CMV can present as an ischemic-like colitis or a polypoid mass suspicious for colon cancer [71–73]. Biopsies of the colon taken during colonoscopy are critical in establishing the diagnosis as seropositivity for CMV is very common in the general population and cannot provide a definitive answer regarding active infection. It is important to take representative biopsies from various parts of the colonic lesions including the edges. The identification on hematoxylin and eosin (H&E) stains of CMV inclusion bodies surrounded by a clear halo ("owl's eye"), surrounded by inflamed cells, is indicative of active CMV colitis. Inclusion bodies surrounded by normal-appearing cells may represent colonization. Due to the low sensitivity of the H&E stains, PCR tests or CMV-specific immunohistochemistry is advisable if the diagnosis is not confirmed initially by H&E stains.

Active CMV colitis should be treated. Treatment is initiated via the intravenous route in severely ill patients and followed by oral treatment. Ganciclovir and foscarnet are the anti-viral medications of choice [74]. Surgical intervention is undertaken in patients who fail medical management or those with persistent bleeding and/or perforation. While perforation can occur in various parts of the digestive tract, most perforations are noted between the ileum and the splenic flexure [75]. Multiple areas of perforations can be encountered, especially in immunocompromised patients. Resection without primary anastomosis and fecal diversion is advisable. The morbidity and mortality of CMV colitis with perforation is significant. Galiatsatos reported a 31% mortality in immunocompetent patients [76]. In immunosuppressed and immunocompromised patients, the mortality can be significantly higher [75].

Other Viral Colitidies

While CMV colitis is the most relevant for a colorectal surgeon's practice, it is important to note that several other viruses can cause inflammation and gastrointestinal infections and are worthy of brief mention in this chapter. Such viruses include rotavirus, Norwalk virus, astrovirus, picobirnavirus, calicivirus, herpes simplex virus (HSV), norovirus, sapovirus, and adenovirus. Most of these viruses cause gastroenteritis with predominant symptoms associated with upper gastrointestinal disease (such as nausea, vomiting, diarrhea); but some can cause colitis as well. HSV-2 is associated with sexually transmitted proctitis. Due to the symptom overlap between gastroenteritis and colitis, i.e., abdominal pain, cramping, and diarrhea, the proper diagnosis requires careful assessment of the patient. These viruses have been implicated in outbreaks but can also affect immunosuppressed and immunocompromised patients such as those with inflammatory bowel disease [77, 78].

Infectious Colitis in Immunocompromised Patients

Inflammatory Bowel Disease

Patients with inflammatory bowel disease (ulcerative colitis and Crohn's disease) and infectious colitis pose specific challenges for the treating clinician for two main reasons: delay in diagnosis and the overall health status of the patient in terms of malnutrition, anemia, and immunosuppression. The clinical presentation and endoscopic findings of inflammatory bowel disease may be indistinguishable from infectious colitis. Furthermore, initial investigative studies including stool analysis and endoscopic biopsies may not demonstrate superimposed infection. Patients with inflammatory bowel disease are susceptible to infectious colitis; but unless promptly diagnosed with a superimposed infection, they are often treated for exacerbation of their inflammatory bowel disease by escalating their immunosuppression therapy which can lead to disastrous complications with sepsis and perforation. Thus, patients with inflammatory bowel disease with progressive symptoms should be evaluated carefully with suspicion for an infectious element entertained. A multidisciplinary evaluation with repeat testing and assessment should be considered in order to optimize the patient's outcome.

All types of infectious colitidies have been reported in inflammatory bowel disease patients including bacterial, mycobacterial, fungal, viral, and parasitic [74, 79–83]. Some patients with infectious colitidies may present with extraintestinal organ involvement such as the liver, lungs, or brain. The incidence of parasitic-related infections can vary depending on endemic areas. Soylu from Turkey reported regional variations in the incidence of amebiasis in patients with ulcerative colitis within the same country [81]. Of particular interest in the setting of inflammatory bowel disease is *Clostridium difficile*-superimposed infection. This entity has been well described and is now routinely tested for in patients with worsening inflammatory bowel disease symptoms [84–89]. Inflammatory bowel disease is associated with a higher rate of treatment failure and recurrence. *Clostridium difficile* infection is addressed in another chapter of this textbook.

CMV infection is prevalent in patients with inflammatory bowel disease, with a reported incidence of 10–33% [80, 90–92]. While CMV infection can occur in both ulcerative colitis and Crohn's disease, it is more common in ulcerative colitis [74]. The multiplex PCR assay of stool is one of the best methods to test for CMV and other causes of infectious colitis [93, 94]. While CMV presence may not be the cause of symptoms, treatment should be strongly considered in patients with severe symptoms or those who are steroid-resistant. Furthermore, the use of anti-viral therapy for CMV may yield a beneficial long-term effect on the management of patients with inflammatory bowel disease [95].

Immunosuppression for inflammatory bowel disease and/or other autoimmune disorders can hinder the immune system's capability to limit the extent or progression of infectious colitis. Steroids and other immune-modulating drugs including biologic therapy, such as anti-TNF inhibitors, may have a profound effect on the immune system. Infectious colitis in patients on steroids therapy can lead to progression of disease and perforation whether there is underlying inflammatory bowel disease or not [22, 96]. Abbas reported a case of perforation in a patient presumed initially to have ulcerative colitis exacerbation and treated with prolonged steroids therapy [22]. Surgical resection revealed severe amebic colitis without evidence of inflammatory bowel disease.

Human Immunodeficiency Virus

The description of the human immunodeficiency virus (HIV) in the 1980s led to significant advances in our understanding of the immune system, its complex cascades of reactions, and interactions with environmental factors such as infections. HIV targets T lymphocytes of the CD4+ type leading to impairment of the immune system and its ability to fight certain infections. In the early days of the HIV epidemic, most patients succumbed to cachexia and overwhelming opportunistic infections affecting the various organs including the lungs and the digestive tract. The digestive tract is a major site for viral replication leading to depletion of CD4+ T cells.

Patients with HIV are susceptible to all the various types of infectious colitidies described earlier in this chapter including bacterial, fungal, parasitic, and viral [74]. Patients with CD4+ T cell count less than 200/mm^3 are at significant risk for developing opportunistic infections. Gastrointestinal symptoms are common in patients with HIV with diarrhea being the most frequent [97–99]. The most common type of opportunistic colitis in HIV patients is CMV [100, 101]. A thorough investigation is necessary especially in patients with low CD4+ count and those who do not respond promptly to conservative medical management. Stool studies and endoscopic evaluation with biopsies can be helpful [97, 102]. A new generation of stool tests such as the multiplex PCR assay can detect many various types of viral as well as bacterial and parasitic infections [94, 103]. The use of highly active antiretroviral therapy (HAART) for HIV improves the immune system response by increasing the CD4+ count [104, 105].

Transplant Patients

Transplantation has revolutionized the world of medicine and provided the opportunity for a cure or long-term survival for previously fatal conditions. However solid organ transplantations are not without risks when it comes to long-term immunosuppression. Despite significant advances in the management of immunosuppression and the introduction of a newer generation of less toxic medications, the risk of infectious complications remains significant. Gastrointestinal infections and diarrhea are common in the solid organ transplant population with some series reporting the incidence of diarrhea between 22% and 52% [106–108]. It is important to differentiate infectious diarrhea in transplant patients from diarrhea associated with immunosuppression medications. A retrospective review of 422 admissions of transplant patients with diarrhea over 18-month period reported that the majority of cases had no identifiable etiology and were often self-limited. The most common identifiable infectious were *Clostridium difficile*, norovirus, and cytomegalovirus [109]. The clinical history especially in respect to any associated symptoms and medication usage, coupled with diagnostic investigation, is of paramount importance. Workup includes blood tests inclusive of complete blood count, renal and liver function tests, blood cultures (if warranted), and stool studies including the PCR-based multiplex GI pathogens testing. Colonoscopy is considered in patients with persistent severe symptoms and negative preliminary workup.

Clostridium difficile Infection

52

Ian M. Paquette and David B. Stewart

Key Concepts

- More virulent strains of *C. difficile* such as ribotype 027 are associated with severe clinical infection.
- CDI in IBD patients should be treated with vancomycin.
- CDI is often associated with an exaggerated leukocytosis.
- Fecal transplant is effective therapy for recurrent CDI.

Introduction

Clostridioides (formerly Clostridium) difficile is an anaerobic, Gram-positive rod bacterium, which often is part of normal colonic flora, but can become a pathogenic organism under the appropriate circumstances when the microbiome is altered. While this was once an uncommon clinical entity, *Clostridium difficile* infection (CDI) is now responsible for at least 20% of the cases of antibiotic-associated diarrhea, and its incidence continues to steadily rise [1]. As the incidence of this disease has increased, the emergence of more virulent strains, such as ribotype 027, has led to increasingly severe clinical presentations [2–4]. As we have seen evolutions in the *Clostridium difficile* bacterium, management strategies have drifted away from the older recommendation of metronidazole as a first-line agent to newer strategies using vancomycin or fidaxomicin [5–9]. This chapter will discuss the epidemiology of CDI and the most pertinent clinical risk factors. We will discuss current microbiological nomenclature and the evolving testing strategies. Finally, we will discuss the current best recommendations for medical and surgical treatment of this disease, as well as the evolving role for fecal microbiota transplantation (FMT) [10] as an alternative to classical medical and surgical options for CDI.

Epidemiology

Evidence is mounting that both the incidence and severity of CDI are increasing [11–13]. In fact, recent evidence suggests that in many hospital settings, CDI has now become the most common cause of hospital-acquired infection, surpassing methicillin-resistant *Staphylococcus aureus* (MRSA) infection [14, 15]. Data from the Centers for Disease Control and Prevention (CDC) suggested a fourfold increase in CDI from 1993 to 2009, while the incidence in those over age 65 increased by over 200% [16].

In addition to an overall increasing incidence, there appears to be an increasing severity as well. At least one ribotype (ribotype 027) has been associated with >15 times the production of toxins A and B compared to other strains, as well as producing a third toxin called binary toxin. This strain has been associated with a higher incidence of toxic colitis and increased mortality [17, 18]. A study by Falcone examined clinical response to antibiotic treatment in 027^{+} vs. 027^{-} subtypes. Overall, metronidazole monotherapy (HR 2.38, 95% CI 1.55–3.60, $p < 0.001$) and immunosuppressive treatment (HR 3.11, 95% CI 1.91–5.09, $p < 0.001$) were associated with recurrent CDI in ribotype 027-positive patients [4]. The authors advocated for vancomycin as primary treatment over metronidazole in cases where ribotype 027 is identified.

The increasing incidence of this condition is both clinically and financially important. A recent meta-analysis by Nanwa examined studies from 1988 to 2014 to determine the economic impact of CDI. The main outcome was the total direct cost attributable from hospital stays for CDI. Attributable direct costs of CDI ranged from $8911 to $30,049 [19]. A second study by McGlone agreed with these estimates for cost of a hospitalization and extrapolated to an

S. R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, https://doi.org/10.1007/978-3-030-66049-9_52

annual US economic burden of $496 million (hospital perspective) and $547 million from a third-party payer perspective [20]. When both estimates from an inpatient and outpatient perspective are considered, the cost to the US healthcare system has been estimated to be a staggering $3 billion [21]. Given the increasing incidence and cost of CDI, it is important to fully understand the most current risk factors, diagnostic testing, and treatment strategies.

Clinical Risk Factors

Advanced Age

Though increasing age is commonly cited as a risk factor for CDI [22–25], patients of any age may be affected. The majority of the literature on age in CDI suggests that both young and older patients with CDI have similar clinical presentations and comorbidities, indicating that medical comorbidities rather than age may be the most important risk factors predisposing to CDI [22, 24]. Lee compared patients younger than 65 to those older than 65 and found more severe colitis in older patients and more frequent failure of first-line treatment, suggesting the need for more aggressive initial treatment in older patients hospitalized with CDI [23]. Louie randomized patients to be treated with vancomycin or fidaxomicin for severe CDI. Compared to patients age 18–40, clinical cure rate was lower, and clinical recurrence was higher for each successive decade [25].

Antibiotic Treatment

The most consistent and potentially modifiable risk factor for the development of CDI is antibiotic use. Though the most commonly reported antibiotics implicated are clindamycin, fluoroquinolones, carbapenems, and cephalosporins [26–34], it appears that almost any antibiotic, used over any period of time, can be associated with the development of CDI. A recent systematic review compared the impact of different classes of antibiotics on the development of CDI in the setting of randomized trials. The results compared all classes of antibiotics and quantified individual risks of CDI. Clindamycin and carbapenems appeared to be the most strongly associated antibiotics with CDI [28]. Another contemporary review by Slimings of 13 heterogeneous studies indicated that second-, third-, and fourth-generation cephalosporins (OR 3.2), clindamycin (OR 2.8), and fluoroquinolones (OR 1.6) were the most commonly cited agents [35]. Though these studies are quite heterogeneous and it is difficult to assess the impact of antibiotics in comparison of the other myriad of risk factors, it does serve to remind us that antibiotics should be used judiciously in both the prophylactic and therapeutic settings and that inciting antibiotics should be discontinued as soon as possible once CDI is diagnosed [26, 28–34]. Though it is postulated that antibiotics cause changes in colonic bacterial flora leading to susceptibility to CDI, most of the available data is descriptive in nature. Certain species of bacteria such as *Bacteroides*, *Bifidobacteriae*, *and Lachnospiraceae* seem to be the most prevalent among species which confer resistance to *C. difficile* colonization [36].

There is some degree of controversy as to whether probiotics should be used for primary prevention of CDI when a course of antibiotic therapy is prescribed. There are meta-analyses suggesting that probiotics could decrease the incidence of CDI when given to patients on antibiotics with no prior history of CDI [37–39]. Arguments against this strategy suggest that the incidence of CDI in hospitalized patients > age 65 on antibiotics tends to be <3% even without probiotics [40]. Additionally, the meta-analyses contained some studies with higher than expected incidence of CDI; excluding these studies makes the magnitude of effect of probiotics much less impressive. Additionally, due to the heterogeneity in types of probiotic and the numerous clinical confounding factors, it is difficult to say at this time whether these agents should be used as a means of primary prevention of CDI.

Contact with a Healthcare Facility

CDI is common both in acute care and longer-term health facility stays. This is likely due to a concentration of patients with the typical risk factors for CDI, as well as the transmission from patient to patient via the fecal-oral route. In addition to the usual clinical risk factors, hospital-related factors such as increasing bed occupancy have been associated with an increased risk of developing CDI [41]. It is increasingly clear that hospitals need to be aware of the potential to transmit CDI among patients and to have proper infection control practices in place [42]. These practices include antibiotic stewardship, contact precautions in the appropriate setting, hand washing, disinfection practices, and CDI treatment protocols. Though literature has shown decreased incidence in CDI when proper disinfection practices [43], antibiotic stewardship [30, 44], and hand washing with soap rather than alcohol-based disinfectants [42, 45] decrease the incidence of CDI, not all hospitals follow these practices. A recent study by Aquina used a New York statewide database to study 150,878 patients in New York having either a segmental colectomy or proctectomy. *C. difficile* incidence ranged from 0% to 11.3% among surgeons and 0% to 6.8% among hospitals. Importantly, patient factors only explained 24% of the variation, while approximately 70% of the variation was from unexplained hospital factors [46]. This highlights the

need to be vigilant when caring for hospitalized patients, as the risks for CDI transmission are significant.

Immunocompromised States

Regardless of the cause, compromise of the immune system appears to be associated with the development of CDI. It remains unclear whether immunosuppression alone is sufficient for the development of CDI, or whether immunocompromised patients frequently become hospitalized and have several of the other clinical risk factors for CDI. HIV patients seem to be at risk to develop CDI, with several of the common risk factors for infection also being cited such as low serum albumin, clindamycin use, prolonged hospital stay, and proton pump inhibitor use [47–50]. The strongest risk factor for CDI in HIV patients appears to be a CD4 count ≤50/mm3, with an adjusted odds ratio of 5.2–27.6 [48, 51]. There are many reports in the literature of CDI in other settings of immunocompromise such as general oncology patients [52], solid organ transplant recipients [53, 54], or stem cell transplant recipients [55–57]. Although these patients do have compromised immune systems, most of them seem to exhibit the classic risk factors for CDI as well such as prolonged hospitalization and antibiotic use [52, 54, 55, 57].

Inflammatory Bowel Disease

CDI has been increasing in inflammatory bowel disease (IBD) patients and may be associated with increased morbidity, mortality, and need for surgery [58, 59]. Patients with both Crohn's disease and ulcerative colitis both appear to be at risk, and clinical presentation with CDI most often happens during an acute disease exacerbation. There is some evidence that specific genetic polymorphisms may be associated with the development of CDI. One such study noted that the TNFRSF14 locus was associated with a sixfold increase in development of CDI [60]. Some of the clinical risk factors for the development of CDI in the setting of IBD are low serum albumin, hemoglobin level below 9 g/dl, active colitis from IBD, biologic use, and antibiotic use [61, 62].

Though most studies consistently show a relationship between active colitis, steroid use, and antibiotic use with CDI, some studies failed to show an association between biologic medication use and CDI [63]. Testing for CDI is recommended in patients with IBD and severe colitis. Though the evidence supports the early administration of vancomycin to treat the CDI [64], these patients need close clinical monitoring in the hospital, as at least one study has estimated a sixfold increase in the need for colectomy in this setting [65].

Perioperative Prophylactic Antibiotics and Mechanical Bowel Preparation

In preparation for elective colectomy, patients for several decades have typically received a combination of mechanical and oral antibiotic bowel preparation [66]. This was thought to minimize infectious complications by decreasing both the load of stool and bacteria in the colon. For many years, bowel preparation was used less and less, as the oral antibiotic preparation was abandoned. Recently, many studies have highlighted improved outcomes with mechanical bowel preparation and oral antibiotics including decreased surgical site infection (SSI) and anastomotic leak [67–71]. Some data also suggests that even in the absence of a mechanical bowel preparation, oral antibiotics may still decrease the incidence of SSI following colectomy [72]. It is possible that beneficial changes in the microbiome may be responsible for these improved surgical outcomes [73, 74]. However, there are some concerns that changes in the colonic microbiome may make a patient more susceptible to pathogens such as *C. difficile*. Literature on this topic is quite sparse. While on one hand, a single study by Morris noted that 9.5% of CDI patients had only preoperative oral antibiotic utilization as the only clinical risk factor [75], this likely does not outweigh the benefits of these agents in reducing SSI and potentially anastomotic leak. Further, the comparative data described above actually showed that patients receiving mechanical bowel preparation with oral antibiotics had a *lower* incidence of CDI postoperatively.

Likely the most important factor in reducing CDI is the appropriate adherence to guidelines and cessation of perioperative antibiotics as soon as feasible. A study by Balch showed that patients who had perioperative antibiotics continued for greater than 24 hours had a 6.7-fold increase in the incidence of CDI compared to those who received 24 hours of therapy alone [27].

Proton Pump Inhibitors

There appears to be a clinical association between proton pump inhibitors and CDI, though it is difficult to directly attribute causation owing to the numerous other clinical risk factors that are often present. The exact mechanism for this association remains unclear, but at least one recent in vitro study by Stewart indicated that omeprazole stimulated the production of *C. difficile* toxins in both acidic and basic environments [76]. Since many conflicting studies have been published, there were 4 recent meta-analyses performed, combining data on over 300,000 patients [77–80]. These analyses were limited due to significant heterogeneity of data, and two of the studies noted publication bias. Combined

studies suggest an odds ratio of 1.6–1.7 for the development of CDI for hospitalized patients on PPIs [77–80].

One observational study by Chitnis examined 984 cases of community-acquired CDI. In this population, 36% had not received antibiotics. The most common risk factor was use of PPI medication, which was present in 31% of patients [81]. Though there appears to be a clinical correlation between use of PPIs and development of CDI, the quality of the evidence is poor. Randomized clinical studies with proper consideration of other clinical risk factors are lacking. Though this does not support the global discontinuation of PPIs in hospitalized patients, physicians should be encouraged to use these medications judiciously, when there is a clinical indication to do so. Many patients are routinely placed on PPI medication as a means of "prophylaxis" or for other questionable clinical indications [82]. The risk of CDI could be a reason to call these practices into question.

Nomenclature and Genetics of *C. difficile* Infection

The proper genus designation for this pathogen is *Clostridioides* and not *Clostridium*. This change in terminology, introduced in 2016, was prompted by phylogenetic studies indicating that the genus *Clostridium* should be restricted to *Clostridium butyricum* and similarly evolutionarily related species that shared genetic and functional characteristics common to *Clostridium* cluster [83–85]. Despite being an anaerobic, spore-forming, Gram-positive rod, *Clostridioides* has more in common with genus *Peptoclostridium*. Its official reassignment to this genus never occurred, however, due to concerns that the pathogen's former name recognition would make the introduction of such a different moniker a source of confusion and generate a significant financial burden to research and medical fields due to re-labelling costs. Therefore, a new genus was proposed (*Clostridioides*), one similar enough to the former name to allow continued broad recognition and one clever enough to allow the continued use of the term "*C. difficile*."

CDI is clinically characterized by a colitis that is, in large part, mediated by bacterial envenomation. The genetic basis for *C. difficile* toxin production includes a 19.6 kb region known as the pathogenicity locus (PaLoc) that contains the genes for clostridial toxins A (*tcdA*) and B (*tcdB*) [86, 87]. These toxin genes, and the regulatory genes that increase and decrease their expression, are actually of bacteriophage (viral) origin [88, 89]. With successive replicative errors, loss of portions of these previously viral genes, under selective pressure, resulted in their retention as bacterial genes that increase the fitness of *C. difficile* [90]. Some, though not all, strains of *C. difficile* can produce an additional toxin known as binary toxin (*CDT*) encoded by genes outside of the *PaLoc*. Toxins A (308 kDa) and B (269 kDa) are classified as large clostridial toxins due to their larger molecular weight [91]. Both of these toxins initiate monoglucosylation of a variety of intracellular Rho GTPases that result in depolymerization of cytoskeletal elements, with resultant cytopathy of colonocytes [92]. Binary toxin has an ADP-ribosyltransferase function that requires internalization by colonocytes; to promote this internalization, binary toxin is able to induce colonocytes to alter the apical aspect of their cell membrane to produce microtubular protrusions, increasing the membrane surface area up to fivefold and promoting the adherence of both *C. difficile* and its toxins, promoting further mucosal damage [93, 94]. Although updated studies are needed, the most current data suggests that binary toxin is present in up to 6% of all *C. difficile* isolates [95]. In virtually all symptomatic infections among humans, toxins A and B will be present.

Ribotype and Clinical Severity

Although more frequently incorporated into research than clinical care, efforts at characterizing the dominant *C. difficile* strain on the basis of bacterial genotype have most commonly involved a process called ribotyping, a process using restriction enzymes to characterize the heterogeneity of the bacterial ribosomal intergenic spacer region [96, 97]. The most frequently identified ribotype associated with severe forms of *C. difficile* infection is ribotype 027 [98]. Though there are exceptions to the following, several associations between this ribotype and the clinical characteristics of CDI have emerged [99]. Ribotype 027 is the most frequently encountered strain among patients admitted from long-term healthcare facilities, with one study identifying an odds ratio of 4.87 for 027 being present compared to patients admitted with CDI from a private residence [100]. This may be a reflection of this ribotype having a selective advantage in terms of colonization and the promotion of a carriage state. Ribotype 027 is able to outcompete endemic bacteria for resources while producing larger volumes of bacterial toxins and producing higher rates of symptomatic infections; this strain also frequently has the ability to produce binary toxin in addition to toxins A and B [101]. Investigations focused on comparative bacterial genomics reveals that ribotype 027 has more than 200 genes not found in other strains of *C. difficile*, with many of these genes having a plausible role in promoting virulence [102, 103]. Other ribotypes, such as 078, represent potentially virulent strains that also have a zoonotic link between human and animal CDI. *C. difficile* as a pathogen has soil, animal, and human reservoirs, creating an important interaction between humans and their environment in terms of the emergence of new virulent strains of this bacteria [104, 105].

Diagnosis of *C. difficile* Infection

CDI is a disease capable of producing both toxin-mediated and toxin-independent forms of colitis (160), and thus the hallmark of symptomatic infection is diarrhea. The term "*C. difficile* infection" should be kept distinct from carrier states, defined as patients without symptoms of infection who nonetheless also have a positive stool test for *C. difficile*. The exact incidence of carrier states in the general population is not known, though small studies of patient populations at risk for CDI suggest the incidence is not small. In 1 study of geriatric patients without diarrhea, 43 (16.4%) out of 262 consecutive patients tested positive for toxin B based on PCR stool testing. Of those 43 patients, 7 (16.3%) eventually developed symptomatic CDI, confirming that carrier states are both more common among patients with frequent healthcare facility contacts and predispose patients to symptomatic infection [106]. Studies have suggested that patients who are able to form antibodies to *C. difficile* toxin A are more likely to remain asymptomatic carriers compared to patients who develop symptoms of CDI [107].

Diarrhea, which is typically grossly non-bloody in this disease, is the primary symptom of CDI. Depending on the severity of CDI, other findings will include abdominal distention, abdominal pain that is frequently colicky due to colitis, tachycardia, and hypotension. In fulminant cases, localized or generalized peritonitis may develop, which serves as an indication for surgery. CT findings include colonic wall thickening and pericolic fat stranding, as would be observed with any form of colitis. Colonic wall thickening is characteristic of severe forms of CDI and can provide a heightened index of suspicion for CDI prior to the results of stool testing. Transudative ascites is frequently associated with more severe forms of colitis. Pneumoperitoneum and portal venous gas are rarer radiographic findings and are generally encountered in patients with fulminant forms of the infection with septic shock and the need for vasopressors; the patients often develop non-viable colon due to severe mesenteric vasoconstriction.

Diagnostic Tests for CDI

In general, the diagnosis of CDI is founded on a clinical suspicion with support from specific laboratory testing. The original confirmatory test for CDI was bacterial culture, which proved to be both difficult and was plagued by a lengthy time interval to final results. This technique was replaced by the cell culture cytotoxicity neutralization assay (CCCNA). This approach uses a filtrate of patient stool applied to a monolayer of one of various cell lines. After a 24–48-hour incubation period, cells are evaluated for evidence of cytopathy attributable to *C. difficile* toxins. If cytopathic changes are observed, a neutralization assay is then performed to assure that these changes are due to *C. difficile* toxins. Historically, this technique was considered to be the gold standard; but with sensitivities as low as 65%, this test has been replaced by more sensitive tests that provide more expeditious results and do not require technical expertise that may limit generalizability [108].

Another, now outdated, method involves toxigenic culture. Though there are multiple methods to accomplish this test, all of them focus on isolating *C. difficile* from stool samples and confirming the presence of its toxin. There were numerous steps and difficulties with this approach. First, there is no one superior approach to isolating *C. difficile* from candidate stool samples. Secondly, once *C. difficile* colonies are isolated, those colonies have to be evaluated for their ability to produce toxin. This technique is considered by some to be a gold standard in terms of serving as a reference for new testing methods, though in terms of current practice, it has been supplanted by simpler, quicker, and less exacting approaches.

A current method of testing involves immunoassays that detect glutamate dehydrogenase (GDH), a conserved metabolic enzyme ubiquitous among *C. difficile*. As it is present among toxigenic and non-toxigenic forms of *C. difficile*, GDH alone lacks specificity for clinical purposes. Therefore, GDH is a useful screening test that, when positive, must be followed by a confirmatory test, which generally involves a toxin enzyme immunoassay (EIA). This approach allows for the use of a GDH as a high sensitivity test (80–100%) with an excellent negative predictive value, with limited cost and limited requirement for expertise and with rapid turnaround. When combined with toxin EIA, the cost per test remains less than PCR-based diagnostics while providing rapid results (<24 hours) and excellent sensitivity.

Nucleic acid amplification tests (NAATs) are a collection of PCR-based diagnostics that are designed to amplify highly conserved *C. difficile* genes, such as those related to toxins A (*tcdA*) and B (*tcdB*). The sensitivity of these tests is greater than EIA and possibly GDH-EIA combinations, though their cost is two to three times greater than GDH-EIA, and NAATs may require longer result times depending on the particular test considered. To leverage sensitivity, specificity, and cost-related issues, many hospitals have adopted an algorithmic approach, where diarrheal stools are first tested using a GDH assay. A negative result marks the end of the testing algorithm, while a positive GDH assay is followed by a confirmatory test, usually a toxin EIA. A positive GDH assay followed by a positive toxin EIA in patients with symptoms of CDI is treated as a case of CDI. A stool that is GDH positive and toxin EIA negative is tested using a NAAT. Routine retesting with NAATs to confirm resolution of CDI is not recommended, given the potential for bacterial DNA to linger for

as long as 30 days resulting in patients who no longer have CDI but who test positive for this infection.

Clinical Measures of Severity

Several clinical severity scoring systems are available, though none has emerged clearly superior to the others. Perhaps the two most commonly utilized are the 2017 Infectious Disease Society of America (IDSA) guidelines [109] and those published by the American College of Gastroenterology (ACG) [21]. In the IDSA schema, initial episodes are classified as (1) non-severe, if a patient's white blood cell count is <15,000 cells/mL and if their serum creatinine is <1.5 mg/dL; (2) severe, if a patient's white blood cell is >15,000 cells/mL and if their serum creatinine is >1.5 mg/dL; or (3) fulminant, if the patient demonstrates evidence of cardiovascular shock, ileus, or megacolon. The ACG schema defines severe CDI as patients with a white blood cell count of ≥15,000 cells/mL or a serum albumin of <3 g/dL. Fulminant disease is then defined as any patient requiring ICU admission, with a temperature of ≥38.5 °C, ileus, significant abdominal distention, altered mental status, a white blood cell count of >35,000 cells/mL or <2000 cells/mL, a serum lactate of >2.2 mmol/L, or any evidence of organ dysfunction. Using scoring systems such as these offers the potential advantages of standardizing patient assessments across providers and institutions.

Antibiotic Therapy for CDI

For more than 20 years, the two principal antibiotics used to treat CDI were metronidazole and vancomycin. Data has accumulated to suggest that vancomycin is the superior treatment option compared to metronidazole. For example, in a 2007 randomized, prospective, double-blind, placebo-controlled trial by Zar, 150 patients with either mild or severe CDI were randomized to either oral metronidazole (250 mg 4 times daily) or vancomycin (125 mg 4 times daily). While no significant difference in clinical cure rates was noted among patients with mild disease, for study subjects with severe disease, vancomycin was associated with a significantly higher cure rate (97% versus 76%; $p = 0.02$) [110].

Additionally, retrospective data specifically focused on the treatment of mild disease suggests that vancomycin is superior to metronidazole in these cases as well, with one study reporting that compared to vancomycin, metronidazole was an independent risk factor for treatment failure [110]. Given these data, the most recent IDSA recommendations state "Use of oral metronidazole, however, should be restricted to an initial episode of nonsevere CDI in cases where other therapies are contraindicated or not available, and treatment should be limited to one course due to case reports of neurotoxicity with prolonged or repeated use." Between these two drugs, vancomycin has emerged as the recommended drug for mild and severe forms of CDI [109].

Fidaxomicin is a macrocyclic drug designed to exhibit a narrow antibiotic spectrum mediated through inhibition of the sigma subunit of RNA polymerase. The first Phase III study comparing fidaxomicin to vancomycin enrolled 629 subjects, demonstrating that fidaxomicin was non-inferior to vancomycin with respect to clinical cure rates [111]. Additionally, lower recurrence rates were noted with fidaxomicin, though only with strains that were not NAP-1 (a nomenclature of strains associated with more virulent infections). A more recent study (the EXTEND study) evaluated 364 patients randomly assigned to either vancomycin or extended pulsed fidaxomicin. Fidaxomicin was associated with an 11% improvement in clinical cure at 30 days after the end of treatment compared to vancomycin [112]. Further, fidaxomicin was just as safe as vancomycin, with no difference in treatment-related adverse events. A recent Cochrane Database Systematic Review evaluated 22 studies representing a total of 3215 patients. This study concluded that "moderate quality evidence suggests that vancomycin is superior to metronidazole and fidaxomicin is superior to vancomycin. The differences in effectiveness between these antibiotics were not too large and the advantage of metronidazole is its far lower cost compared to the other two antibiotics" [113].

For a first episode of non-severe CDI, the best available evidence supports the use of either vancomycin 125 mg orally every 6 hours or fidaxomicin 200 mg every 12 hours, either for 10 days. For fulminant cases, the most effective treatment remains the use of oral vancomycin 500 mg every 6 hours. In many instances, patients with fulminant CDI will develop an ileus, potentially decreasing the safety and efficacy of orally administered drugs. Therefore, for patients with fulminant CDI with concerns regarding the appropriateness of orally administered therapies, vancomycin can be administered as a retention enema (500 mg diluted in 100 cc of normal saline every 6 hours) [114], though the quality and strength of clinical data supporting vancomycin enemas is weak. In the setting of fulminant CDI, the Infectious Diseases Society of America also recommends administering 500 mg of parenteral metronidazole every 8 hours in conjunction with oral or rectal vancomycin, as the risks and side effects of a limited course of metronidazole are small in comparison to the risk of progressively worsening CDI.

Surgery for CDI

The incidence of patients who undergo surgery (Figs. 52.1, 52.2, and 52.3) for CDI has been estimated to be as high as 10% [115–117]. Inherent in these estimates are decisions

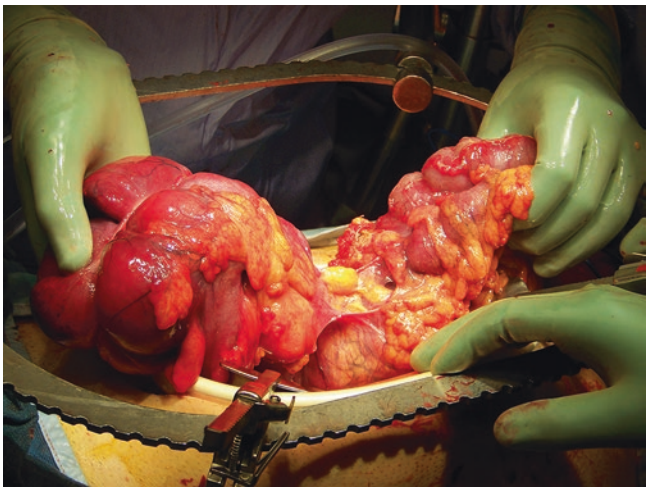

Fig. 52.1 Patient with fulminant CDI with a dilated and thickened colon, with telangiectasias and serositis indicative of severe, transmural inflammation mediated by *C. difficile* toxins

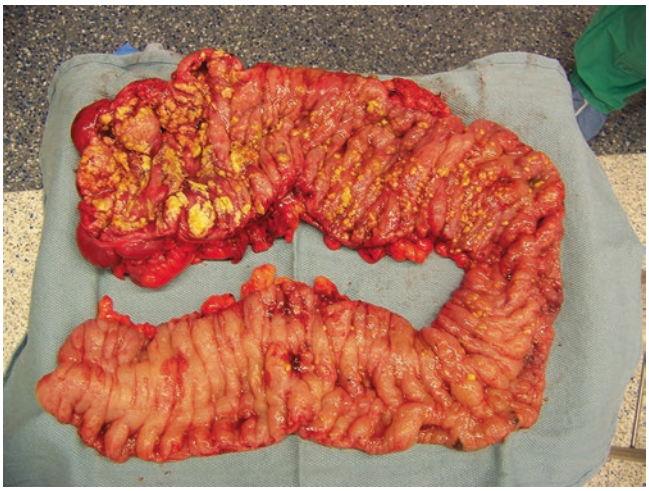

Fig. 52.3 Gross findings of mucosal thickening, inflammation, and pseudopolyps, consistent with severe CDI

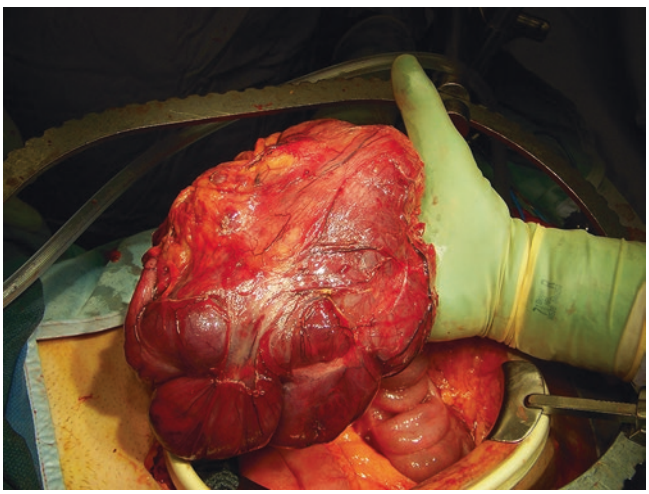

Fig. 52.2 Non-confluent regions of transmural ischemia observed in a patient with fulminant CDI. The combination of bacterial toxins as well as septic shock can produce non-viable large intestine

assessing whether a patient has received maximal medical therapy for CDI with surgery remaining as the only option, as well as selecting which patients might meet this qualification but are not considered to be candidates for surgical intervention. Multiple series indicate that only a small percentage of patients with fulminant CDI will undergo surgery; this suggests that the majority of CDI patients will not develop medically refractory disease severe enough to warrant surgery [115–117]. With the more recent introduction of diversion and colonic lavage [115], if it becomes more commonplace, it may increase the incidence of surgical intervention for CDI as it may be considered a "more survivable" surgery than total colectomy, which serves as the traditional procedure of choice.

There are two systematic reviews that compare the survival benefit of total abdominal colectomy to continued medical therapy in the setting of fulminant CDI, although the particular vantage points by which they evaluate this question differ in important respects. In a review by Bhangu, 31 studies were included in an effort to compare survival rates among patients with fulminant CDI who either underwent colectomy or who continued with medical therapy. In the surgical cohort, 89% of patients underwent a total colectomy, but patients who underwent a partial colectomy were also included. Findings from this review included a statistically significant association between preoperative clinical findings of septic shock and the incidence of postoperative mortality. Of interest, patients who underwent a partial colectomy experienced a 16% reoperation rate with resection of an additional length of colon. This review provided support for a survival benefit for surgical intervention in cases of fulminant CDI, with total colectomy arguably the preferred form of surgery compared to partial colectomy [118].

A second systematic review described outcomes among 510 patients for the purpose of evaluating whether total colectomy was associated with a survival benefit in the setting of medically refractory, fulminant CDI. The pooled odds ratio for mortality was significantly lower in patients undergoing total colectomy (OR = 0.70) [119]. Importantly, this study excluded patients undergoing partial colectomy.

In 2011, Neal described an alternative to total colectomy, involving the construction of a diverting loop ileostomy allowing for intraoperative colonic lavage with 8 liters of polyethylene glycol, followed by postoperative intraluminal vancomycin provided per stoma. In this study, 42 patients with fulminant CDI were treated with intestinal diversion, and their outcomes were compared to a historical control group of patients treated with colectomy and an end ileos-

tomy. The colectomy and diversion populations demonstrated similar preoperative APACHE scores as well as preoperative clinical indices, suggesting similar degrees of CDI severity. The group undergoing diversion was observed to have a significantly lower postoperative mortality (19% versus 50%) and shorter length of surgery, and 83% of the patients undergoing diversion had their surgeries completed laparoscopically [115]. This study provided the first modern description of diversion for life-threatening colitis of an infectious etiology, providing ostensibly superior survival utilizing a much smaller and more tolerable surgery that would also offer a higher likelihood of restoring gut continuity.

Since the study by Neal and colleagues, a number of primarily retrospective studies on diversion for fulminant CDI have been published using either institutional- or population-level data. One such study was undertaken in 2017 by the EAST Multi-Center Trials Committee that collected data from ten participating centers [120]. Certain details, such as the definition of CDI and the form of stool testing used at the participating centers, were not described. Comparing patients who underwent total colectomy to those who underwent diversion, there were no statistically significant differences in median vital sign measurements, white blood cell counts, lactate levels, INRs, or APACHE scores.

There were no differences between the surgical cohorts with respect to postoperative outcomes such as the rate of any complication, pneumonia, acute renal failure, sepsis, and acute respiratory distress syndrome. Just as importantly, there was no difference in rates of overall as well as unplanned reoperations, while ventilator days, ICU, and hospital lengths of stay were also similar between these groups. Unadjusted mortality was comparable between the cohorts (23.8% in the diversion cohort and 33.8% in the colectomy cohort; $p = 0.44$). The authors of this study also performed calculations for what they termed adjusted mortality, which involved an inverse probability of treatment weights propensity score analysis. With this adjustment, mortality was significantly lower among the diversion group (17.2% versus 39.7%; $p = 0.002$) [120].

A 2019 study using data from the Nationwide Inpatient Sample suggests that more surgeons are adopting diversion as the surgery of choice for fulminant CDI. In a retrospective review of this dataset from 2011 to 2015, 2408 patients were identified as undergoing surgery for CDI. Of these, 613 patients (approximately 20% of the study population) underwent diversion with a loop ileostomy; during the study period, the use of this procedure increased from 11% in 2011 to 25% in 2015 [121]. Although important details regarding the severity of CDI and the management of study subjects were not available using this data source, the authors also reported that in-hospital mortality did not significantly differ between these cohorts. One important limitation with the data source used for this study was the inability to identify the selection criteria used for choosing the form of surgical intervention, which has implications for the measured outcomes such as mortality rates.

In summary, patients with severe, complicated/fulminant CDI should be managed in a multidisciplinary fashion. Surgical consultation is recommended when CDI of this severity is first recognized, in an effort to allow for surgical intervention at the earliest appropriate time. CDI is frequently associated with organ failure, including hematologic failure characterized by an exaggerated leukocytosis that is often >30,000 cells/mm. It is critical that patients are euvolemic when assessing severity of sepsis, with a greater emphasis on trending organ function than on absolute cut-off values for laboratory abnormalities. De-escalating or discontinuing antibiotics that are not *C. difficile* targeted is also important; though the data is limited [122], CDI outcomes are worse when the inciting antibiotics are continued while CDI is being treated. While de-escalation of antibiotics is not always appropriate, certain infections (mild bladder infections) that are not life-threatening can have their treatment deferred, while life-threatening CDI is first addressed.

When patients are deemed to be too ill to allow for ongoing medical therapy, or demonstrate continued deterioration, surgery should be recommended for patients who are candidates for surgery. The largest body of evidence supports the use of total abdominal colectomy with an end ileostomy; partial colectomies have an extremely limited utility given a significantly higher incidence of reoperation due to postoperative fulminant CDI. Loop ileostomy has enough data at this juncture to be an acceptable alternative to total colectomy, though as described in a letter to the editor [123] in response to the recent EAST study [120] on loop ileostomy, there are several unanswered questions regarding this newer surgery. In the EAST study, diversion provided no advantage compared to total colectomy in terms of postoperative sepsis, renal failure, acute lung injury, overall mortality, and mortality related to unplanned reoperation. This may indicate that the particular strain of *C. difficile*, which is information frequently missing from the surgical literature on CDI, may influence postoperative outcomes, especially when a diverting stoma is created and an infected colon is left in situ.

Fecal Microbiota Transplant (FMT)

With access to commercially screened and prepared stool from vendors, FMT in either a liquid form for endoscopic or nasogastric application, or in capsule form for oral consumption, is now more readily available for inpatient use than in earlier times when providers had to collect, screen, and prepare stool from donors. FMT is extremely effective for treating recurrent CDI, with cure rates greater than 80% routinely

described [124]. FMT for fulminant CDI has the least exploration of all FMT applications, though the few studies on this topic are promising [125, 126]. One of the challenges with FMT for fulminant CDI is that of disease recrudescence and a measurable mortality from that disease recurrence. The incorporation of vancomycin in addition to FMT for fulminant cases appears to be important for ensuring reliable cure rates [127].

FMT is no longer an experimental therapeutic for outpatients, or inpatients, with CDI. Its cure rates for recurrent forms of CDI are superior to conventional antibiotics, leading some to question whether FMT should be the first intervention to address the recurrence of this infection. Of note, FMT does not currently represent the first-line therapy for a primary case of FMT. The availability of commercial vendors who can provide screened and prepared transplant material has simplified the process of FMT, making it more accessible for clinicians. The use of inpatient FMT for inpatient cases of CDI has increased in recent years, though physicians continue to treat the majority of cases of this infection with conventional antibiotics. At this time, there is insufficient data to recommend the routine use of FMT for the treatment of fulminant CDI; though there are limited numbers of small series that suggest safety and efficacy with FMT, more data in this patient population is required before FMT can be recommended for patients with life-threatening CDI.

Radiation, Microscopic, and Ischemic Colitis

53

Jamie A. Cannon and Gregory D. Kennedy

Key Concepts

- Radiation injury to the colon and rectum can cause significant morbidity, and effects can be seen many years after initial exposure.
- Surgery should be considered the last resort for radiation injury as complications are frequent. Surgical treatment should be individualized and based on symptoms and clinical context.
- Microscopic colitis is a rare cause of non-bloody diarrhea characterized by nonspecific inflammation in the lamina propria with infiltrates of lymphocytes and plasma cells.
- Budesonide is the only evidence-based treatment of microscopic colitis.
- Ischemic colitis results from disruption of blood flow from small vessels and is distinct from mesenteric ischemia. The treatment of ischemic colitis is based on symptom management and patient optimization.
- Long-term complications of ischemic colitis include strictures and chronic ischemia which may be indications for elective surgery in an otherwise medically optimized patient.

Radiation Colitis

Radiation therapy is routinely used to treat anal, cervical, prostate, and rectal cancers and less often bladder and endometrial cancers. An estimated 400,000 patients are diagnosed annually with these conditions, so encountering patients with previous pelvic radiation is routine in any colorectal surgery practice. While radiation is quite effective in treating these malignancies, managing the consequences of radiation treatment has become an important part of survivorship.

Definition and Manifestation

Radiation colitis or proctitis is classified as acute or chronic. Acute colitis occurs during therapy or within 6 months of completion of therapy. The vast majority of patients undergoing pelvic radiation will experience some side effects during the course of their treatment. Acute symptoms are related to radiation-induced cell loss of the rapidly turning over superficial rectal mucosa. Over time, as cellular turnover replaces the damaged epithelium, symptoms resolve. These treatment-related side effects are seen in between 50 and 75% of patients and manifested by diarrhea, mucous discharge, cramping, tenesmus, urgency, incontinence, and pain. Diarrhea is the most common symptom [1].

Chronic radiation colitis is defined as symptoms from the acute phase that persist beyond 6 months or development of symptoms after a latent period. The most common time for radiation colitis to present is between 8 and 12 months after cessation of treatment [2]. Hemorrhagic proctitis is the most common manifestation. It can range from mild bleeding to life-threatening hemorrhage. This is a result of microvascular changes that lead to ischemia, fibrosis, and bleeding. Other symptoms of chronic radiation colitis are similar to those of acute colitis and include pain, urgency, incontinence, mucous discharge, and tenesmus. Chronic colitis can also manifest with strictures and rarely perforations or fistulas. Unfortunately, unlike acute colitis, chronic colitis is not a condition that improves over time. Chronic hemorrhagic proctitis has been diagnosed as late as 30 years after radiation treatment. Several grading systems exist, with the most commonly used one developed by the Radiation Therapy Oncology Group (RTOG) (Table 53.1).

Table 53.1 Toxicity criteria of the Radiation Therapy Oncology Group (RTOG) and the European Organization for Research and Treatment of Cancer Radiation Morbidity Scoring Criteria

Grades	Acute	Late
Grade 1	Increased frequency, change in bowel habits, or rectal discomfort not requiring medications or analgesics	Mild diarrhea, mild cramping, bowel movement five times daily, slight rectal discharge, or bleeding
Grade 2	Diarrhea requiring parasympatholytic drugs, mucous discharge not necessitating sanitary pads, abdominal or rectal pain requiring analgesics	Moderate diarrhea or colic, bowel movement > 5 times daily, excessive rectal mucus, or intermittent bleeding
Grade 3	Diarrhea requiring parenteral support, severe bloody or mucous discharge necessitating sanitary pads, abdominal distention	Obstruction or bleeding requiring surgery
Grade 4	Obstruction, fistula, perforation, bleeding requiring transfusion, abdominal pain, or tenesmus requiring tube decompression or diversion	Necrosis, perforation, or fistula

Etiology and Risk Factors

The incidence and severity of chronic radiation colitis vary with the effective dose of radiation therapy administered and are influenced by patient-related factors. The incidence of chronic radiation colitis has been previously described as high as 30% [3]. Improvement in the delivery of radiation therapy places estimates in the current era from 1 to 5% [4]. Patients with preexisting inflammation, such as inflammatory bowel disease, are at increased risk for the development of chronic radiation colitis. Risk factors for vascular disease, such as diabetes, hypertension, nicotine use, peripheral vascular disease, adjuvant chemotherapy, and previous surgery, also predispose patients to radiation-associated vascular injury [5].

The likelihood of developing radiation colitis is dose related. Standard long-course radiation treatment for rectal cancer is delivery of 45–54 Gray (Gy). In contrast, treatment for cervical cancer involves administration of 45–50 Gy with external beam therapy, followed by a brachytherapy dose that focally escalates to 90 Gy. Doses less than 45 Gy rarely lead to chronic radiation colitis, while doses greater than 70 lead to significant injury [6]. While fistulization is a rare complication of radiation treatment, rectovaginal fistulas are most often seen after treatment of cervical cancer and rectourethral fistulas after treatment of prostate cancer. Such complications are unusual with standard rectal cancer treatment.

Prevention

The primary method of prevention is to limit radiation exposure to adjacent tissues. Classic methods of protecting uninvolved bowel include changing patient position during treatment and administering radiation when the patient has a full bladder to displace bowel out of the pelvis. Techniques in administration of the external beam continue to advance which has decreased the incidence of radiation colitis [7]. CT-based planning has helped radiation oncologists move the dose away from uninvolved bowel. Complex methods of treatment delivery, such as intensity-modulated radiation therapy (IMRT) and volumetric-modulated arc therapy (VMAT), use a combination of multiple beams of varying intensities and real-time organ motion managements to precisely deliver the external beam to the target tissue.

Both medications as well as surgical maneuvers have been proposed to protect uninvolved bowel during the administration of radiation, but are not routinely utilized. Sucralfate enemas, short-chain fatty acids, and probiotics have all been studied without demonstration of a clear benefit [8, 9, 10]. Nascimento demonstrated a reduction in symptoms when glutamine enemas were administered during treatment [11], but Vidal-Casriego did not find the same benefit [12]. The most promising agent appears to be amifostine, an oxygen free radical scavenger. Amifostine is thought to protect normal tissue and has shown some success in reduction of radiation-related symptoms [13, 14], but is not used in routine practice. Surgical prevention, by placing either mesh or omentum to exclude the small bowel from the pelvis, has been described, but has not been shown to decrease the incidence of radiation colitis or enteritis. If postoperative treatment is expected, exclusion of the small bowel can be considered if anatomically appropriate. Preoperative laparotomy for this sole purpose is not recommended.

Diagnosis

There are no specific laboratory studies used to diagnose radiation colitis. Those with severe hemorrhagic colitis may present with significant anemia, and patients presenting with obstruction from a stricture may have associated metabolic disturbances. Imaging studies are also nonspecific. Thickened, inflamed bowel may be present but is not specific to radiation colitis, and not seen when the damaged tissue is limited to the mucosa. Complications associated with radiation colitis may be seen on CT, such as obstruction, perforation, or fistula.

Clinical history and endoscopic appearance are the mainstays of diagnosis. The classic endoscopic appearance

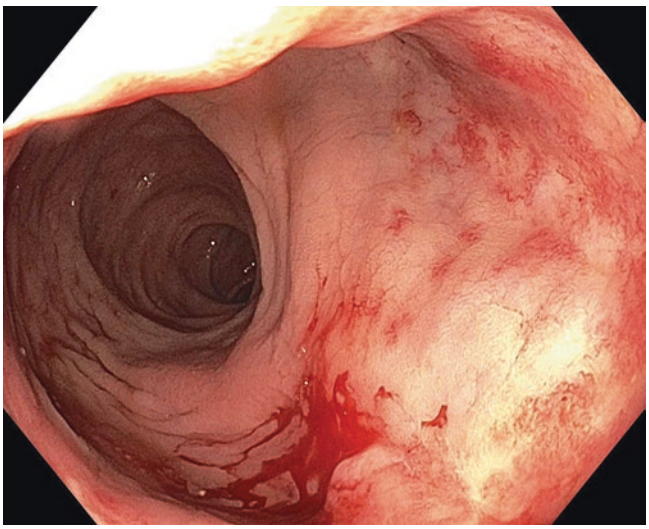

Fig. 53.1 Telangiectasias and easy friability associated with radiation proctitis

includes pallor with telangectasias and easy friability (Fig. 53.1) [15]. Biopsies can be performed to rule out malignancy and confirm the diagnosis. However, if the diagnosis is not in question, biopsies are not necessary and have been demonstrated to increase the risk of fistula development [16].

Mucosal biopsies of acute radiation colitis demonstrate inflammatory changes, including eosinophilic infiltration of the submucosa, crypt atrophy, and crypt abscesses. In the chronic phase, the vascular component becomes apparent, with small vessel vasculopathy that is not seen in the acute phase [17]. There is obliterative endarteritis with ulceration and fibrous induration [18], focal distortion of small arterioles, and vascular intimal fibrosis without inflammation.

Management

Medical

Medical management focuses on control of pain, mucous discharge, tenesmus, and rectal hemorrhage. Multiple anti-inflammatory agents have been investigated, including sucralfate, metronidazole, antioxidant vitamins, ASA derivatives, and short-chain fatty acids (SCFA). Of these agents, sucralfate has the best data supporting its use and is thought to help repair microvascular injury. Kochhar treated 26 patients with 20 mL sucralfate enemas administered twice daily. Seventy-seven percent of patients had improvement in symptoms at 1 month and 92% at 4 months [19]. While this shows promise, the difficulty of long-term self-administration of enemas for moderate improvement of symptoms limits its practical utility.

Metronidazole has been demonstrated in two studies to reduce symptoms [20, 21], but an ideal treatment regimen has not been developed. It is unknown how durable these effects are once the metronidazole is discontinued. Antioxidants such as vitamins A, E, and C have been shown in small studies to reduce symptoms [22, 23]. While there is likely little harm to adding an antioxidant regimen, sufficient data does not exist to make this a standard recommendation. Mesalamine and other ASA derivatives, as well as steroids, have been proposed but without sufficient data to recommend their use. SCFA, which are the primary nutrient for healing colonocytes, may speed recovery in the acute phase but have not been shown to be effective in the management of chronic colitis [24].

Hyperbaric oxygen therapy (HBOT) has been demonstrated to be effective in the treatment of radiation proctitis [25, 26]. Oscarsson published one of the larger series, in which 39 patients were treated with an 89% success rate [26]. While HBOT appears effective, practical constraints limit its applicability. The studies examining HBOT report 36–40 treatments at a considerable financial and time expense. Endoscopic therapies, discussed below, are more readily available with equivalent or superior results.

Endoscopic

Formalin

Multiple studies have demonstrated the effectiveness of topical formalin in the treatment of hemorrhagic radiation proctitis. While formalin is a medication, it is usually administered endoscopically. When topically applied to telangiectatic neovasculature, formalin induces a chemical-mediated necrosis, thereby sclerosing the small vessels [27]. A number of different techniques for administration of formalin have been described.

Sharma described using 50 mL of 4% formalin [28]. A flexible sigmoidoscope was used to spray the formalin over the involved mucosa. The formalin was left on the mucosa for a period of 3 minutes, suctioned out, and the rectum was rinsed with saline. They repeated these maneuvers three times during each treatment session, for a total exposure time of 9 minutes. Patients underwent from one to three treatment sessions depending on response. Of a total of 29 patients, all but 1 had either complete cessation of bleeding (62%) or a reduction in bleeding (34%). They reported no complications.

Raman administered 100 cc of 2% formalin as an enema, which patients held for 2 minutes if able [29]. Of 24 patients, 48% had complete resolution of bleeding, and an additional 30% had a reduction in bleeding. All patients experienced subjective improvement in their overall symptoms, and endoscopic findings were improved in all patients. Complications were limited to transient tenesmus and bleeding.

An alternative method of administration is described by Haas, in one of the largest series investigating formalin [30].

They report a 93% success rate in 100 patients. In this series, a proctoscope is used to visualize the affected mucosa. A 16″ cotton-tipped applicator dipped in 10% formalin was held against the mucosa for 60 seconds.

Variations on the above techniques include instillation of formalin while instructing patients to roll around to maximize contact surface area [31] and placing formalin-soaked gauze on tissue until it blanches [32]. Some studies have reported success rates as high as 100% [33, 34], and all studies have reported very promising results.

The use of sedation and pre-procedure bowel prep varies among protocols. Most of the above studies report from one to three treatment sessions to produce the desired result. Care should be taken not to allow the formalin to come in contact with skin, particularly the perianal skin. Sharma described using lidocaine jelly on the perianal skin in order to protect it [28]. While some authors have recommended caution due to concerns about serious toxicity (Luna-Perez reported a 20% rate of severe complications [35]), the vast majority of studies demonstrate excellent success with few or no complications.

The ease of use, ready availability, excellent success rate, and low rate of complications make the use of formalin the authors' choice for management of hemorrhagic radiation proctitis. While there are clearly multiple options for administration, we find that the simplest method of administration is using a flexible sigmoidoscope. In our practice, patients undergo a fleet enema pre-procedure. This is done in the clinic; setting and sedation are not required. With patients in the left lateral decubitus position, 4% formalin is injected through the scope over the affected mucosa. After 3 minutes, it is suctioned out and the colon irrigated with saline. This is similar to the technique describe by Sharma [28], with the exceptions that we do not find full bowel preparation or sedation necessary, and just one application is performed per session.

Argon Beam Coagulation (ABC)

The use of the argon beam to coagulate the involved mucosa appears to have an effectiveness similar to that of formalin. ABC involves the delivery of high-frequency energy to the tissue through ionized argon, administered through the working channel of a flexible sigmoidoscope. Flow is generally 1–2 L/min, with a power of 40–65 watts, at pulses of 1–2 seconds. Sebastian reported on treatment in 25 patients, all of whom showed improvement, and 81% had complete cessation of bleeding [36]. Zinicola reported an 86% success rate [37]. Failures were seen in patients with the most severe disease, who then responded to formalin. Advantages of ABC include uniform, predictable application, with a depth of penetration generally 1–3 mm. Care must be taken to make sure the probe is not discharged too close to the mucosa, as this can create a deeper injury. Yeoh performed a direct comparison of ABC to formalin and found nearly equivalent results [38]. Complications appear to be rare. One study reported a 20% rectal ulcer rate. However these ulcers were only detected on endoscopy, were asymptomatic, and resolved over time, and so were likely not clinically significant [39]. ABC therefore appears to be an acceptable alternative to formalin therapy, though its use may be limited by lack of training and access to the equipment.

Other endoscopic treatments that have been studied include bipolar electrocoagulation, laser treatment, radiofrequency ablation (RFA), and cryotherapy. Administration of these treatments requires specialized equipment. While they may be effective, less data is available to support their use. One study performed a direct comparison of bipolar electrocoagulation with ABC and found equivalent results [40]. The use of the Nd:YAG (neodymium-doped yttrium aluminum garnet) appears to be effective. However, the depth of penetration is more variable (estimated at 5 mm), so there is a higher risk of perforation, and increased rates of complications have been seen [41]. RFA uses a needle electrode to transmit an alternating radio frequency current into the tissue adjacent to the electrode's tip. Ions in adjacent tissue attempt to change direction following the alternating current, and this movement creates a friction that generates heat. There is very limited data concerning its use. Cryoablation, via spraying liquid nitrogen over the affected tissue, has also been described, again with very limited data.

For radiation-related strictures, endoscopic dilation is an option. While these strictures tend to be firm and do not stretch well, success with endoscopic balloon dilation has been reported [42]. Distal strictures that are accessible transanally can be dilated via Hegar dilators, which allows for a more aggressive dilation to a larger diameter.

Surgical

Surgery is a last resort for the treatment of radiation colitis. Surgical treatment consists of either resection, with or without reconstruction, or diversion alone. Surgery is reserved for complications of radiation colitis such as refractory bleeding, strictures leading to obstruction, fistulas, or disabling symptoms. Resectional procedures are by definition technically difficult. Radiation causes alteration of anatomical planes, loss of tissue compliance, altered anatomy, and severe adhesions. Patients need to be counseled concerning the greatly increased risk of complications, such as small bowel injuries, anastomotic leak, fistula formation, and injury to other structures. The degree of difficulty correlates with the degree of radiation damage. Rectovaginal fistulas secondary to cervical cancer treatment are particularly challenging due to the high doses of radiation and often preclude successful reconstruction. The management of complex rectourethral and rectovaginal fistulas is addressed in a separate chapter.
