An older French study reviewed 85 patients that underwent laparotomy for radiation injury to the small bowel or colon and reported a mortality rate of 33% and enterocutaneous fistula rate of 30% [43]. This study was published in 1985, and the exceedingly high rate of morbidity and mortality may reflect selection bias as perhaps only the most complicated patients underwent surgery. Nonetheless, it demonstrates the complexity and high risk of these operations. The Mayo Clinic also published data on patients undergoing resection secondary to radiation colitis from 1950 to 1983 and found a complication rate of 80% and mortality of 14% [44]. Zelga found that in patients with a radiation-induced rectovaginal fistula, resection was only possible in 4% of patients and the remaining patients underwent diversion alone [45]. Zhong reported on 26 patients with rectovaginal fistulas from radiation from gynecologic cancers [46]. While resection was successful in 10 of 26 patients (the remaining 16 underwent diversion alone), only 3 patients were ever able to have their ostomies closed.

The complexity and complication rate associated with these operations can make diversion alone an appealing alternative, and diversion does indeed improve quality of life [47, 48]. While diversion can improve incontinence and symptoms related to obstruction or fistula, other symptoms such as rectal bleeding, pain, mucous drainage, and tenesmus generally persist. In patients with reasonable health status, resection should be considered as it offers the potential to remove all active disease. Reconstruction should be attempted when tissues are amenable, but both the surgeon and the patient need to be prepared that reconstruction is often not technically feasible or medically appropriate, and a permanent ostomy is often required.

Summary

Radiation colitis is a common condition in the current era, where radiation is used to treat a number of pelvic malignancies. Familiarity with radiation colitis is essential for a practicing colorectal surgeon. The severity of symptoms corresponds with quantity of radiation. Treatment options include anti-inflammatory medications, generally administered topically. The most common complication of pelvic radiation is hemorrhagic radiation proctitis. Topical formalin application is very effective in the management of this condition and is readily available and easily performed. Argon beam coagulation is also effective. Surgical treatment is reserved for patients with refractory bleeding, obstructing strictures, medical refractory symptoms, and fistulas. Surgical reconstruction can be very difficult, and patients must be counseled that these operations are associated with a high rate of morbidity and mortality; many such patients will require a permanent ostomy.

Microscopic Colitis

Definition

Microscopic colitis is a chronic, relapsing, and recurring inflammatory condition of the colon that results in nonbloody diarrhea. It is characterized by grossly normal appearance of the colonic mucosa, with characteristic abnormal findings on histologic biopsies. Because the symptoms of microscopic colitis (MC) can be fairly vague and attributable to a number of conditions, establishing the diagnosis requires a high level of suspicion. When patients with consistent symptoms are identified, colonoscopy with biopsy is required to rule this condition in or out. Microscopic colitis is classified as either collagenous colitis (CC) or lymphocytic colitis (LC). These two conditions have the same presentation and are managed in the same way, with minimal differences in epidemiology and response to treatment. Lymphocytic and collagenous colitis are differentiated based on histologic assessment. There is some debate as to whether these are differing presentations of the same entity, versus two separate diseases with many similarities.

Etiology and Risk Factors

A number of epidemiology studies from multiple countries over the last few decades have attempted to determine the actual incidence of this disease [49–51]. A study from Minnesota found that the incidence in the late 1980s was 3.1/100,000 for collagenous colitis and 5.5/100,000 for lymphocytic colitis but by 2001 had increased to 19.6/100,000 [52]. European studies over the same time period found similar results, with the incidence increasing during the 1990s from 1.1 to 5.2/100,000. Whether these changes reflect an actual increase in the prevalence of the disease versus an increase in awareness and diagnosis is not clear. Some more recent studies have suggested an incidence as high as 219/100,000 [53].

Microscopic colitis most often presents later in life. The mean age at time of diagnosis is 61, with an increasing incidence with age. Presentation in middle age is not uncommon, and rare cases in children have been seen [54, 55]. There is a female predominance, with an odds ratio for women estimated at 2–8, so there is likely a hormonal or genetic link. Autoimmune diseases have an increased incidence in women, and there is a very strong link between MC and other autoimmune disorders; this may suggest that this disease is autoimmune in nature. Forty percent of patients diagnosed with MC have another autoimmune disorder [56]. Associated conditions include type 1 diabetes mellitus, autoimmune thyroiditis, and polyarteritis. A diagnosis of polyarteritis is associated with an odds ratio of 20.8 for collagenous

colitis and 8 for lymphocytic colitis [51]. Forty percent of patients with celiac disease also demonstrate the histologic changes of MC.

While no direct genetic link has been identified, familiar clustering has been observed. The pathophysiology of MC is not well understood, but one theory is that affected patients have a mucosal barrier dysfunction that predisposes them to an increased epithelial inflammatory response to antigens. An increased frequency of pleomorphisms of genes that code for HLA and TNF-alpha, which predispose to autoimmune disorders, has been demonstrated in patients affected by MC.

Alterations in the microbiome have been observed in MC patients. This is an interesting area of future research, though not clinically applicable currently. It has been noted that there is an increased incidence of previous infection with yersinia enterocolitica in patients with MC [57], and previous Clostridia difficile infection has been proposed as a cause. These observations support the theory that an outside antigen in patients with a genetic predisposition leads to MC, but there is no direct evidence to identify causation.

Smoking is associated with an increased incidence of MC and an earlier age at diagnosis [58, 59]. A study from 2013 investigating 248 patients with MC found smoking was associated with an odds ratio of having collagenous colitis of 2.4 and lymphocytic colitis of 3.8 [51]. Smoking cessation is therefore recommended in the management of MC, although no studies have demonstrated that smoking cessation results in MC remission.

Multiple studies have demonstrated a correlation between MC and various medications, including NSAIDS, PPIs, SSRIs [60], and statins. The use of NSAIDS has an estimated odds ratio of developing collagenous colitis of 3.8 and in lymphocytic colitis of 4.7 [51]. PPIs have an estimated odds ratio of developing collagenous colitis of 6.4 and lymphocytic colitis 2.7 [51, 61]. However, a direct cause and effect relationship has not been identified, and a large database study out of Pennsylvania failed to show a medication-related correlation [62]. One theory to explain this contradiction is that diarrhea can be a side effect of these medications. This may prompt colonoscopic evaluation in otherwise normal individuals, which may increase the rate of diagnosis in patients who otherwise may not have been evaluated. While cause and effect has not been established, cessation of suspect medications can be an initial step in managing this condition.

Manifestations

Patients with microscopic colitis present with watery, non-bloody diarrhea as the predominant symptom. Active disease is defined as three or more bowel movements/day and one or more episodes of night time diarrhea. Other associated symptoms include abdominal pain, fecal incontinence, weight loss, and fatigue. While this disease causes significant impact on quality of life, it does resolve in most patients. Symptoms once resolved often recur, so it can be an intermittent, relapsing, and recurring chronic disease. Seventy-five percent of patients will achieve remission, defined as no symptoms without any medication for 1 year. Those who undergo spontaneous remission without the use of medication are more likely to experience a prolonged remission, as compared to those who undergo a drug-induced remission [51].

MC is generally considered to be a benign disease. It does not lead to an increased colorectal cancer risk [60] and has actually been associated with a decreased incidence of colorectal adenomas [63]. Serious complications are very rare, but incidences of colonic perforation, both spontaneous and during colonoscopy, have been reported [64].

Diagnosis

Criteria for diagnosis have been defined by the Spanish Microscopic Colitis Group [51]:

- Chronic or intermittent diarrhea without blood
- Macroscopically normal or near normal colonic mucosa on colonoscopy
- Characteristic histopathological appearance on colonoscopic biopsies

Any patient with non-bloody diarrhea that does not respond to simple conservative measures should undergo colonoscopy with biopsies, which are diagnostic. The differential diagnosis includes inflammatory bowel disease, irritable bowel syndrome, bile acid malabsorptionq, celiac disease, small intestinal bacterial overgrowth, and lactose intolerance. There may also be overlap between these conditions and MC.

Laboratory Studies

No laboratory studies are diagnostic of the disease. Fecal calprotectin has been studied as a fecal marker of MC. Batista et al. found average levels in those with MC 175 micrograms/gram as compared to 28 for the control group [65]. This is a nonspecific finding, however, as elevated fecal calprotectin levels are seen in other diseases as well; there is no evidence to suggest that this can establish the diagnosis or monitor treatment of this disease.

Imaging Studies

Imaging studies may be useful to look for other causes of colitis but will be normal in patients with microscopic colitis.

Endoscopic

Colonoscopy is mandatory to establish the diagnosis of MC. This disease is characterized by normal appearing colonic mucosa. Signs of inflammatory bowel disease should not be present. While uncommon, some have described altered vascular patterns, which may present as pale mucosa, erythema, edema, or linear ulcers [66]. Biopsies for histology need to be taken throughout the colon. Two biopsies should be taken in each segment. Sampling individual areas of the colon, such as the rectum or sigmoid, decreases the diagnostic sensitivity, as characteristic changes may not be present throughout the entire colon. Full colonoscopy, and not flexible sigmoidoscopy, is mandatory. When colonoscopy with appropriate biopsies is performed in patients with symptoms consistent with MC, 10–15% of patients will be found to have MC [53].

Histology

MC is characterized by inflammation in the lamina propria, with an increase in lymphocytes and plasma cells. While some patients may have cryptitis, crypt architecture is generally preserved [67]. Collagenous colitis is characterized by a subepithelial collagen band that is 10 or more micrometers in thickness (see Fig. 53.2). While this is the defining criterion for collagenous colitis, the significance of the collagen band itself is unclear. The collagen band has been shown to decrease in thickness with treatment [68, 69], but the severity of symptoms correlates with the degree of inflammation in the lamina propria, rather than the size of the collagen band [67]. Lymphocytic colitis is characterized by an increased proportion of surface intraepithelial lymphocytes. The collagen layer may be present or absent but is less than 10 μm. Routine H&E staining is generally sufficient (Fig. 53.3); but in cases where the diagnosis is in question, CD3 staining better visualizes the intraepithelial lymphocytes (Fig. 53.4) [70].

Management

Medical

The majority of patients with this condition are on antidiarrheal medication, such as loperamide and/or diphenoxyl-

ate. These medications may improve symptoms but do not induce remission or decrease histologic inflammation. Probiotics have been investigated and show no improvement over placebo [71]. In one study of 64 patients, mesalamine showed promising results, with an 84% induction of clinical remission in 2 weeks [72]. The response rate was even higher when co-administered with cholestyramine. However, there was no control group in this study, and a large randomized trial investigating mesalamine did not demonstrate improvement over placebo [73].

While the data is limited, a number of small studies have demonstrated improvement in symptoms with administration of bismuth salicylate [69]. Dosage is three 262 mg tablets tid for 8 weeks, with a mean response occurring at 2 weeks. One small study randomized 14 patients to placebo vs bismuth salicylate and found 100% clinical success with bismuth and no response to placebo. While the study was small, it was double blinded and reported a dramatic treatment effect. A meta-analysis showed an 81% response rate to bismuth salicylate [74].

Antibiotics have been investigated. There are only a few studies with a small number of patients, so antibiotics cannot be recommended as treatment currently. Metronidazole is attractive in that it has both anti-inflammatory and antibiotic properties. Other antibiotics that have been investigated include erythromycin and penicillin, which have shown response in very small groups of patients [57, 75].

Budesonide is the mainstay of treatment for this disease. A potent corticosteroid, budesonide, concentrates its effects on the bowel, as extensive first pass metabolism minimizes systemic effects. A number of randomized trials demonstrate the superiority of budesonide over placebo with minimal side effects [73, 76–78]. Miehlke randomized 57 patients in a double-blind fashion to receive either budesonide, mesalamine, or placebo. Budesonide had a 68% success rate as compared to 21% for placebo and 26% for mesalamine [73]. Unfortunately, the recurrence of disease is common once budesonide is stopped [79].

Munch administered budesonide to 110 patients with an 84% treatment success [78]. Those that responded were then randomized to continue budesonide as maintenance therapy vs placebo. The initial induction dose was 9 mg/day, and the maintenance dose was 4.5 mg/day. At 1 year, 61% of the patients on maintenance budesonide remained in remission as compared to only 16% for placebo [78]. This demonstrates that budesonide can be used not only as initial treatment but also for recurrent disease or to maintain remission. Given the efficacy of budesonide, it is not surprising that prednisolone can also induce remission. Munck studied prednisolone at a dose of 50 mg daily. A moderate response was seen at 2 weeks but at the cost of steroid-associated side effects [80]. As systemic prednisolone has not been shown to be superior to budesonide and is associated with a higher rate of side effects, it should not be considered for primary therapy.

In very small studies and case reports, immunomodulators have been used with good results. As the side effects associated with these medications can be severe and MC generally has a benign course, the use of such medications is fairly limited. Because of this, there is no large-scale data supporting their use. However, Vennamaneni demonstrated success with 6-MP and azathioprine [81] and Esteve with anti-TNF-alpha medications [82].

Surgical management is not considered part of a standard algorithm for this disease. However, occasional patients present with failure to respond to medical treatment and such life-disabling symptoms that surgery is warranted. Diversion is the mainstay of surgical treatment, with or without colonic resection. Both result in symptomatic improvement. The purported benefit of diversion alone is the potential for restoration of continuity. However, if the ostomy is reversed, symptoms recur. In addition to clinical improvement with diversion, the diverted segment demonstrates a decrease in inflammation on biopsy. In collagenous colitis, the size of the collage band decreases after diversion [68]. There are two case reports of total proctocolectomy with ileal pouch-anal anastomosis to treat this disease with acceptable results [83, 84], but there is no data to support this as a management strategy.

To summarize, medical therapy is the mainstay of treatment. Given the association of MC with tobacco use, smoking cessation should be encouraged, although there is no evidence that this leads to remission. Associated medications should be discontinued if possible. For very mild disease, anti-diarrheal medications can be used to treat symptoms. If patients continue to experience significant symptoms after these conservative measures, treatment with budesonide should be initiated. If budesonide induces remission, the drug can be stopped, with the recognition that many patients will again become symptomatic. Budesonide can be restarted to maintain remission. In rare circumstances, severe symptoms continue, in which case treatment with immunomodulators, such as 6-MP, azathioprine, or anti-TNF medications, can be tried. The severity of symptoms and the effect on the patient's quality of life must be balanced with the risks associated with these medications. The creation of an ostomy with or without colon resection is a last alternative.

Ischemic Colitis

Definition

Ischemic colitis (IC) occurs when the metabolic demands of the colon mucosa is greater than the resources provided through the vascular system. While a common cause of isch-

emia is the complete disruption of blood flow or mesenteric ischemia, such a situation is different than classic IC (Table 53.2). Mesenteric ischemia results from disruption of blood flow through some type of vascular accident—embolic, thrombotic, or other mechanical forces that impair blood flow. These types of accidents tend to affect the large, named blood vessels resulting in injury to extensive regions of both the small and large intestine. In contrast, ischemic colitis is thought to occur from disruption of blood flow in the small mesenteric vessels that are near the wall of the colon (Fig. 53.5). The disruption of blood flow can certainly occur as a result of a vascular accident such as thrombosis; however, it commonly occurs as a result of decrease in blood flow without major vascular disruption.

Table 53.2 Differences between mesenteric ischemic and ischemic colitis

Characteristic	Mesenteric ischemia	Ischemic colitis
Symptom onset	Sudden	Hours
Cause	Vascular accident (thrombotic, embolic, dissection, etc.)	Multifactorial
Blood supply loss	Total to effected segment	Transient
Symptoms	Pain out of proportion to exam	Moderate pain and tenderness over affected segment, hematochezia
Management	Emergent surgery	Most managed medically, surgery may be indicated if disease progresses

Anatomy, Epidemiology, and Risk Factors

Branches from the superior and inferior mesenteric arteries and the paired internal iliac arteries supply blood to the colon and rectum. While these named vessels arising directly from the aorta are important, almost as important is the collateral vasculature of the colon. The marginal artery of Drummond parallels the wall of the colon and gives rise to the vasa recta. This meandering artery receives blood flow from the terminal branches of each colic artery. The regions of the large intestine can be very dependent upon this collateral flow as the splanchnic vessels are some of the most reactive in the body and can receive anywhere from 10% to 35% of the cardiac output depending on physiologic or pathologic conditions [85]. During states of low flow, the major watershed regions of the colon require that this collateral circulation be fairly robust. If the marginal artery of Drummond is not intact when these times of low flow occur, symptomatic ischemia may result [86]. Griffith's area at the splenic flexure and Sudeck's point at the rectosigmoid junction are two major watershed regions, and states of reduced blood flow can cause relative ischemia in these areas.

The colon is the most frequent site of gastrointestinal ischemia [87, 88]. While the exact rate of ischemic colitis in the general population is difficult to know, it is clear that certain groups of patients are at increased risk for developing IC [89]. In a large review by Higgins, rates of IC in the general population were estimated to be between 4 and 9 per 100,000 patients. In this review, the authors did note that patients with COPD had rates of IC as high as 100 per

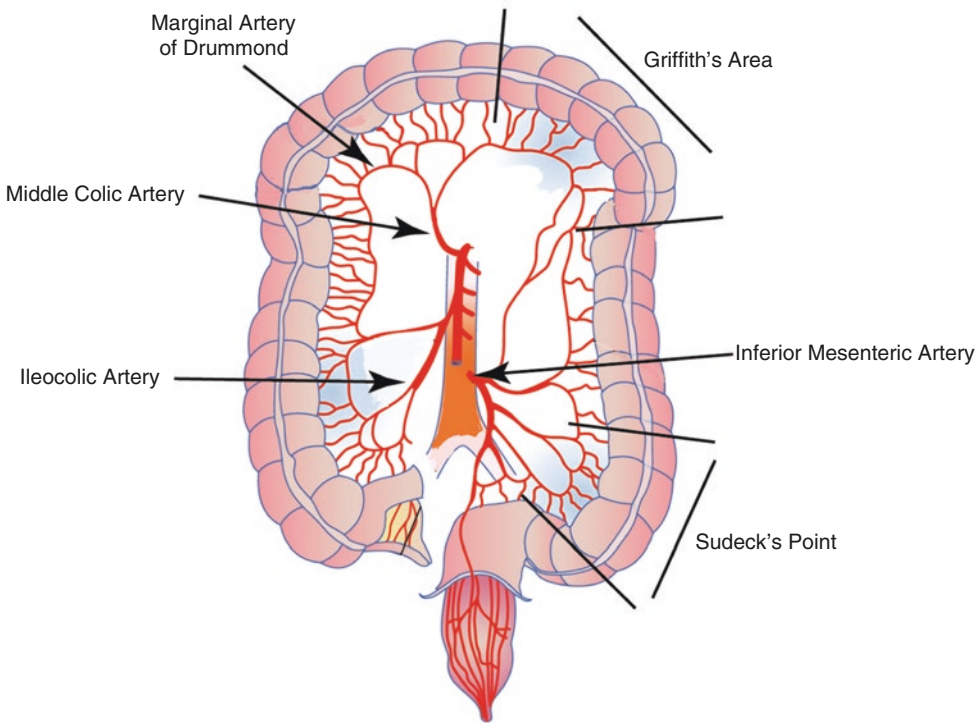

Fig. 53.5 Vascular anatomy

100,000 patients with a relative risk between 2.6 and 4.3 [89]. Other groups of patients are also known to have an increased risk for IC. For example, there is a classic association between IC and AAA repair. In fact, a recent review of the topic including 110,000 patients revealed rates of IC to be 0–4.6% after elective repair and as high as 21% after emergency repair of a ruptured AAA [90].

Clinical Presentation

Abdominal pain and rectal bleeding are often the earliest symptoms associated with acute IC. In a review of patients presenting with lower GI bleed, Newman found that IC was the cause of the bleed in nearly 20% of patients, second only to diverticulosis [91]. This observation has been confirmed by others in similar local studies. For example, Hreinsson examined patients presenting with an acute GI bleed in their hospital in Iceland and found that almost 15% had bleeding as a result of IC [92]. Given these results, ischemic colitis should be high in the differential diagnosis for lower GI bleeding.

Other symptoms might include pain, nausea, vomiting, abdominal distention, dizziness, and syncope. Right-sided colitis is less likely to be associated with rectal bleeding and should be kept in mind in those patients with isolated right-sided abdominal pain [93]. Physical examination often reveals only mild to moderate tenderness over the involved segment. Of course, if full-thickness necrosis occurs and the segment perforates, diffuse peritonitis will ensue. However, most patients present early without evidence of transmural involvement.

Diagnosis

Diagnosis of ischemic colitis requires one to think about the diagnosis first and foremost. IC should be prominent on the differential diagnosis in someone presenting with lower GI bleeding and abdominal pain. Laboratory evaluation is nonspecific. Increased white blood cell count and acidosis may indicate full-thickness ischemia. However, there is no reliable marker of ischemia. One must consider all causes of bloody diarrhea including infectious causes such as *Klebsiella* or *Salmonella*.

Imaging with plain films can be normal or show nonspecific findings of distention and ileus. Free air can be seen with free perforation. Classic findings of bowel ischemia such as thumbprinting and pneumatosis are present in 20–30% of plain films in patients with IC [88]. Contrast enemas have little to no use in the acute phase of the disease, as they may worsen tissue ischemia through unnecessary distention. However, such a study can be useful to assess stricture formation in patients who have recovered from IC [88].

Abdominal CT scan is frequently performed as the initial evaluation in patients presenting with abdominal pain and bloody diarrhea. The accuracy of CT scan in determining bowel ischemia varies between 74 and 79% depending on the protocol used and the experience of the radiologist [94]. Most patients with IC will have findings consistent with ischemia on CT scan if imaged in the acute phase. In fact, in a recent review of 130 patients undergoing CT for the suspected diagnosis of IC, Iacobellis found that 100% of patients with IC had a CT finding consistent with the diagnosis [95]. Most frequently, they found pericolonic and free fluid, change in bowel wall densities, and bowel wall thickening [95].

While pneumatosis is a particularly ominous finding, it is present in only a small fraction of examinations in patients with the diagnosis of IC. In the study by Iacobellis, <5% of patients in the acute phase had findings consistent with pneumatosis [95]. In general, the findings of pneumatosis and portal venous gas do not always signify bowel necrosis [96]. However, in the clinical setting of IC, the presence of pneumatosis and bowel wall necrosis portends a mortality rate over 70% [96].

Colonoscopy can be used to confirm the diagnosis of IC and to exclude other causes of colitis. It goes without saying that colonoscopy should not be done in patients with findings consistent with free perforation or with signs of peritonitis. Luminal findings consistent with ischemia include erythema (84% of cases), edema (70%), friability (43%), superficial ulceration (57%), deep ulceration (22%), stenosis (8%), and intraluminal blood (8%) [88]. As the ischemic process progresses, evidence of submucosal bluish-black blebs or nodules protruding into the lumen of the bowel can be seen. These lesions create the characteristic thumb printing seen on radiographic studies [88].

In addition to visual inspection, colonoscopy allows for biopsy of the superficial mucosa. Histologic evaluation of the endoscopic findings helps differentiate IC from changes due to infections or inflammation. The pathognomonic finding of IC is the presence of ghost cells [97]. Other features of acute ischemic colitis include preserved architecture of the colonic crypts, necrosis of the superficial portion of the crypts, sparing of the deep portion of the crypts, mucin depletion, and reactive changes in the residual crypt epithelium. Sloughed necrotic mucosa may produce a microscopic appearance of a pseudomembrane, composed of fibrin admixed with numerous neutrophils and mucin.

Management

When the diagnosis of ischemic colitis is made and the patient does not show signs of perforation or toxicity, it is generally appropriate to start with conservative treatment. This includes bowel rest, intravenous hydration, and broad-

spectrum antibiotics. While antibiotics have not been shown to alter the disease, they are thought to be beneficial for 2 reasons: (1) colonic ischemia increases mucosal permeability, thereby increasing bacterial translocation, and (2) animal studies have shown that antibiotics may reduce the length and severity of bowel damage [98, 99]. The choice of antibiotics is based on expert opinions. In general, coverage should include the gut flora, including anaerobic coliforms [93].

The use of anticoagulants is not routinely recommended for patients with IC due to microvascular pathology or low-flow states. If the patient has an ileus and suffers from intractable nausea and vomiting, nasogastric decompression may be indicated. Medications should be carefully reviewed, and those promoting splanchnic vasoconstriction should be stopped if possible, and cardiac output should be optimized. No medications have been shown to increase blood flow to the colonic mucosa and shorten the duration of the ischemic insult [88]. Improvement should be seen in a relatively short timeframe measured in hours to days. The absence of improvement or delayed improvement may indicate chronic progression towards transmural ischemia.

After symptom resolution patients should undergo an elective diagnostic colonoscopy to ensure complete healing and assess for possible stricture [100]. Strictures that are not clinically significant can be observed, and some may resolve on their own over 12–24 months with no further therapy [101].

Signs of clinical deterioration such as fever, hypotension, tachycardia, increased abdominal tenderness, and increasing white blood cell count indicate that the disease is progressing and surgical intervention may be warranted. If colonic infarction is suspected, exploratory laparotomy or laparoscopy is necessary. The use of laparoscopy in this patient population will be dictated by the clinical situation and the comfort of the surgeon. Surgical resection will be driven by how much of the colon is involved; resection should be from normal bowel to normal bowel. Primary anastomosis should be avoided in general, and the fundamental goal should be to perform a safe operation. Stoma creation does not necessarily need to be permanent, and elective reversals can be performed once the patient has functionally recovered. Regardless of procedure performed, patients requiring an operation for ischemic colitis have mortality rates as high as 40% [102].

Prognosis

In most cases of IC, the signs and symptoms resolve within 24–48 hours, and complete clinical and radiological resolution occurs within 1–2 weeks, after which no further therapy is required [103]. Approximately 10% of patients who initially recover from the ischemic event may present several months later with obstructive symptoms secondary to a significant stricture [104]. Diagnosis of a stricture can be made by colonoscopy, CT colonography, or barium enema. Surgical resection may be indicated in patients with symptomatic strictures, but these should be done on an elective basis with anticipation of a primary anastomosis. In addition to strictures, another 20–30% of patients go on to develop chronic colitis from irreversible ischemic injury, manifested by persistent diarrhea, rectal bleeding, and/or weight loss [100]. If confirmed, this too may be an indication for elective surgery.

Intestinal Stomas

54

Michael F. McGee and Peter A. Cataldo

Key Concepts

- Preoperative stoma site marking and patient education improve stoma-related clinical outcomes, patient quality of life and experience, while decreasing healthcare resource utilization.
- The finished stoma should protrude from the skin, thereby improving the seal between the appliance and the peristomal skin and decreasing complications.
- Optimal care for patients undergoing ostomy surgery includes preoperative and postoperative care by an ostomy nurse specialist, such as a WOCN-certified nurse.
- Early stoma-related complications such as leakage, peristomal dermatitis, and dehydration can often be remedied with stoma care and patient education.
- Loop ileostomy is preferred over transverse loop colostomy for temporary fecal diversion in most circumstances.
- Stapled and hand-sutured techniques are both acceptable for loop ileostomy closure.

Introduction

Stomas are employed as temporary or permanent means of fecal diversion in the management of a variety of gastrointestinal, neurologic, and genitourinary conditions. Dated estimates suggest that approximately 120,000 stomas are created annually in North America, with an estimated prevalence of 450,000–800,000 ostomates [1]. Stomas can be fashioned in an "end" or "loop" configuration depending on surgical strategy and perioperative conditions and are classified by the location of exteriorized bowel (e.g., colostomy, ileostomy, jejunostomy).

Intestinal stoma creation, often relegated as a minor component of a larger operation, will significantly impact the patient and their support system. Stoma-related complications are common, but even absent complications patient dissatisfaction with stoma appearance and body image can negatively impact quality of life. Societal stigmas, ignorance, and misunderstandings can further complicate care. Conscientious surgical stewardship and collaborative nursing care can decrease complications and improve quality of life for ostomates. As such, mastery of preparing, creating, caring for, and reversing stomas are a hallmark of the colorectal surgeon's armamentarium.

Colostomy

Configuration

Creation of an end colostomy may be indicated in several benign and malignant diseases for permanent or temporary fecal drainage (Fig. 54.1a). Low rectal cancer, recurrent anal cancer, severe anorectal Crohn's disease, and severe radiation proctitis may require a permanent end colostomy. An end colostomy may be used emergently for severe sigmoid diverticulitis (i.e., Hartmann's procedure) and as means of trauma-related damage control. An end colostomy may be a better option for patients who are not suitable candidates for restorative procedures; examples may include fecal incontinence, severe neurologic impairment, the elderly, prohibitive medical comorbidities, and prior resection of the anal sphincter complex. Although sphincter-preserving operations increasingly garner attention, the end colostomy remains the preferred option in many cases.

A loop colostomy can be used to divert fecal flow proximal to a tenuous anastomosis or problematic distal bowel, on

a temporary or permanent basis (Fig. 54.1b). The redundant, non-peritonealized nature of the sigmoid and transverse colon make each suitable for a loop colostomy, although high outputs and prolapse may hinder transverse colostomies. The dual lumen nature of the loop colostomy allows proximal diversion with retrograde venting of the distal segment, rendering the loop colostomy an excellent option for palliative diversion of obstructing lesions of the distal bowel. The loop colostomy may be used to temporarily protect a colorectal or coloanal anastomosis.

A loop colostomy may also be used to temporarily divert stool and facilitate staged repair for pelvic sepsis, rectal trauma, nonhealing sacral decubitus ulcers, and anorectal fistulizing processes. Rarely, an iatrogenic or traumatic perforation of the colon can be mobilized and exteriorized as a loop colostomy, with the injury incorporated as the stoma orifice. Although a transverse loop colostomy is a relatively simple stoma to create, it is often poorly tolerated by patients due to its large size, cephalad location on the abdominal wall, and frequent stoma-related complications. In most instances, a loop ileostomy provides better short-term and long-term outcomes. Since both proximal and distal bowel conduits are readily accessed through the stoma trephine, loop stomas can often be closed easily through a local peristomal dissection, thereby avoiding laparotomy.

Physiology

Colostomy function is dependent upon the level of diversion. The colon receives approximately 1500–2000 mL of liquid stool from the small bowel daily, of which it reabsorbs approximately 90% of the water (1350 mL) and excretes 100–150 mL of water within solid waste [2, 3]. The majority of colonic fluid and electrolyte reabsorption occurs in the right colon. Distal colostomies arising from the sigmoid or left colon tend to produce more solid stool than proximal stomas fashioned from the transverse or ascending colon. Transverse colostomies may be more prone to fluid and electrolyte imbalances akin to small bowel stomas.

Similar to the wide range in bowel movement frequency and consistency observed in individuals, colostomies function variably. Since colonic transit time varies between 24 and 150 hours [2], distal colostomies may function periodi-

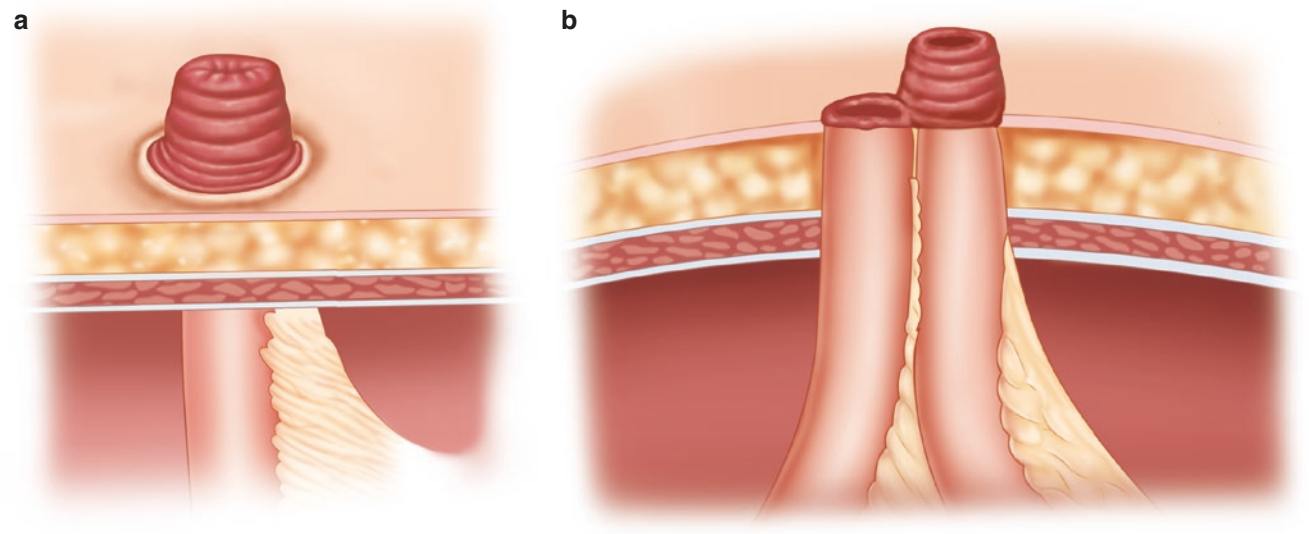

Fig. 54.2 (**a**) End ileostomy. (**b**) Loop ileostomy

cally as solid stool is propelled through the colon, whereas gas tends to pass more continuously. The episodic nature of stool passage through distal colostomies can lend itself to specialized colostomy irrigation techniques, which may enable patients to regulate stool passage or occasionally avoid a stoma appliance altogether [4, 5]. Proximal colostomies with liquid stool tend to function more continuously akin to small bowel stomas, and are not well suited for stoma irrigation techniques.

Small Bowel Stomas

Configuration

Like colostomies, small bowel stomas (e.g., ileostomy, jejunostomy) can be used for permanent or temporary enteric drainage. A permanent end ileostomy (Fig. 54.2a) is commonly used following a total proctocolectomy for Crohn's disease, whereas a temporary end ileostomy may be used following a total abdominal colectomy for ulcerative colitis in a staged ileal pouch-anal anastomosis. Patients with hereditary cancer syndromes (e.g., familial adenomatous polyposis, hereditary nonpolyposis colon cancer) or ulcerative colitis who are poor candidates for restorative procedures may be offered a permanent end ileostomy. Repetitive bowel resections, which may be seen occasionally in Crohn's disease, may require creation of a jejunostomy since no ileum may remain from prior resections. As with colostomy, a temporary small bowel end stoma may be created in a damage control situation when anastomosis creation is inadvisable due to contamination, hemodynamic instability, poor tissue quality, or preoperative patient factors including malnutrition and immunosuppression.

Like a loop colostomy, a loop small bowel stoma (Fig. 54.2b) is a helpful adjunct commonly utilized as temporary means of fecal diversion, although a well-constructed loop stoma can be permanent if needed. The small bowel caliber, robust vascularity, and distance from the distal colon and rectum make loop ileostomy a favorable choice for temporary diversion by many surgeons. Liquid ileostomy output can lead to pouching problems, dehydration, electrolyte imbalance, and renal failure. A comparison of temporary diverting loop ileostomy and colostomy is debated elsewhere in the text.

Physiology

Since small bowel stomas obviate colonic sodium and water reabsorption, they may render patients with variable, but occasionally profound, fluid and electrolyte imbalances. Small bowel length is highly variable ranging from 275 cm to 850 cm [6, 7] with a mean in situ length of approximately 500 cm [8] and receives between 9 to 10 L of fluid daily from proximal gastrointestinal sources. The majority of small intestinal nutritional absorption occurs within the first 150 of intestine, as nearly 6 L of fluid is reabsorbed from the jejunum while only 2.5 L is reabsorbed in the ileum [2]. Normal end ileostomy outputs can be highly variable ranging from 200–1200 mL daily (see Table 54.1). As a result, stomas created more proximally in the small bowel (e.g., jejunostomy) bypass absorptive intestinal surface area and may cause nutritional, electrolyte, and fluid imbalance. Since fat-soluble

Table 54.1 Composition of normal ileostomy effluent

	Daily excretion	Range	Concentration	Range
Wet weight	500 g	200–600 g		
Dry weight	38 g	24–48 g		
Water content			92%	88–94%
pH			6.3	6.1–6.5
Sodium	55 mEq	30–80 mEq	115 mEq/L	100–130 mEq/L
Potassium	4 mEq	3–6 mEq	8 mEq/L	5–11 mEq/L
Chloride	20 mEq	15–30 mEq	45 mEq/L	15–40 mEq/L
Calcium	18 mEq	15–40 mEq	25 mEq/L	10–64 mEq/L
Magnesium	8 mEq	7–9 mEq	15 mEq/L	10–28 mEq/L
Phosphorus	150 mEq	122–202 mEq

nutrients are absorbed in the terminal ileum, proximal fecal diversion (greater than 100 cm proximal to the ileocecal valve) can render a patient with steatorrhea and vitamin B12 deficiency. Even creation of a new terminal end ileostomy that preserves the total length of small bowel may be transiently prone to high outputs due to diversion of the ileocecal valve and colon. Management of high ileostomy outputs is detailed later in the chapter.

Preoperative Considerations for the Ostomate

As with most aspects of surgery, conscientious preoperative preparation is essential and can profoundly impact the patient. Preoperative stoma site marking and patient education improves stoma-related clinical outcomes, as well as patient quality of life and experience, while decreasing healthcare resource utilization. Although many medical centers provide robust complimentary ancillary resources to assist the ostomate and surgeon, the surgeon is ultimately responsible for perioperative care and should be competent in preoperative stoma preparation.

Stoma Site Marking

Routine preoperative identification of potential stoma sites is crucial when stoma creation is being considered and is recommended by national care guidelines and professional societies such as ASCRS and the Wound, Ostomy, and Continence Nurses Society [9–13]. Preoperative stoma site marking decreases postoperative complications [14–16]; improves stoma-specific quality of life, and overall patient quality of life, patient confidence, and independence compared to non-marked patients and may decrease stoma care costs [17]. Creating any intestinal stoma, whether permanent or temporary, in a properly chosen location is the most important predictor of an ostomate's quality of life following stoma construction.

The ideal stoma site is based on individualized assessment of the patient with respect to body habitus, contours, scars, bony prominences, and the umbilicus assessed in the standing, sitting, and laying position [18]. Special consideration to the patient's lifestyle, occupation, impairments, and preferences should be sought in conjunction with the patient. The "stoma triangle" (Fig. 54.3a) is bounded by the anterior superior iliac spine, the pubic tubercle, and the umbilicus and has been used by some groups to initially direct the surgeon to a preliminary area suitable for stomas [19]. The stoma site is at the geometric center of the triangle within the rectus sheath. Alternatively, the surgeon may identify the intersection of the infraumbilical fat pat summit and the rectus sheath as a preliminary stoma site (Fig. 54.3b, c) [20]. Efforts are typically made to locate the stoma centered within the rectus sheath, as this may decrease the risk of parastomal herniation, although this premise has been challenged in the literature [21–24].

After preliminary selection of a site, the surrounding peristomal skin must be carefully inspected ensuring the site avoids scars, folds, creases, and the umbilicus, which may hinder stoma appliance application and cause leakage (Fig. 54.4a–c). Ideally, the site should have a 2-inch perimeter of clear, intact skin to adequately seal with a stoma appliance; a commercially available stoma siting disk may help with siting (Fig. 54.3c). The costal margin, anterior superior iliac spine, and pubic symphysis should be avoided since these bony prominences may dislodge the stoma appliance (Fig. 54.4b). Skin folds and creases are not typically appreciated until the patient is sitting, so the correct site should be reconfirmed once the patient is sitting (Fig. 54.4c).

While the patient is sitting, it is equally important that the patient has a clear sight line to the stoma site. Patients with a large pannus may require moving the site superiorly along the rectus to a supraumbilical location, ensuring sight lines to the intended area. Moreover, an obese pannus may be thinner superiorly compared to inferiorly, easing stoma trephine

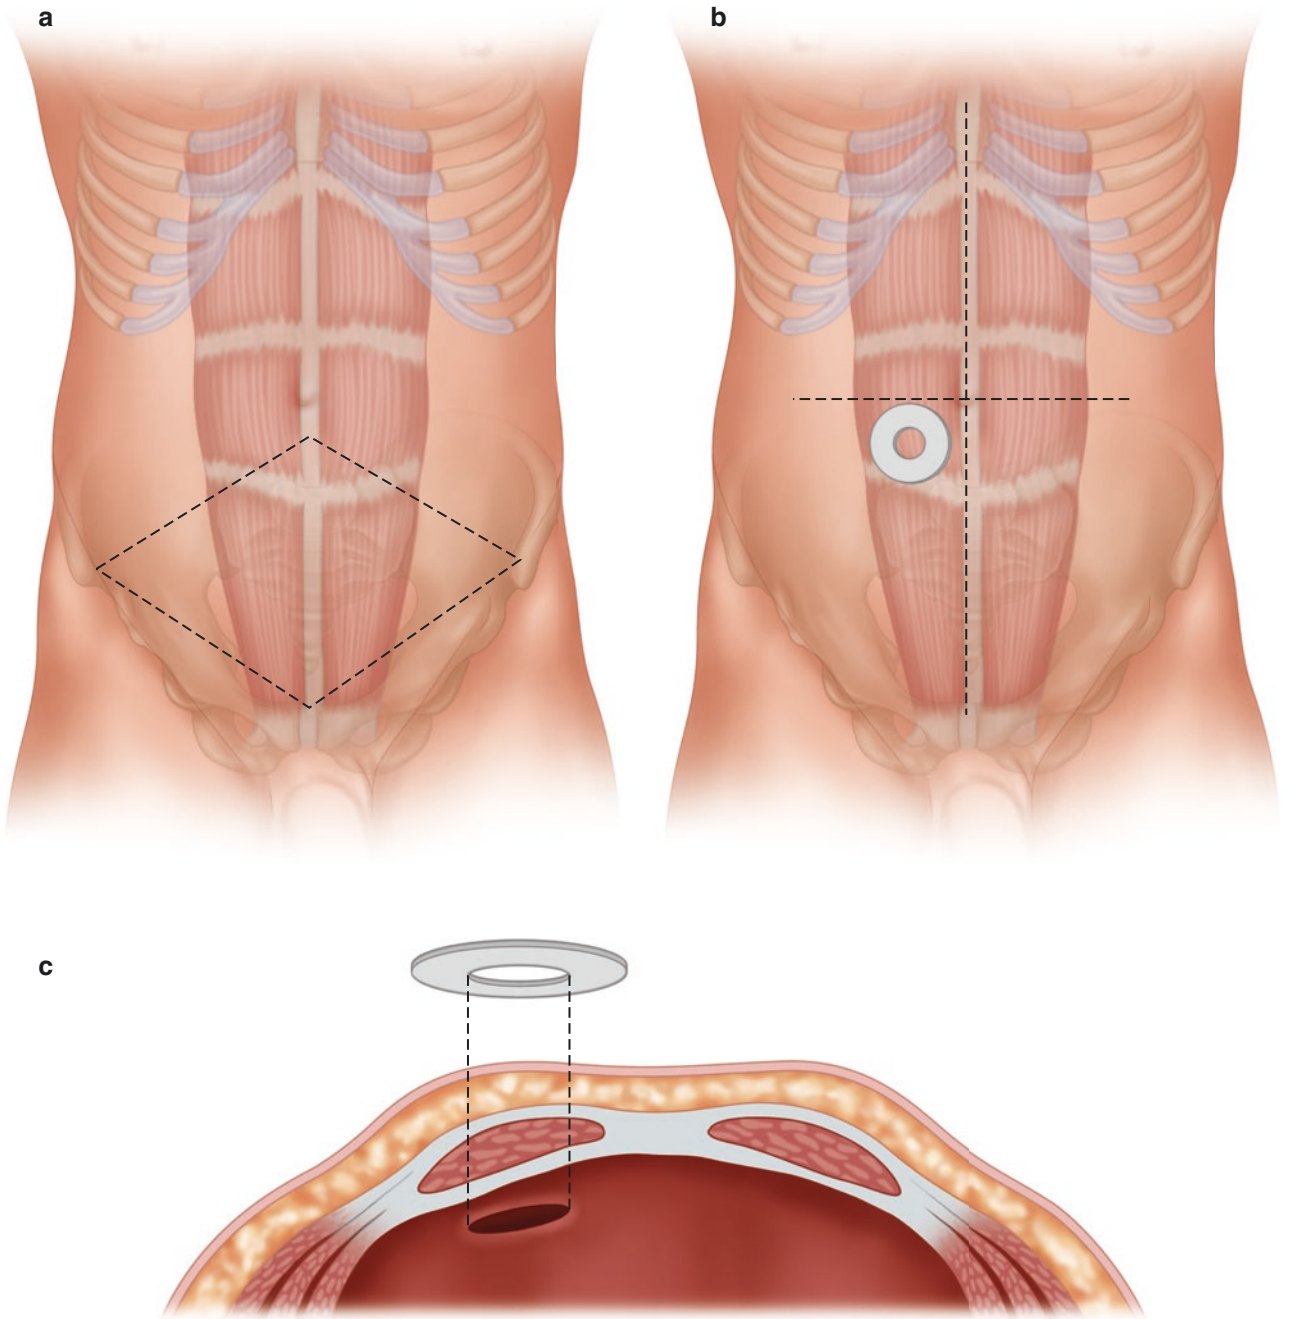

Fig. 54.3 (**a**) The "stoma triangle.". (**b**) Intersection of the infraumbilical fat pad and rectus sheath, marked by a stoma siting ring. (**c**) Cross-sectional view of the stoma trephine path and stoma siting ring, fashioned perpendicular to the abdominal wall without veering medially or laterally

creation. Lastly, the patient should be assessed while standing to confirm that the intended site avoids the pants waistline, pendulous breasts, or hernias. While standing, attention to the patient's posture, contractures, and stoma site location while bending should be assessed. Finally, reviewing potential stoma sites with the preoperative patient confirms suitable sites for both patient and practitioner.

Stoma sites should be marked with an indelible marker or tattooed with a fine gauge needle (26 gauge) and India ink [20]. Stoma sites can be marked several days in advance and protected with an occlusive transparent dressing to minimize effects of bathing. Multiple potential stoma sites can be identified, marked, and ranked in order of preference affording the surgeon options should intraoperative findings require

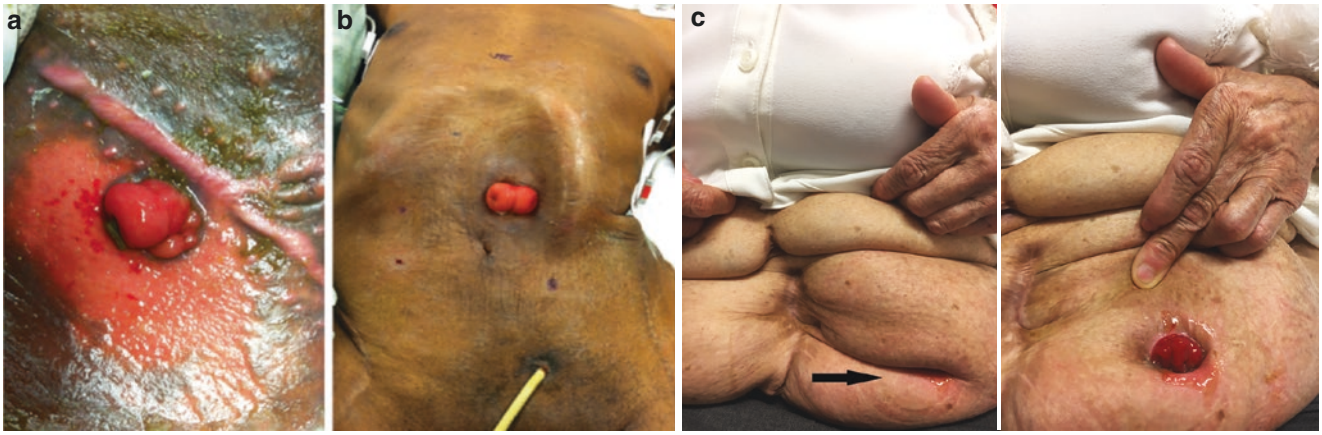

Fig. 54.4 (**a**) A loop ileostomy created too close to an incision which interfered with stoma appliance sealing, resulting in leaks and marked skin excoriation. (**b**) A transverse loop colostomy created too close to the costal margin, causing frequent appliance dislodgement. (**c**) Stomas created in a skin fold, which may not be realized until the patient is sitting or bending over. (Courtesy of Michael McGee, MD)

alternate stoma locations. Rarely, two stomas may be required for urinary and fecal drainage (e.g., for pelvic exenteration), and each stoma site should be created on opposite sides and at different levels, avoiding interference in case a stoma belt is needed. Since preoperative stoma site markings may wipe away with antiseptic skin preparations, the surgeon may find it helpful to etch a small epidermal scratch mark at each site with an 18-gauge needle following anesthesia induction to mark the site for the duration of the operation.

Preoperative Stoma Education

The mainstay of stoma education traditionally occurs in the postoperative period; however evidence suggests that preoperative educational programs may be equally important. Accordingly, societal care guidelines recommend patients receive preoperative stoma education by a specialty nurse, such as a wound and ostomy, and continence nurse before undergoing ostomy surgery [13]. Several factors may hinder postoperative stoma education. Pain, medications, and psychological stress may diminish educational effectiveness in the early postoperative period, thereby increasing the value of preoperative education. Chaudhri reported that two 45-minute preoperative visits with audiovisual aids and instruction, decreased time to postop stoma proficiency from 9 to 5.5 days, decreased hospital length of stay from 10 to 8 days, and decreased unplanned provider encounters with a net cost savings of $2104 per patient [25].

Similarly, Younis reported that preoperative patient education sessions reviewing stoma models, sample appliances, and supplies decreased inpatient length of stay from 14 to 8 days [26]. Free or low-cost commercially prepared preoperative resources are available from stoma supply manufacturers and through the American College of Surgeons (ACS). The ACS Ostomy Home Skills Kit (Fig. 54.5) contains an instructional DVD demonstrating stoma care techniques, sample stoma supplies, and a plastic model stoma that allows the patient to simulate preoperative stoma care.

The standardized interactive program has been developed by the American College of Surgeons (ACS) in collaboration with the American Society of Colon and Rectal Surgeons (ASCRS) and other societies and organizations. Over 134,000 kits have been distributed since release in 2010. Preliminary unpublished data from the ACS reveals that patients receiving the Ostomy Home Skills Kit preoperatively were more confident with stoma care, were less likely to have problems, required less provider help once home, and were more satisfied with their care compared to patients receiving standard postoperative stoma education.

Technical Considerations of Stoma Creation

Small Bowel End Stoma

Small bowel end stomas are typically easy to create owing to the mobility of the robustly collateralized small bowel mesentery. Laparoscopic or open approaches may be used, although the laparoscopic approach is favored, if feasible [9]. After selecting the target small bowel segment, care is taken to ensure the mesentery is fully mobilized and all adhesions are freed to allow tension-free reach beyond the abdominal wall. Division of some mesenteric vessels may be necessary to obtain adequate reach, particularly in patients with thick abdominal walls. If mesenteric vessels are divided to gain sufficient reach, care should be taken to ensure adequate perfusion at the tip of the stoma conduit as evidenced by palpable mesenteric pulses, arterial bleeding from the cut

Fig. 54.5 The American College of Surgeons Ostomy Home Skills Kit. Reused with permission from the American College of Surgeons

edge of the mesentery, or novel imaging perfusion assessments such as indocyanine green (ICG)-enhanced fluorescence (see section "End Colostomy" for a discussion of ICG perfusion assessment).

During open surgery, identification of mesenteric vessels can be facilitated by transillumination of the mesentery with a light source, providing guidance on which vessels to preserve or sacrifice to sustain stomal perfusion, if needed. Akin to preparing bowel for an anastomosis, careful assessment of bowel perfusion can avoid ischemia-related stomal complications such as stenosis and retraction. Obese patients or those with thickened or inflamed small bowel mesentery may require additional lengthening maneuvers detailed later in this chapter (see section "Special Circumstances: The Difficult Stoma").

Once adequate mobilization of the small bowel segment is obtained, a cylindrical stoma trephine is created at the previously marked stoma site. For an end ileostomy with normal caliber bowel and mesentery, the authors prefer to excise an approximately 2-cm diameter skin disk and vertically divide the subcutaneous tissues down to the level of the anterior rectus sheath without "coring" or removing subcutaneous tissues. During open surgery, an assistant's two fingers firmly pushing a folded gauze sponge anteriorly at the intended point of peritoneal entry may ease trephine creation by compressing the tissue girth and ensuring the trephine cylinder remains orthogonal to the abdominal wall (Fig. 54.6). The anterior rectus sheath is incised with a 3-cm vertical incision. The exposed fibers of the rectus muscle are carefully spread with a large clamp to allow lateral and medial distraction of the split rectus muscle to expose the posterior rectus sheath. Special care is taken to ensure all fibers of the rectus muscle and inferior epigastric vessels are completely retracted to avoid pesky muscular bleeding. With the posterior rectus sheath exposed, cautery is used to make a 3-cm vertical incision directly onto the assistant's gauze sponge, whereby completing the stoma trephine. Passage of one or two fingers through the completed trephine gently dilates and confirms trephine size. If necessary, the trephine diameter can be further enlarged by making a radial skin incision at the skin level or extending either anterior or posterior rectus sheath incisions.

Laparoscopic approaches follow the same general principles as open surgery. After assuring adequate mobilization laparoscopically, an abdominal wall trephine is made. If an extraction site is present, a trephine can be made akin to open surgery with an assistant using two digits pressing upward. If no extraction site exists, careful trephine creation is needed to avoid injuring intra-abdominal contents while incising the posterior rectus sheath and peritoneum. Once the trephine is completed, pneumoperitoneum is quickly lost, and it can be difficult to locate the target segment of bowel through the small trephine. An extra-small plastic sleeve wound retractor placed in the stoma trephine may aid visualization. The authors suggest placing a locking atraumatic bowel grasper on the tip of target loop of bowel, left immediately under the peritoneal side of the stoma trephine, so that the bowel can easily be visualized once pneumoperi-

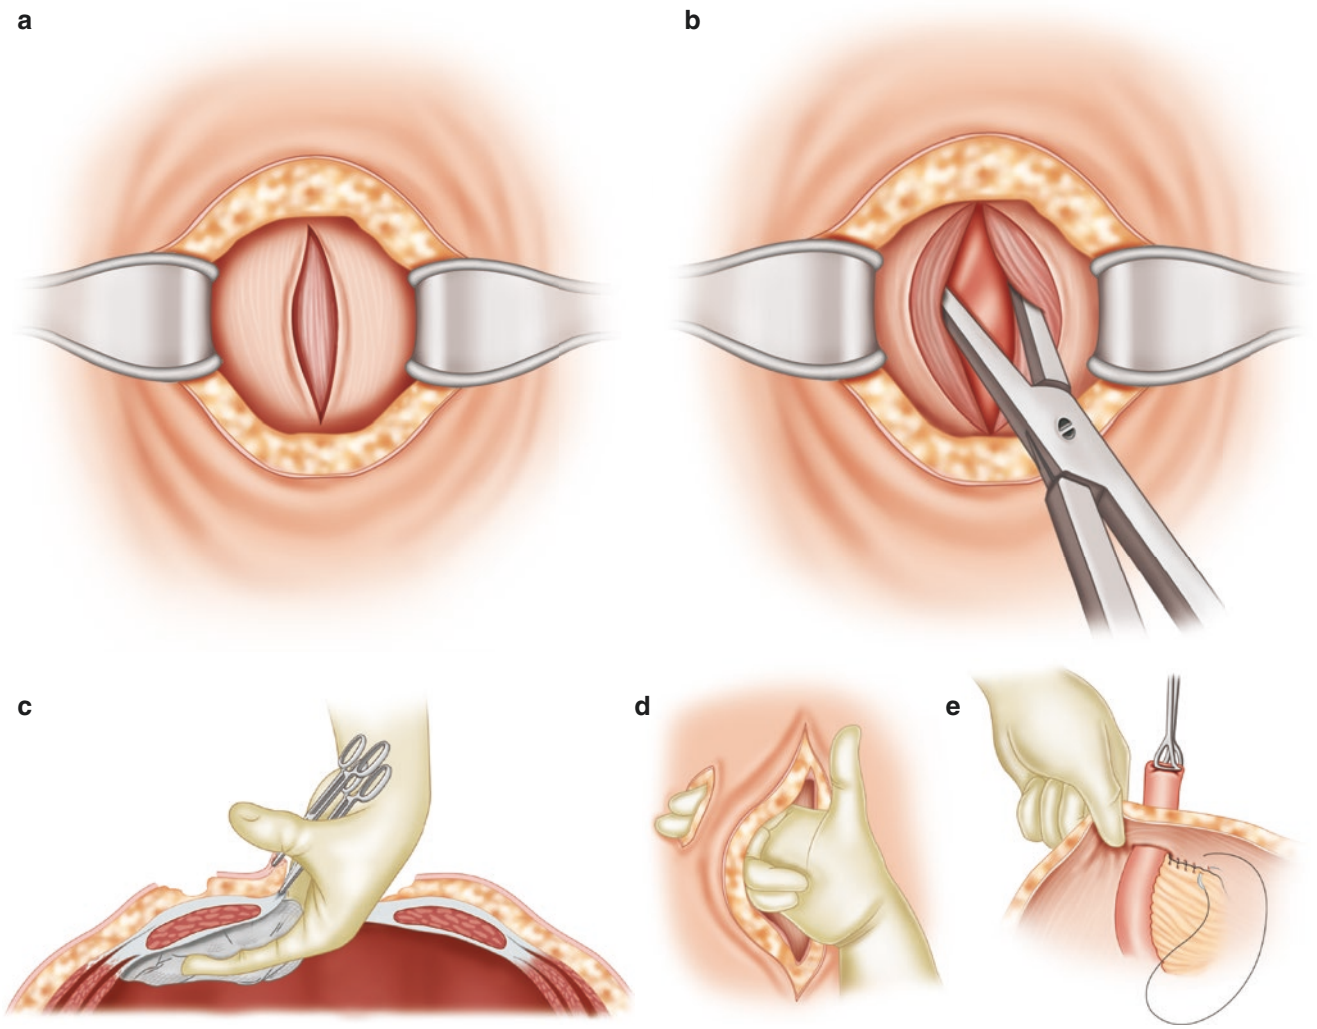

Fig. 54.6 Creation of an end small bowel stoma. (**a**) A 2-cm skin disk is excised, and the subcutaneous tissues are split to the level of the anterior rectus sheath. (**b**) The anterior and posterior rectus sheaths are incised vertically, and the rectus muscle is split. (**c**) An assistant may assist in stoma creation by pushing anteriorly using a folded sponge to protect intra-abdominal contents. (**d**) Two fingers are passed through the completed stoma trephine to assure adequate sizing. (**e**) The ileostomy is eviscerated with assistance of a Babcock clamp

toneum is lost. Once the abdomen is desufflated, the laparoscopic bowel grasper can be directed to a stoma trephine. Once the target bowel is identified through the trephine, it can then be transferred to a Babcock clamp placed through the trephine.

For both open and laparoscopic techniques, the previously mobilized bowel segment is carefully delivered through the properly sized trephine with assistance of a Babcock clamp. To avoid stoma retraction, 5–6 cm of small bowel and corresponding mesentery should be completely pulled through and be left above the level of the skin. The authors generally recommend to pull slightly more intestine through than needed to ensure adequate mobilization. Care should be taken to carefully coax the corresponding bowel mesentery through the trephine without injury or avulsion. A bimanual approach may be necessary to gently push and guide the bowel mesentery from the peritoneal trephine while the surgeon is gently pulling. The blunt side of an Adson tissue forceps can be used as a shoehorn and facilitate the stoma mesentery mobilization, if it lodges at the rectus sheaths or subcutaneous tissues. Additional techniques are described to help coax the difficult stoma through the abdominal wall later in the chapter (see section "Special Circumstances: The Difficult Stoma").

With an adequate length of bowel exteriorized through the abdominal wall, the stoma should be assessed for tension, viability, and mesenteric bleeding. A persistently dusky stoma may be related to mesenteric vascular injury, venous outflow occlusion from a narrow trephine, or unin-

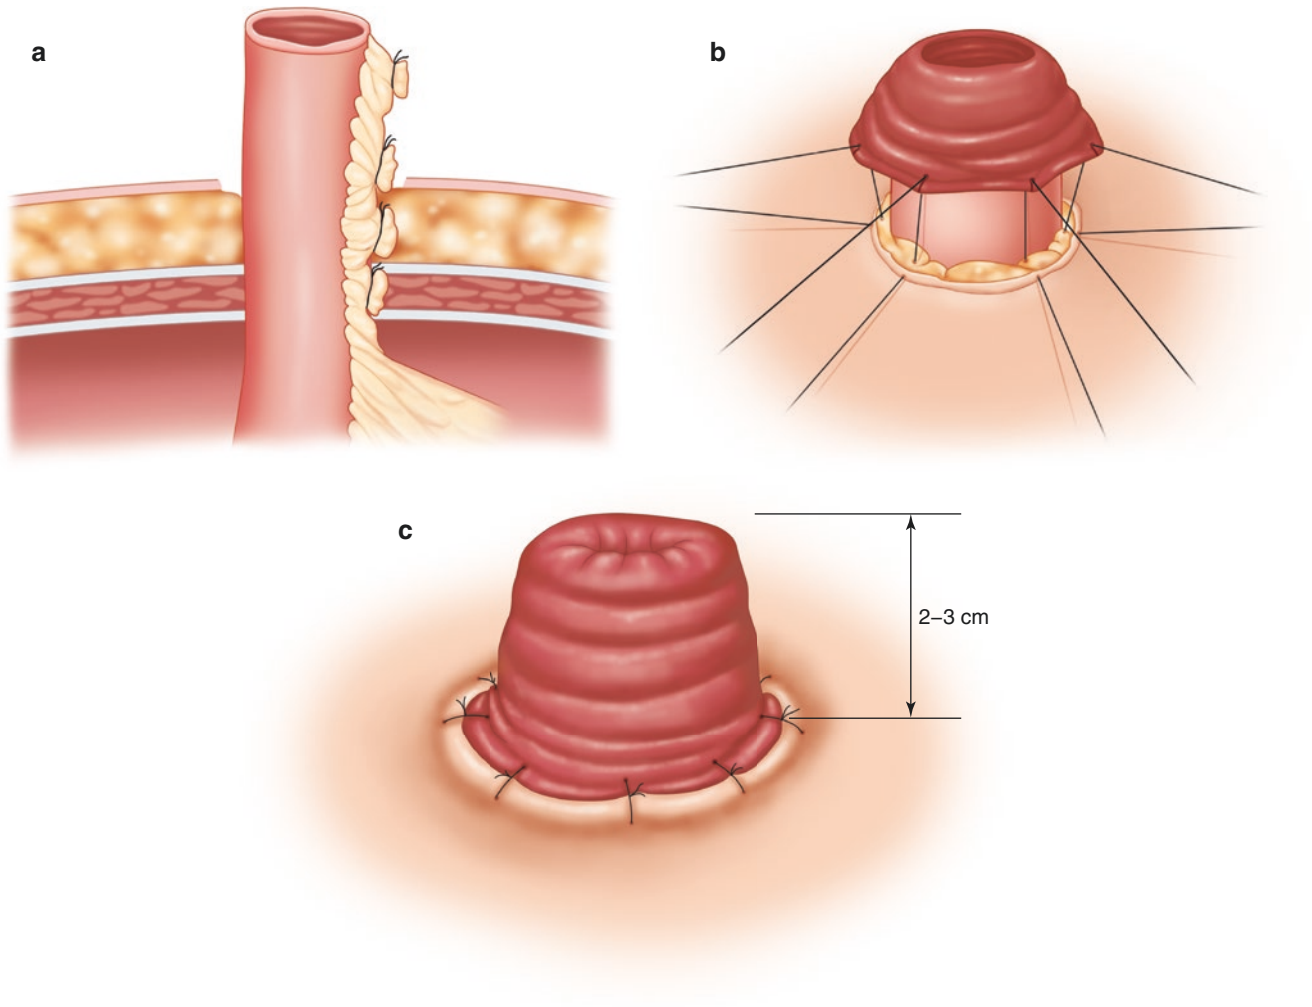

Fig. 54.7 Maturation of an end small bowel stoma. (**a**) An adequately mobilized, tension-free, length of small bowel is eviscerated through the stoma trephine. (**b**) Multiple interrupted absorbable sutures are used to mature the stoma. (**c**) The completed small bowel stoma should ideally protrude 2–3 cm from the skin level

tentional vascular division during mesenteric mobilization and should be revised prior to closing the abdomen. Typically, the stoma is left for maturation until all other abdominal wounds are closed to minimize incisional contamination.

Once all remaining abdominal wounds are closed and protected from topical contamination, the end ileostomy is matured to ideally protrude 2–3 cm. Ileostomy maturation is necessary to cover and protect the eviscerated bowel serosa with mucosa, whereby shielding it from the caustic bowel effluent which can cause inflammatory serositis and ileostomy stricture. If the ileostomy was stapled closed, the staple line is excised, and the full thickness of the bowel wall is everted. Occasionally, thick or fatty mesentery may require careful debulking to allow complete bowel wall eversion; however these maneuvers should be performed carefully to avoid devascularizing the stoma. Multiple interrupted absorbable sutures are used to suture the everted bowel wall to the skin (Fig. 54.7).

Classically, such "Brooke" sutures also incorporate a seromuscular purchase of the bowel at the skin level that fixes the everted structure at the skin. Historically, dogma dictated that sutures should carefully be placed through the dermis, but not the epidermis, to avoid mucosal cellular implants that have been reported to migrate along suture lines and colonize the epidermis with ectopic mucosal islands. Such dermal mucosal islands were thought to secrete mucus on the peristomal skin and interfere with stoma appliance adhesion [27]. A recent prospective, randomized study showed a modest reduction in postoperative peristomal excoriation using full-thickness (dermal and epidural) skin fixation sutures compared to "intradermal" (dermal but no

epidermal) fixation during ileostomy maturation [28]. Despite a reduction in nurse-assessed skin excoriation from 52% to 41% using full-thickness skin sutures, there was no difference in stoma-specific quality of life outcomes, stoma supply costs, or other complications between skin fixation modes. Broader applicability of the study may be limited by the short 3-month study follow-up and suture material variation between groups.

The finished end small bowel stoma should ideally protrude 2–3 cm from the skin, which improves sealing and decreases complications [9, 12, 15]. Flush or inadequately protruding small bowel stomas may be fraught with leakage since caustic liquid small bowel contents can easily leak underneath the stoma flange causing painful, excoriated, weeping skin wounds that are difficult to pouch. Ileostomy heights less than 2 cm are associated with problems, and the height of the stoma is inversely proportional to likelihood of complications [29]. Since a significant portion of end stomas will be permanent, the surgeon should take great care in making the perfect stoma, which may save the patient, surgeon, and family a lifetime of frustration.

Small Bowel Loop Stoma

Small bowel loop stomas are fashioned with either laparoscopic or open techniques with a segment of well-mobilized bowel free of adhesions. For open loop stomas, a fine-tipped clamp is passed to create a small defect at the bowel wall mesentery interface, and a thin Penrose drain or umbilical tape is passed underneath the bowel (Fig. 54.8). Some prefer to place different colored seromuscular marking stitches to orient the bowel limbs and prevent twisting and inadvertently maturing the distal limb of the loop. Alternatively, correct bowel orientation can be insured by drawing an arrow on the anti-mesenteric border of the bowel indicating the proper direction of intestinal flow. A 2.5-cm diameter stoma trephine is made at a previously marked site using the previously described technique. Generally, the stoma trephine is made slightly larger for loop stomas than end stomas, and the final trephine typically accommodates two fingers easily. The Penrose drain is then used to safely pull the loop of bowel through the stoma trephine while minimizing trauma to the bowel. The surgeon confirms that there is no twisting

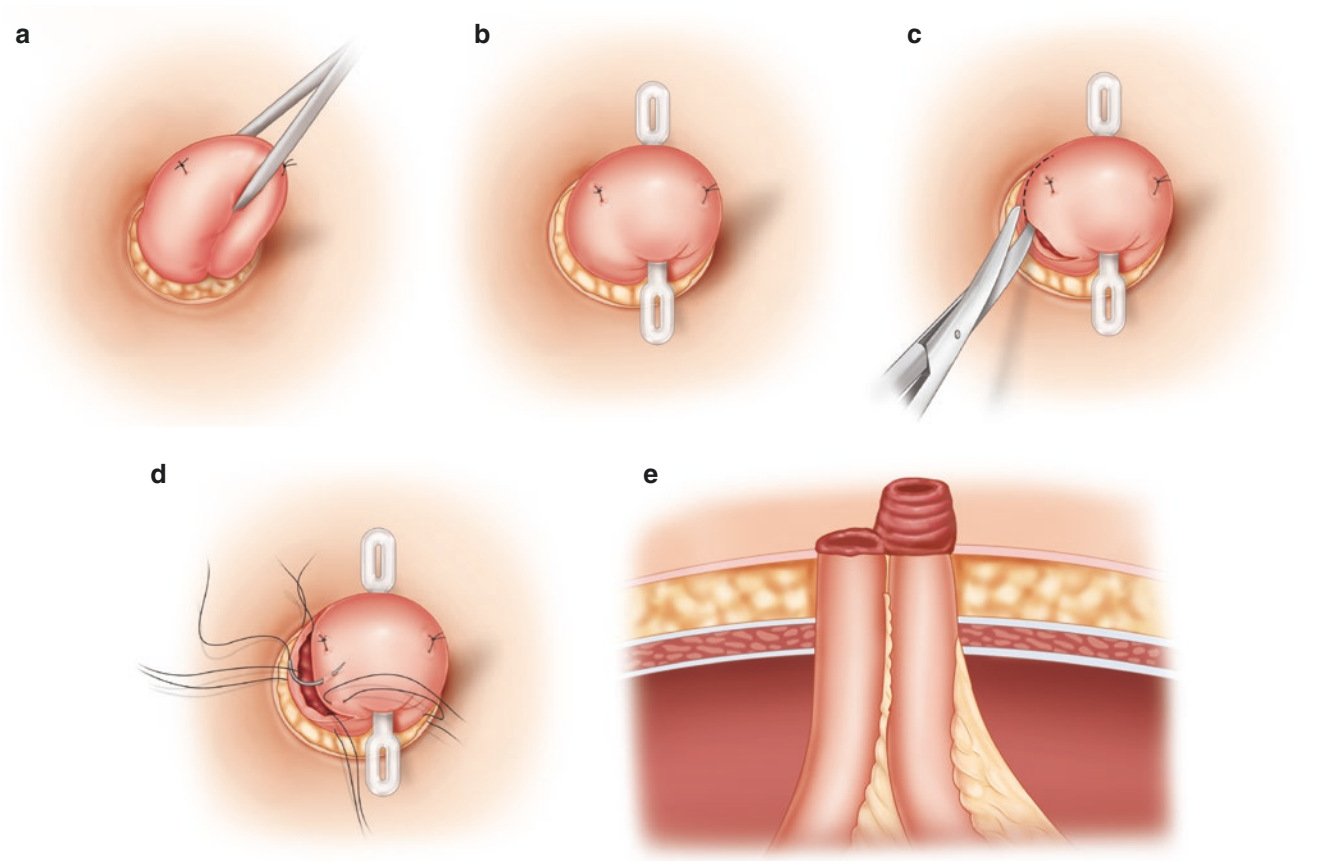

Fig. 54.8 Creation of a loop small bowel stoma. (**a**) A narrow Penrose drain is passed through a mesenteric defect and used to gently pull the target loop through the stoma trephine. (**b**) The Penrose drain may be exchanged for a stoma rod. (**c**) The distal segment of the loop stoma is opened at the skin level. (**d**) The distal "hood" of small bowel is then everted and sutured over the proximal limb to create a spout. (**e**) The completed small bowel loop stoma

of the mesentery. The blunt paddle-like back end of an Adson forceps is again helpful if the bowel is caught at the fascia or dermal level. Laparoscopic loop stomas are made similarly to laparoscopic end stomas as detailed above.

The Penrose drain may be exchanged for a plastic stoma rod to temporarily support the bowel loop above the skin until adhesions form between the trephine and bowel wall, although the utility and type of a supporting rod is debatable [30]. If used, the rod should not be under significant posterior tension, and additional bowel should be mobilized or pulled through the trephine if the rod is causing a deep indentation. A 2019 meta-analysis of five studies suggested that the use of stoma rods did not alter rates of stoma retraction and were associated with increased rates of stoma necrosis and peristomal dermatitis. Broader applicability of the study is limited by assignment biases, low BMI patients, and questionably long periods of stoma rod use that ranged from 7 from 14 postoperative days [31]. Given the ambiguity surrounding the therapeutic index of stoma rods, the authors espouse conditional use of stoma rods until more conclusive data is available.

Following closure and protection of all abdominal wounds, a near-circumferential incision is made along the distal limb bowel wall at the level of the skin. The mesenteric portion of the bowel wall is left intact and is not divided. Absorbable sutures are used to secure the defunctioned segment to the dermis. The remaining "hood" of bowel is then everted with the blunt back end of an Adson clamp and sutured to the dermis. As with end small bowel stomas, the proximal bowel limb should protrude 2–3 cm from the skin when finished allowing a watertight fit between the stoma appliance and the peristomal skin, whereby decreasing postoperative stoma-related complications. When used, the stoma rod is typically removed in 3–5 days once adhesions have formed assuming there is no tension between the rod and skin. Although loop stomas are often considered temporary, they should be constructed durably in the event that distal intestinal continuity cannot be restored. The use of intra-abdominal anti-adhesion materials may be considered to decrease adhesions and possibly ease subsequent reversal at temporary ostomy sites [9, 32–34].

End Colostomy

Creation of an end colostomy follows similar techniques as described for small bowel stomas, but the tenuous colonic blood supply requires special consideration. Both laparoscopic and open approaches can be used. For either approach, great care should be taken to assuredly and completely mobilize the intended segment of colon so that several centimeters of bowel reaches above skin level in a tension-free manner. Unlike the relatively mobile small bowel mesentery, the colonic conduit and mesentery may require substantial mobilization depending upon the level of diversion. An end sigmoid colostomy may not require significant mobilization due to the redundant nature of the sigmoid loop in a thin patient; however a proximal end descending colostomy may require full mobilization of the splenic flexure with high vascular ligation to obtain sufficient reach in an obese patient. The authors strongly suggest that the surgeon treats the colonic conduit akin to an anastomosis by eliminating tension with adequate colonic mobilization and assuring adequate perfusion. It may be helpful to excise all epiploic appendages from the anti-mesenteric bowel wall easing eventual evisceration.

For open end colostomies, once the segment of colonic conduit is chosen and prepared, a 2.5-cm diameter stoma muscle-splitting trephine is fashioned at the site of previous marking using the previously described techniques. An end colostomy may require a larger trephine depending upon the bowel caliber and mesentery thickness. Epiploic appendages may be excised to ease colon passage through the abdominal wall trephine. The colon is passed through the stoma trephine with a Babcock clamp and eviscerated. The surgeon confirms a pink, well-perfused stoma that rests comfortably for 3–4 cm above the skin level without tension or retraction. Following closure and protection of abdominal wounds, the colostomy is opened everted and sutured to the skin to produce a colostomy that protrudes 1–2 cm. Typically, the solid nature of colostomy effluent is not toxic to surrounding skin, and a lengthy stoma eversion is not necessary. If necessary, a colostomy can be made flush with the skin, but the authors suggest 1–2 cm of protrusion helps patients with stoma pouching and skin care. Once matured, the colostomy should be evaluated to confirm adequate perfusion with a pink glistening mucosa. Laparoscopic end colostomies utilize the same principles as detailed above.

When creating end stomas, particularly colostomies, maintaining perfusion to the distal tip of the stoma can be difficult. Often seen in obese patients and those with inflamed or foreshortened mesenteries, there may be a balance between maintaining conduit length in order to avoid stoma retraction and guaranteeing reliable perfusion. In such circumstances, assessing perfusion to the most distal aspect of the stoma is both difficult and essential. Intraoperative gross "naked-eye" optical evaluation of the stoma can be misleading since visible ischemic changes to the mucosa or serosa may take hours to days to develop. Since an error in evaluating stoma perfusion can lead to mucosal sloughing, mucocutaneous separation, stenosis, retraction, and necrosis, assessing stoma perfusion should be a critical step in stoma creation.

Many intraoperative assessments can guide the surgeon to ensure adequate perfusion to the distal aspect of the stoma. Generally, simple measures such as confirming palpable

mesenteric pulses or pulsatile arterial bleeding from the cut edge of the mesentery at the stoma tip are cheap and straightforward. Recently, the advent of near-infrared fluorescence with indocyanine green (ICG) infusion has been used to evaluate intestinal perfusion prior to anastomoses. This technology can also be used to evaluate stomal perfusion. The segment of the colon or ileum to be used for stoma creation is mobilized, and the stoma trephine is created using the aforementioned principles. The bowel is passed through the stoma site and exteriorized. ICG is then infused intravenously while a specialized near-infrared camera is focused on the stomal segment. Well-perfused tissue will fluoresce, while non-perfused tissue will lack enhancement. Any non-perfused segment is excised and the stoma recreated using well-perfused intestine. On occasion, venous congestion may cause the stoma to appear congested and dusky to the naked eye despite ICG fluorescence, whereby indicating venous outflow compression from an overly tight stoma trephine. When venous outflow obstruction is suspected, the trephine can be enlarged slightly, and the perfusion will improve. If ICG fluorescence indicates adequate perfusion, the stoma will very rarely develop any ischemic consequences. Venous congestion may last for several days, and occasionally self-limited inconsequential mucosal sloughing will develop. ICG fluorescence is a fast and highly accurate test but relies on proprietary optical systems that may not be available to all surgeons. Whether simple and cheap methods such as assessing for palpable pulses or pulsatile arterial bleeding at the tip of the mesentery or using specialized technology like ICG fluorescence, the authors recommend that some form of perfusion assessment be used during end stoma creation.

Loop Colostomy

A loop colostomy is typically fashioned from the non-peritonealized sigmoid or transverse colon, although any segment of colon can be used in a loop configuration with adequate mobilization via open or laparoscopic techniques. After identifying the target segment of colon, an assessment of reach and mobilization is performed assuring the colon loop reaches several centimeters above the previously marked stoma site without tension. For open surgery, a narrow Penrose drain is passed through an avascular recess at the junction of the mesentery and colon wall. After creating an approximately 3-cm diameter trephine using the aforementioned techniques, the colon loop is gently pulled through the trephine and delivered over a stoma rod. Following closure and protection of abdominal incisions, the loop colostomy is matured by incising along the long axis of the bowel and maturing the cut edge of bowel to the skin circumferentially (Fig. 54.9). The matured loop colostomy

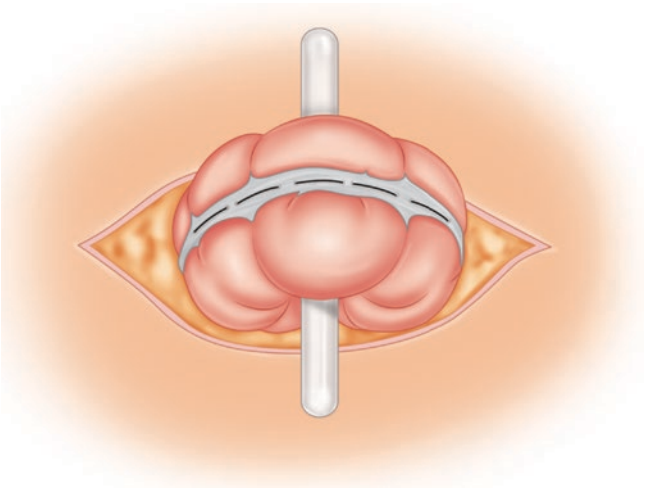

Fig. 54.9 Creating an incision along the long axis of the colon to create a loop colostomy

may be quite large depending upon the bowel caliber, mesenteric thickness, and postoperative edema. As with loop small bowel stomas, loop colostomies may be temporary or permanent and should always be constructed durably if stoma reversal will be inadvisable. Laparoscopic techniques follow similar principles as detailed above. As with loop small bowel stomas, the use of intra-abdominal anti-adhesive products may be considered with temporary loop colostomies to potentially ease future reversal [9].

Postoperative Care for the Stoma

Early Inpatient Postoperative Care

Immediately after creation, the stoma will become edematous and swell to two to three times the original size. The stoma will typically shrink to normal size after approximately 4–6 weeks. The new stoma should be monitored daily and assessed for color, viability, and retraction and should remain pink, moist, and protrude well. If a stoma rod was used, the rod may be removed 3–5 days postoperatively or when centripetal tension decreases and the rod easily slides out. The stoma rod can be left for longer periods of time for difficult or tenuous stomas.

Both small bowel and colonic stomas do not typically function immediately. Stoma outputs initially resemble small volumes of serosanguinous or mildly bilious thin fluid without particulate matter, described as "bowel sweat." Bowel function will recover with time and stoma outputs will increase. Colostomies tend to produce gas first, followed by liquid stool, and ultimately more solid waste as time proceeds – although this cadence can be variable. Small bowel stomas tend to function sooner than colostomies. Even dur-

ing fasting, small bowel stomas will produce significant volumes or dark green bilious outputs. As diet is advanced, particulate materials intensify, and small bowel effluent becomes increasingly thicker.

As described earlier, small bowel stoma outputs can be high leading to profound dehydration and electrolyte abnormalities. As early postoperative bowel function returns, a deluge of backlogged bowel contents may rush out producing initially high stoma outputs. Small bowel stoma outputs generally taper with time but may require dietary and medical management if outputs are persistently high (see Section "Stoma Complications: The High Output Stoma"). Over 30% of new ileostomy patients may experience dehydration with early postoperative readmission rates exceeding 15% [35]. Recent studies show that perioperative stoma care pathways focusing on patient education, standardized discharge criteria, output logs, visiting nurse care, and early follow-up may decrease postoperative readmissions related to dehydration and should be strongly considered for new ostomates [9, 36, 37].

Patient-centered postoperative stoma education should begin as soon as the patient can participate. Since approximately half of stoma care is provided by a spouse and a quarter of stoma care is provided by an offspring, caregiving family members should participate in stoma education [17]. The ultimate goal is to train the patient and caregivers to become proficient in caring for the stoma. Postoperative patients typically follow a graduated program that focuses on both knowledge and skills training for emptying, applying, and troubleshooting common stoma problems. Many new ostomates are only capable of emptying a stoma pouch at time of discharge. As a result, patients are often discharged home lacking knowledge on how to manage common pouch-related issues. Unpublished data from the American College of Surgeons revealed only 53% of homegoing new ostomates were capable of applying a new pouch and only 28% were able to fix pouch leaks. As a result, 45% of all new homegoing ostomates worried about self-care, 40% felt sad and/or depressed, and 62% were uncomfortable leaving home. Accordingly, many institutions bridge inpatient postoperative stoma care and education into the outpatient domain with home nursing.

Postoperative Outpatient Care

Many groups, including ASCRS and the Wound, Ostomy, and Continence Nurses Society (WOCN), believe that optimal care for patients undergoing ostomy surgery includes preoperative and postoperative care by an ostomy nurse specialist, such as a WOCN-certified nurse [9, 13]. Periodic stoma assessment and educational reinforcement should continue following discharge from stoma surgery, particularly in the early postoperative period when stoma-related complications are most frequent. Attention should be paid to stoma outputs and the frequency with which the stoma flange is changed, which is a good surrogate for peristomal skin quality and leakage. Ideally, a flange should last 3–5 days between changes. More frequent appliance changes may indicate improper technique, inappropriate appliance, peristomal skin disease, or a poorly located or constructed stoma. A published survey indicated that on a scheduled postoperative visit with a WOCN nurse, over 60% of new ostomates had peristomal skin irritation that was unrecognized by nearly half of patients of patients. Once identified and treated, stoma-specific quality of life improved [38]. In addition, structured postoperative group sessions may prove beneficial to the ostomate even in the late postoperative period [39]. Ostomy support groups, which are organized online and in person, may provide ongoing support for novice and experienced ostomates alike [40].

Stoma Appliances

Stoma appliances come in a variety of sizes and configurations but generally consist of an adhesive flange (wafer) that seals to the skin and a collecting bag which may come in one- or two-piece models (Fig. 54.10). Two-piece appliances allow the collection bag to completely detach from the flange and allow inspection of the stoma without completely removing the flange and may be advantageous in the early postoperative period while the stoma is examined daily. Stoma flanges are generally comprised of a pectin-like adhesive wafer ring surrounded by waterproof tape-like layer. The inner diameter of the ring comes in various sizes and can often be trimmed with scissors to accommodate larger or irregularly shaped stomas. Generally speaking, the wafer should be trimmed to the exact size of the stoma leaving little to no peristomal skin exposed to bowel contents. Disposable stoma sizing templates are available from most stoma supply manufacturers. Appropriate sizing and trimming of stoma appliances are crucial – particularly during the first 6 weeks as stoma edema subsides. Survey data indicates the average ostomate places a new flange every 4–5 days. The flange should be changed every 3–7 days depending upon peristomal skin care needs [41].

Collection bags come in a variety of sizes in both clear and opaque models based on patient preference. Venting charcoal filter bags may be used to help patients with voluminous gaseous outputs. High output bags may be used to connect to a leg collection system akin to a Foley catheter. Bags should be emptied at the discretion of the patient. New small bowel stoma patients are encouraged to log outputs for the first several weeks and monitor for high outputs.

Specialized stoma appliances may be necessary depending upon the condition of the peristomal skin, stoma morphology, and body habitus. Convex stoma appliances feature

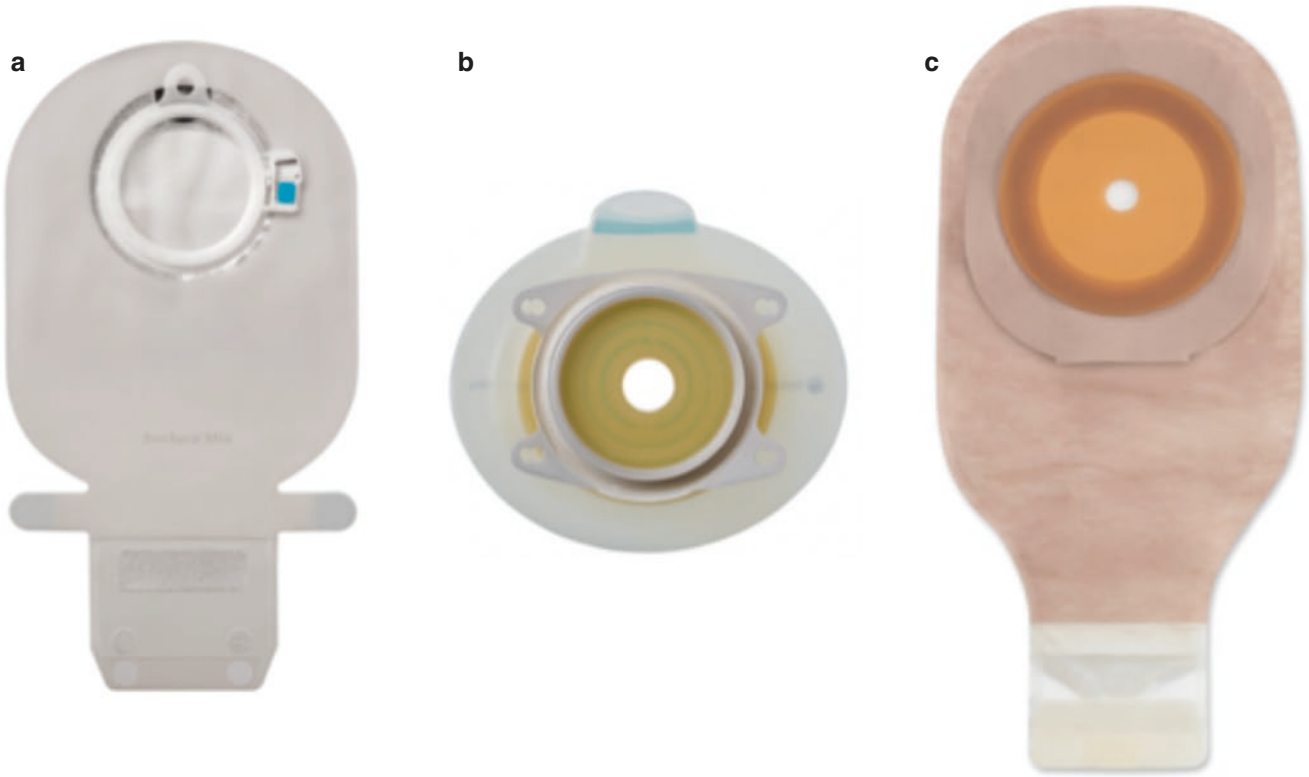

Fig. 54.10 (**a**) and (**b**) Two-piece stoma appliance with flange and pouch. (**c**) One-piece stoma appliance

a bowl-shaped wafer that assists sealing flush or retracted stomas. Elastic stoma belts may be used to bolster skin sealing for leak-prone stomas. Stoma paste and preformed stoma barrier rings may be used to improve sealing between the peristomal skin and wafer and may be particularly useful when skin folds or scars create an uneven peristomal skin surface. A variety of skin adhesives, protectant wipes, adhesive removers, and topical powders are available to assist with difficulties surrounding the peristomal skin.

Table 54.2 Stoma complications

Complication	Incidence rates (%)
Retraction	0–22
Parastomal hernia	0–40
Stoma prolapse	0–10
Stoma necrosis	0–7
Peristomal skin problems	10–42
Total complications	12–72

Adapted from Salvadalena [43]

Stoma Complications

Stoma problems are ubiquitous and profoundly impact ostomate quality of life but can often be mitigated with proper care and education in collaboration with stoma care professionals such as WOCN nurses. American Colloege of Surgeons American College of Surgeons National Surgical Quality Improvement Program data showed a 37% unadjusted complication rate for elective cases involving a stoma and 55% complication rate for emergency operations [42]. Stoma-specific complications are even higher when considering patient-reported outcomes (Table 54.2). Early stoma-related complications such as leakage, peristomal dermatitis, and dehydration tend to arise from stoma management issues that can be remedied with stoma care and education. Prolapse, stenosis, and parastomal hernia are late-term stoma-related complications and may require surgery for definitive correction. Although specialized stoma care nursing is available at many institutions, recognition, care, and management of stoma-related complications are under the purview of the colorectal surgeon.

Stomal Ischemia: Necrosis, Retraction, and Stenosis

Poorly perfused stomas can necrose in the early postoperative period (Fig. 54.11a). Arterial insufficiency is the most common cause of stoma necrosis; however venous ischemia

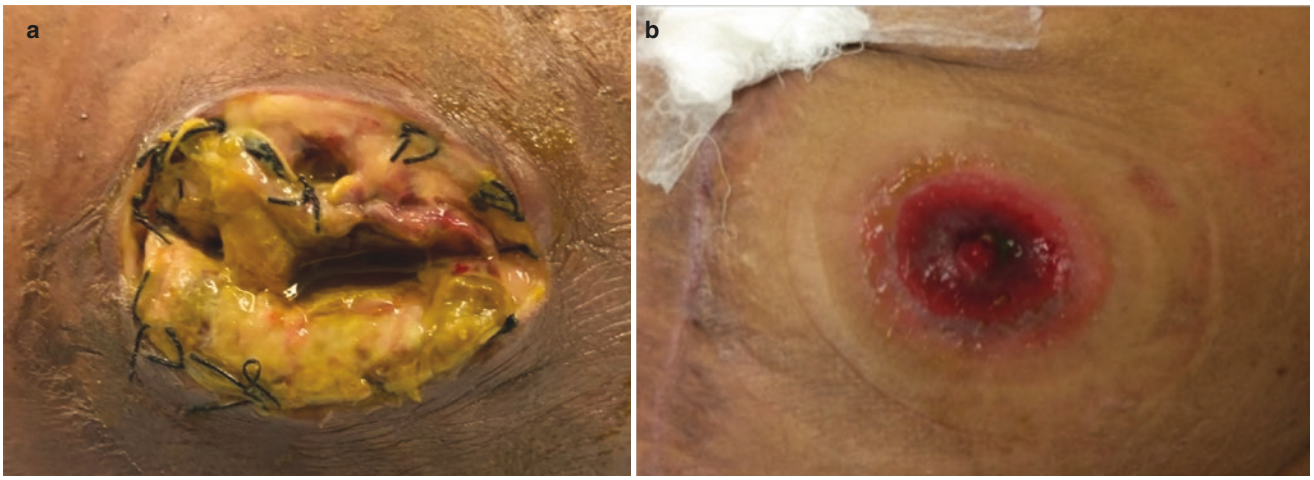

Fig. 54.11 (**a**): Acute postoperative stoma necrosis with mucocutaneous separation [courtesy of Michael McGee]. (**b**) Chronic ileostomy ischemia leading to retraction, stenosis, difficulty pouching, and peristomal erosions. (Courtesy of Adam Stein, MD)

can rarely arise from fascial obstruction within the trephine. Loop stomas, which preserve collateralized mesenteric vasculature proximal and distal to the stoma, are more resistant to ischemia than end stomas, which require mesenteric division and typically rely upon unidirectional arterial flow. Proper stoma creation techniques can help avoid ischemia-related stoma complications by assuring adequacy of bowel perfusion. Intraoperative assessments of mesenteric pulses, pulsatile bleeding from the cut edge of the mesentery, nuisance bleeding from the cut edge of the bowel wall, ICG fluorescence, and mucosal evaluation can mitigate risk of stoma ischemia and related complications.

Akin to ischemic colitis, marginally perfused stomas may demonstrate variable degrees of ischemia with regard to timing, length, and depth of the ischemic bowel segment, rending early postoperative assessment of stoma viability crucial. Stoma ischemia typically begins with mucosal pallor and progresses to petechiae, cyanosis, and purple-black mucosal necrosis. Mild stomal ischemia may cause limited, partial-thickness mucosal necrosis and slough; but deeper bowel wall layers may remain viable. The most distal edge of the stoma, typically matured to the peristomal skin, is the segment most vulnerable to ischemia. As the everted bowel wall courses proximally, a perfusional gradient may be seen where ischemia may transition to a viable bowel wall.

Identification of the proximal extent of the ischemic stoma is crucial and can often be identified with a bedside "test tube" examination. A lubricated clear glass test tube is inserted through the stoma os while a flashlight is directed down the stomal lumen. The illuminated glass permits bedside mucosal evaluation for the length of the tube, allowing the surgeon to assess the proximal extent of mucosal ischemia along the stomal conduit. Management of early postoperative stoma ischemia varies between small bowel and colonic stomas. Any stoma with early evidence of subfascial ischemia (i.e., posterior to abdominal wall fascia) should be revised, since deep ischemia may progress to frank intraperitoneal necrosis and perforation. A colostomy appearing viable anterior to the fascia may be carefully observed without revision, since intraperitoneal perforation is unlikely, and solid colostomy outputs can be reasonably pouched even if distal stoma necrosis renders the stoma flush with the skin. A partially viable permanent end ileostomy with significant ischemia of the muscularis, however, should be revised promptly in the early postoperative period in suitable operative candidates, since distal necrosis may result in a flush ileostomy that is difficult to pouch.

Long-term mild ischemia may result in late-term stoma stenosis and retraction (Fig. 54.11b). Nonischemic stomal retraction can be seen in patients with inadequately mobilized stoma conduits and the obese. Akin to ischemic colitis, necrosis and atrophy of the bowel conduit may cause variable degrees of stomal stricturing and/or retraction that may necessitate surgical revision depending upon symptom severity. Asymptomatic mild stoma stenosis or retraction can be carefully observed provided an adequate seal is maintained with pouching and the peristomal skin remains healthy (Fig. 54.12). Skin-level symptomatic colostomy stenosis can be locally revised provided the majority of the supra-fascial colon is normal. Subfascial stomal stenosis may require intra-abdominal approaches to mobilize a new segment of well-perfused bowel. A chronically retracted colostomy can be observed absent stenosis or pouching problems; however a difficult-to-pouch small bowel stoma may require local revision or complete resection and creation of a new stoma.

Peristomal Skin Disorders

Peristomal skin disorders are the most commonly occurring complication for ostomates [43]. Although skin irritation can occur at any time during the course of the stoma, dermatologic conditions are most commonly seen in the early postoperative period as the ostomate learns proper stoma care techniques. Up to 70% of new ostomates may have peristomal dermatitis, which is often unrecognized by the patient [38, 44–47]. Fortunately, most peristomal skin complications arising from a well-constructed and properly located stoma can be successfully managed with local wound care.

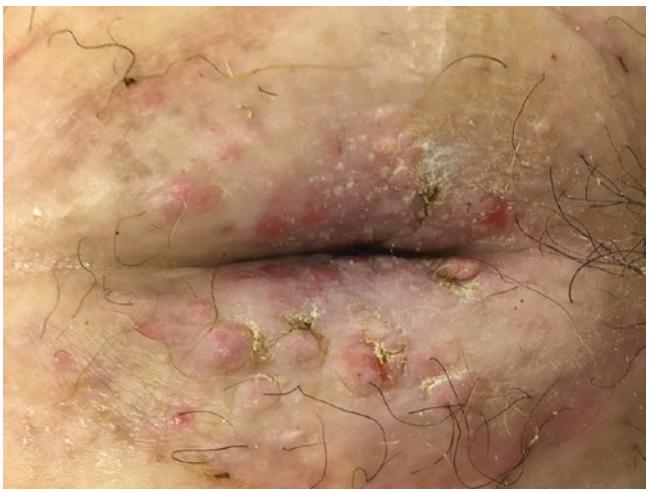

Fig. 54.12 (**a**, **b**) Chronic stoma stenosis. (Courtesy of Michael McGee, MD)

Most peristomal skin irritation arises from poorly fitted or improperly sized appliances that expose vulnerable peristomal skin to potentially caustic stoma effluent (Fig. 54.13) [46]. Leakage begets leakage, as irritated peristomal skin weeps exudative fluids that hinder stoma appliance adhesion; this further worsens leakage, excoriation, and appliance maladhesion. Leakage often requires frequent appliance changes, which inflicts additional mechanical trauma to vulnerable peristomal skin. Pouch leaks and peristomal skin excoriation are best treated with a critical reappraisal of pouching apparatus and sizing. Care should be taken to ensure the stoma flange aperture is sized and trimmed to fit the mucocutaneous junction perfectly, so that no skin is exposed to stoma effluent. Flush or poor-fitting stomas may benefit from a convex pouching system or application of a stoma belt which may improve sealing at the mucocutaneous junction. Protective skin barrier wipes can be used to create a thin polymeric layer to improve and protect skin integrity at the pouch-skin interface. Weeping superficial peristomal skin excoriation can be treated with a thin layer of topical stoma powder. Peristomal contour issues such as peristomal indentations, skin folds, and mucocutaneous separation may be filled with stoma paste or a preformed barrier ring to "caulk" under-the-flange leakage.

Fungal peristomal infections typically appear as reddened, shiny patches with satellite papules involving the skin underlying the stoma appliance flange [45]. *Candida albi-*

Fig. 54.13 Peristomal skin excoriation and ulceration attributed to an ill-fitting stoma appliance. (Courtesy of Michael McGee, MD)

cans, the most common skin fungus, can proliferate in the warm moist environment at the skin-appliance interface causing itching, irritation, and pain. A fungal infection is first treated by removing and assessing the pouching system for occult leaks that add to skin moisture and irritation. Topical antifungal powder such as nystatin is then applied and rubbed into the irritated peristomal skin. Excess powder is then brushed off, and a skin sealant is typically applied over the powder to enable application of a new stoma appliance. This process is repeated with each appliance change until the rash resolves which usually occurs within 1–2 weeks. In rare cases, topical miconazole and clotrimazole or oral antifungal agents may be required for treatment of resistant fungal dermatitis.

The importance of assessing the peristomal skin cannot be overstressed, particularly in the early postoperative period. High-risk patients, such as those with low health literacy, poor support systems, and emergently created stomas, require special attention. Additionally, obese ileostomy patients are at a higher risk of developing peristomal skin issues owing to the liquid nature of effluent and stoma creation challenges seen in thick abdominal walls [48]. As postoperative stoma edema subsides, the first several postoperative weeks require gradual adaptations in the pouching system to accommodate a shrinking stoma. New homegoing ostomates should be made aware that the stoma diameter will gradually shrink and that the flange aperture should be trimmed smaller over time. Since the majority of peristomal skin disorders can be treated with pouching adjustments, postoperative WOCN support, if available, is an immensely valuable tool for the duration of the patient's stoma. Studies indicate a majority of ostomates do not realize a treatable dermatologic condition exists [44, 48] and, when treated, can expect an improvement in quality of life [38]. To that end, routine postoperative follow-up with a stoma care professional, such as a WOCN-certified nurse, is recommended [9, 41].

Peristomal Pyoderma Gangrenosum

Pyoderma gangrenosum is a rare inflammatory skin disease characterized by painful ulcers with well-defined erythematous or violaceous undermined borders (Fig. 54.14) [49]. Approximately 0.5–5% of patients with inflammatory bowel disease can develop peristomal pyoderma gangrenosum (PPG). Pyoderma gangrenosum is also associated with rheumatoid arthritis, paraproteinemia, or hematologic malignancy in half of patients; PPG appears to be idiopathic in 25–50% of patients [49–51]. Peristomal pyoderma gangrenosum can be seen in approximately 0.6% of ostomates; however some postulate the actual incidence may be higher due to underdiagnosis [50]. For unclear reasons, peristomal pyoderma is associated with female gender, autoimmune disorders, and obesity in IBD patients [50–52]. Nearly 70% of patients presenting with peristomal pyoderma were noted to have reported a concurrent flare of underlying systemic disease in a 2019 meta-analysis [53]. Pyoderma, although poorly understood, is felt to arise from pathergy arising from local skin trauma, which may explain a predilection for the peristomal skin. While peristomal pyoderma is associated with inflammatory bowel disease (IBD), nearly 20% of peristomal pyoderma patients will not have IBD [53].

Diagnosis of PPG is made clinically and requires a high index of suspicion. Lesions characteristically begin spontaneously with a firm, pink, or purple hemorrhagic nodule at the peristomal skin in contact with the stoma appliance. The nodule typically enlarges and ulcerates rapidly, to produce a painful and occasionally purulent ulcer with a raised border [49]. Thin bridges of persisting epidermis may be seen spanning the ulcer. Biopsies of the ulcer margin typically reveal nonspecific epidermal neutrophil infiltration, edema, and perivascular lymphocyte infiltration. Although skin biopsies may exclude other dermatologic processes such as malignancy and infection, biopsies and cultures are usually not helpful in diagnosing pyoderma due to a lack of pathognomonic histologic and microbiologic findings [54, 55].

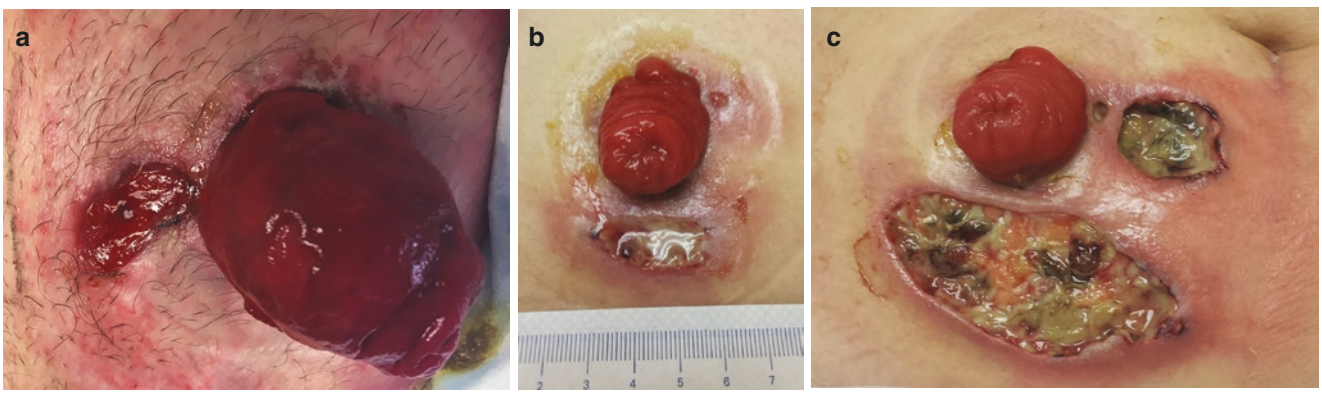

Fig. 54.14 Peristomal pyoderma gangrenosum. (Courtesy of Michael McGee, MD)

There is currently no standard treatment algorithm for pyoderma gangrenosum. Management of peristomal pyoderma utilizes a multidisciplinary approach to treat causative underlying disorders with early and aggressive wound and stoma care [54]. Pyoderma often parallels intestinal IBD activity and may indicate occult intestinal disease activity. Topical, intralesional, and systemic steroids, immunomodulators, and antibiotics have been used to successfully treat peristomal pyoderma [53, 56]. Following a stepwise approach, increasingly powerful systemic immunomodulators and biologics have also successfully healed peristomal pyoderma [54]. Absorbent-type dressings such as protective foam, calcium alginate, and hydrogel dressings covered with an occlusive dressing can be used to create a protective dry barrier over the wound while controlling for wound seepage [55]. Treatment efficacy can be assessed by monitoring the characteristically raised and undermined wound edge that flattens as the wound heals [54].

A combination of intralesional steroid injections and gentle ulcer debridement has been reported to completely heal 40% and partially heal an additional 40% of parastomal pyoderma patients [57]. Some investigators have begun to question if intralesional injections exacerbate pathergy and advocate the use of topical agents such as tacrolimus and steroids while touting healing rates approach 60% [53]. These acceptable results should be interpreted cautiously, since over 50% of treated patients ultimately required stoma resiting for disease control. A 50% healing rate with medical therapy including a combination of topical, intralesional, and systemic steroids and antibiotics, systemic cyclosporine, and infliximab has also been reported [50]. A large case series reported complete healing of peristomal pyoderma with separate surgical resection of nonstomal bowel containing active IBD [53]. Ultimately, stoma resiting may be necessary for treatment refractory peristomal pyoderma; but relocation does not guarantee against pyoderma recrudescence.

Peristomal Varices

Akin to esophageal, gastric, and rectal varices, portosystemic venous shunts may also develop between the stoma and abdominal wall arising to peristomal varices in the setting of chronic portal hypertension. Parastomal varices are identified as a circumferential blue or purple subcutaneous ring extending from the mucocutaneous junction to the peristomal skin (Fig. 54.15). Additional clinical findings of parastomal varices include a raspberry appearance of the stoma, visibly dilated stomal submucosal veins, peristomal caput medusa, and easy bleeding hyperkeratotic skin [58]. Peristomal varices may also be found within the stomal lumen. Commonly seen in IBD patients with concomitant primary sclerosing cholangitis, parastomal varices can also be seen in ostomates with alcoholic cirrhosis and those with an extensive metastatic burden to the liver. The incidence of peristomal varices is unknown but may occur in 27–50% of ostomates with portal hypertension [59, 60].

Peristomal variceal hemorrhage can be heavy and occasionally life-threatening. Approximately 40% of patients with parastomal varices will bleed and require transfusion, with the average time from stoma formation to first hemorrhage being 70 months [58]. Following stabilization and correction of any coagulopathy, hemorrhage can typically be first treated with local measures such as digital pressure, application of epinephrine-soaked gauze, and suture ligation [61]. Suture ligation of the bleeding varix is not typically durable but may temporize heavy bleeding. Approximately 85% of patients will rebleed after local non-

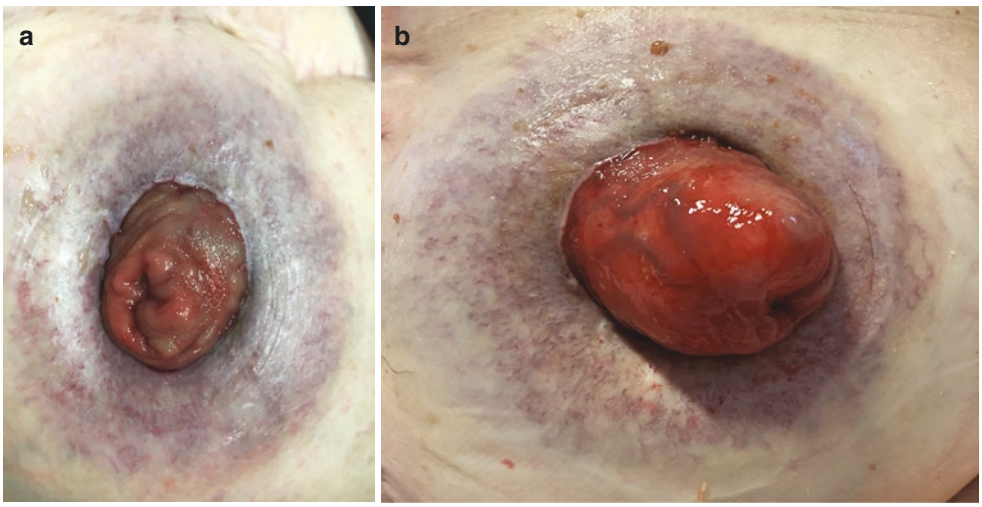

Fig. 54.15 Peristomal varices. (Courtesy of Michael McGee, MD)

operative management of parastomal hemorrhage [58]. Portal decompression, most commonly with a transjugular intrahepatic portosystemic shunt (TIPS), is approximately 5 times more effective than local nonoperative measures in durably treating hemorrhage and cured variceal bleeding in nearly 80% of patients [58, 62, 63]. Moreover, liver transplant may be indicated depending upon the etiology of liver disease but may only be possible for a fraction of patients with stomal varices [58]. Alternative nonoperative treatments using injection sclerotherapy, systemic octreotide, and percutaneous embolization may effectively treat parastomal varices [58, 59, 64–66]. Following local treatments, proper and gentle stoma care with a flexible flange should be employed since the friable varices dwell at the skin-pouch interface [67].

Surgical mucocutaneous disconnection may be employed when local therapy fails and portal decompression is not possible. This local surgery involves a cylindrical incision around the mucocutaneous junction to the level of the anterior fascia with identification and ligation of varices and re-maturation of the stoma. Preoperative peristomal infiltration of dilute epinephrine may assist with hemostasis during this potentially bloody procedure [61]. The surgeon should prepare for significant blood loss, and necessary blood products should be available for transfusion. Varices will recur over time, but the local procedure can be performed repeatedly if needed. Stoma resiting procedures can be carefully considered for suitable variceal patients experiencing concomitant pouching difficulties arising from a parastomal hernia or poorly constructed stoma. The risks of this highly morbid procedure in a high-risk patient need to be thoughtfully balanced with anticipated benefits and life expectancy.

While a stoma is not always avoidable, special situations may arise where portal hypertensives and early cirrhotics can be offered stoma-sparing surgery with the goal of potentially avoiding parastomal varices. Stoma avoidance is particularly germane in the setting of primary sclerosing cholangitis (PSC)-associated inflammatory bowel disease where reports of peristomal variceal hemorrhage can occur in up to 53% of patients within 4 years of total proctocolectomy with end ileostomy [68]. Since patients with ulcerative colitis and PSC can successfully undergo restorative proctocolectomy with an ileal pouch-anal anastomosis (IPAA) and avoid a permanent stoma and varices [69, 70], IPAA is usually the treatment of choice [71]. If necessary, IPAA may be performed safely following TIPS or liver transplant [72, 73]. Although IPAA avoids a permanent stoma, PSC-associated pouchitis can develop in over 50% of patients with PSC within 4 years of pouch creation [70].

Stoma Prolapse

Bowel proximal to an end stoma may intussuscept through the matured stoma, creating stoma prolapse (Figs. 54.16 and

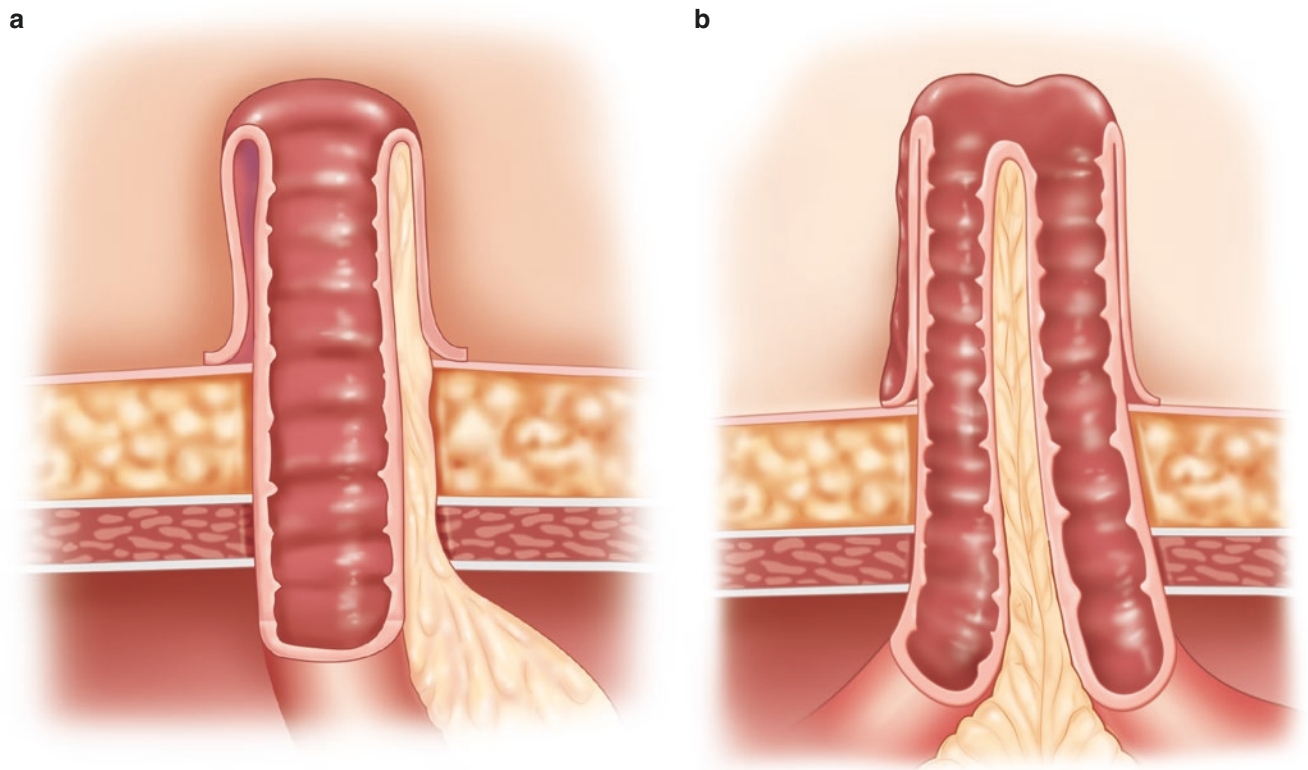

Fig. 54.16 (**a**) Prolapsed end stoma. (**b**) Prolapsed loop stoma

Fig. 54.17 (**a**) Prolapse of a prolapsed loop transverse colostomy (**b**) ischemic mucosa at the tip of the prolapsed stoma. (Courtesy of Michael McGee, MD)

54.17). Loop stomas may prolapse bowel from either limb. Stoma prolapse is categorized as fixed or sliding depending upon the mobility of intussusceptum. A mobile sliding prolapse classically describes the problematic variant that can be seen in up to 8% and 47% of end and loop stomas, respectively [74]. Stoma prolapse is theorized to arise from a combination of a mobile bowel mesentery, increased intra-abdominal pressure, enlarged stoma trephine, or fixation failure of the opposing everted stomal serosa surfaces. Stoma prolapse can cause from mild cosmetic concerns to moderate difficulties pouching to cases of incarceration and strangulation.

Minimally symptomatic stoma prolapse may be managed with reassurance, modification of stoma appliances, and addition of an external fixation device. Significantly symptomatic stoma prolapse may require surgical revision in suitable operative candidates via local parastomal or open abdominal approaches. Anecdotal reports describe various stoma prolapse repair techniques, but no compelling method prevails. In the absence of steadfast evidence, conventional wisdom dictates local procedures are first attempted, relegating more extensive intra-abdominal procedures for recurrent or complicated prolapse. Prolapsing temporary loop stomas are best treated with timely reversal when possible. Prolapsing permanent stomas can be treated with local amputation of the prolapse with reanastomosis, local excision of the stoma and intussusceptum with de novo stoma creation, or prolapse reduction and fixation. Some advocate concomitant seromyotomies to promote serosa-to-serosa bonding along the apposed serosal surface of the everted matured stoma to minimize future prolapse. A series of 10 patients successfully underwent subcutaneous placement of a permanent prosthetic mesh cerclage strip surrounding the peristomal subcutaneous skin without recurrence or infection at a median follow-up of 25 months [75].

Intra-abdominal correction of stoma prolapse has been described using a myriad of techniques, largely focusing on fixation of the intussusceptum and corresponding mesentery. Intra-abdominal techniques may be preferable when prolapse is associated with a concomitant parastomal hernia. Intra-abdominal approaches facilitate suture fixation of prestomal mesentery and/or bowel conduit directly to the peritoneum with variable rates of success. Some propose routing the prestoma conduit through a preperitoneal tunnel lateral to the linea semilunaris prior to exiting through a transrectus trephine, thereby fixating bowel and mesentery; the utility of this technique is debatable (Fig. 54.18a) [76]. Prolapsing permanent loop colostomies commonly are related to prolapse of the distal limb and can be converted to an end or loop-end stoma by dividing the distal limb. Alternatively, the distal limb of a loop colostomy may be sutured to the peritoneum to limit excursion (Fig. 54.18b). Ultimately, a prolapsing stoma can be moved to a new site using any of the above adjuncts to mitigate future prolapse, although isolated stomal prolapse without associated parastomal hernia rarely benefits from stoma relocation.

Rarely, prolapsed stomas will become incarcerated, and reduction may become increasingly difficult to reduce, as cumulative lymphatic and vascular compression worsens stomal engorgement and edema. Beside attempts to reduce a viable incarcerated prolapse may be aided with sedation, anxiolytics, and analgesics, whereas strangulated prolapse mandates immediate surgery. Topical ice and table sugar have been reported to decrease edema within the prolapsed stoma and ease reduction [77]. Incarcerated prolapse may progress to infarction and require immediate surgery (Fig. 54.19).

Transient short-segment stomal "pseudoprolapse" may be seen during pregnancy owing to increased intra-abdominal pressure related to uterine displacement of abdominal vis-

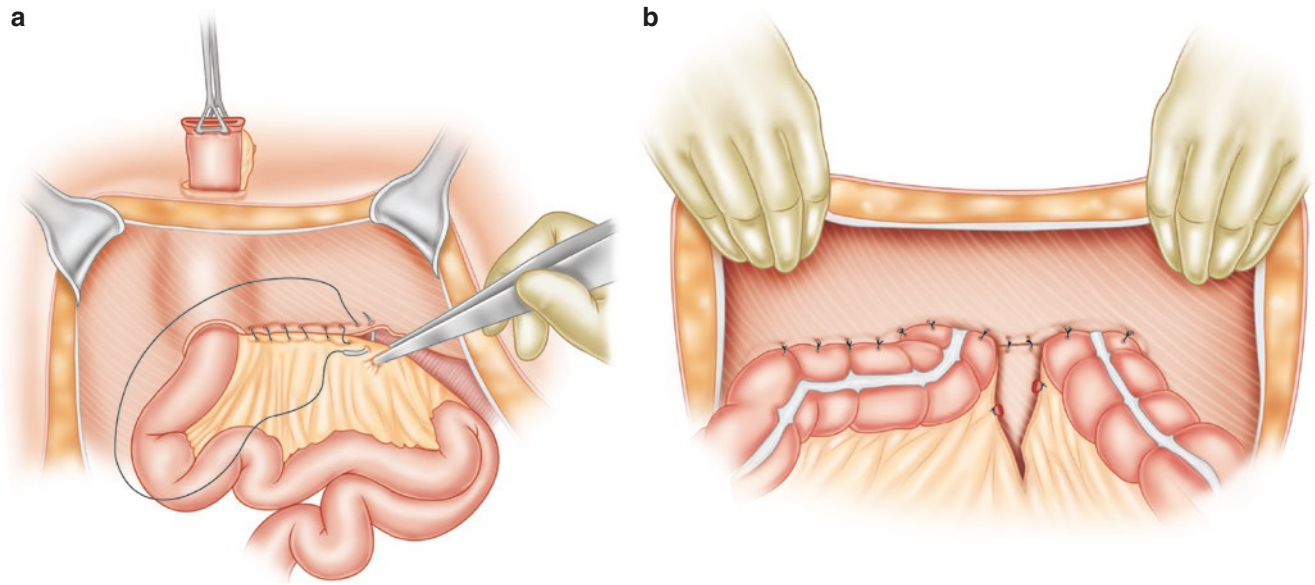

Fig. 54.18 (**a**) Retroperitoneal tunneling of an end ileostomy with suture pexy of the prestomal mesentery to limit prolapse. (**b**) Suture pexy of the distal limb of a loop colostomy to mitigate prolapse of the distal limb

cera. Such prolapse is typically less than 3 cm long and resolves following delivery. Pregnancy-related pseudoprolapse does not typically merit surgical revision unless symptoms persist beyond the postpartum period [78].

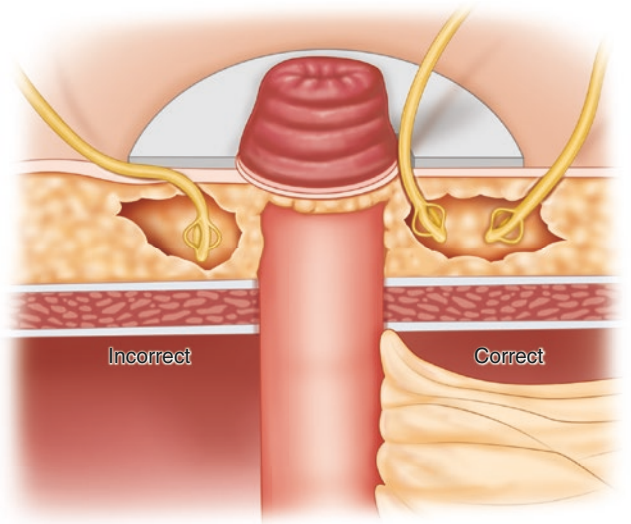

Fig. 54.20 Percutaneous drainage of a parastomal abscess

Peristomal Abscess

Rarely, an ostomate may develop a peristomal abscess. Peristomal tenderness, swelling, and erythema may indicate a subcutaneous collection. Peristomal abscesses are typically seen in the early postoperative period resulting from intraoperative contamination; however late peristomal abscesses can be seen in the setting of penetrating Crohn's disease of the stoma or from an intra-abdominal source. Initial management of a peristomal abscess includes drainage via image-guided or standard operative techniques. To avoid pouching problems, the drainage catheter should either be inserted remote to the peristomal skin-appliance interface or directly through the mucocutaneous junction (Fig. 54.20). If fistuli-

zation from the stoma is suspected following drainage, further endoscopic or radiographic evaluation may determine if the abscess is arising from a diseased stoma.

High Output Small Bowel Stomas

Normal ileostomy outputs are typically between 800 and 1200 mL/day, and outputs exceeding 1200–2000 mL per day are considered to be high [79]. High stoma outputs can cause severe fluid, electrolyte, and nutritional deficiencies and are typically seen with small bowel stomas and rarely proximal (i.e., ascending or proximal transverse) colostomies. High output stomas can be transiently seen in the new ostomate as ileus resolves, and the initial deluge of bowel contents exits the body. Approximately half of postoperative high output stomas will resolve spontaneously within 2 weeks [79]. With time and resumption of a normal diet, stoma outputs typically plateau to a level proportional to the length of remaining proximal bowel; but high outputs can commonly necessitate treatment. This section will focus on small bowel stomas (ileostomy, jejunostomy), the most common culprit in high output situations.

Once postoperative ileus resolves and stomal outputs reach a steady state, daily output assessments determine the need for treatment. Small bowel stomas outputting less than 1200 mL/24 hours are usually well tolerated without clinical derangements and do not typically require treatment. Outputs between 1200 mL and 1500 mL per day are borderline high and may cause problems for some ostomates. Persistently high stoma outputs can be treated with dietary, behavioral, and medical means via a proposed algorithm described in Fig. 54.21. Behavioral alterations include avoidance of large bolus feedings in lieu of smaller, more frequent aliquots. Large meals can be replaced with smaller frequent meals, fluids can be sipped rather than gulped, and solids and liquids can be consumed at different times to minimize bolus effects.

Concentrated sweets including juice, soft drinks, and candy should be limited to decrease the effects of osmotic diarrhea. Breads, crackers, peanut butter, and bananas may naturally thicken stoma outputs and help decrease volumes. Psyllium powder mixed in water helps to absorb excess fluid from the intestinal tract and thicken outputs. Hypotonic oral fluid restriction (500–1000 mL/day) and treatment with the cheap and easily made World Health Organization oral rehydration solution (Table 54.3) [80] help limit sodium loss and may produce a more favorable osmotic intestinal gradient [79]. It has been shown that most high output patients can avoid IV fluid and electrolyte supplementation if oral intake is restricted to 500–1000 ml/24 h of oral rehydration solution [81].

Following dietary and behavioral changes, pharmacotherapy may be required to manage high output stomas. Medical therapy typically begins with stepwise titration of antimotility agents beginning with loperamide and adding diphenoxylate/atropine. It is useful to take such antimotility agents approximately 30 minutes before meals (three times daily) to preemptively slow transit time before eating. Rarely, intestinal transit may be so rapid that tablet medications do not have enough time to completely dissolve; elixir forms of antimotility agents may be preferable in this setting. Antisecretory therapy with either H2 or proton pump blocking agents may be added to decrease stoma outputs by reducing gastric secretions. If dietary, antisecretory, and antimotility therapies fail, oral opium tincture (paregoric, camphorated tincture of opium) or oral codeine phosphate can be added. Paregoric can be costly and can cause sedation and is typically added as a later measure for recalcitrant high output stomas. Common medicines to manage high output stomas are detailed in Table 54.4.

Unexpected and persistently high stoma outputs merit a workup to exclude other potentially treatable causes. Cross-sectional abdominal imaging or a small bowel fluoroscopic series should be performed to exclude partial bowel obstruction, which can cause paradoxically high outputs. High outputs can be caused by small bowel Crohn's disease, which can be evaluated with small bowel enteroscopy through the stoma or cross-sectional imaging. *Clostridium difficile* enteritis is a reported cause of both small and large bowel high output stomas and can be evaluated with stool testing. Steatorrhea may develop in patients with significant ileal resections and can be treated with oral cholestyramine. Pancreatic insufficiency may rarely cause persistently high stoma outputs and can be remedied with a trial of pancreatic enzyme replacements.

During periods of high stoma outputs, fluid, electrolyte, and nutritional support may be necessary. Periodic surveillance of serum electrolytes, daily weights, and strict recording of inputs and outputs guide resuscitation and replacements. Short gut situations with a proximal jejunostomy may not respond to standard therapies and may require parenteral fluids or nutrition. On rare occasions with proximal stomas, patients may require fasting and total parenteral nutrition as a last resort to sustain euvolemia. Octreotide, a somatostatin analogue, teduglutide, a glucagon-like peptide 2 analog, and human growth hormone all show promise in managing the most recalcitrant high output stoma associated with short gut syndrome [82, 83].

Stoma Reversal

Preoperative Preparation

The surgeon should have a clear understanding of the patient's anatomy prior to attempting stoma reversal. For patients with a stoma created by another surgeon, it may be

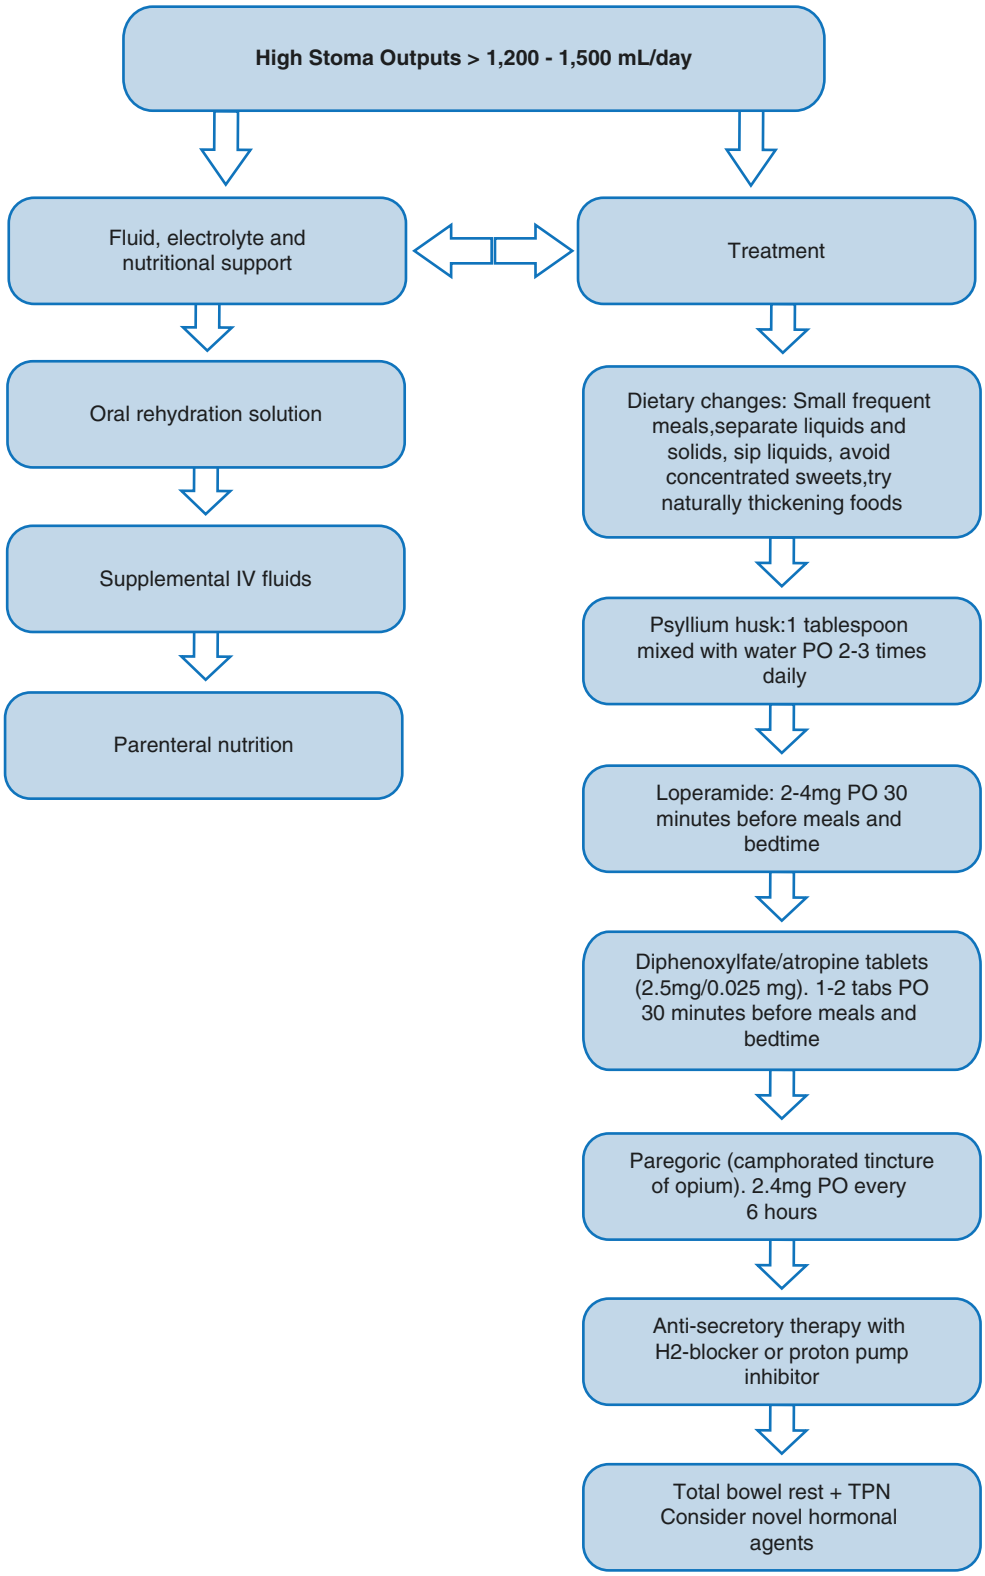

Fig. 54.21 Proposed management algorithm for management of high output small bowel stomas

crucial to review the prior operative and pathology reports to understand the surgical indications, encountered pathology, and remaining anatomy. Record review is particularly important when reversing an end colostomy performed for diverticulitis or malignancy, since additional resection of the rectosigmoid stump, descending colon, and/or splenic flexure mobilization may be needed to complete an adequate resection. Close or threatened margins found on oncologic

Table 54.3 Oral rehydration solution

Ingredients
3/8 tsp. salt (sodium chloride)
¼ tsp. table salt substitute (potassium chloride)
½ tsp. baking soda (sodium bicarbonate)
2 tbsp +2 tsp. sugar (sucrose)
Add tap water to make one (1) liter
Optional: Nutrasweet® or Splenda® based flavoring of choice, to taste

Directions: Mix dry ingredients with water and serve. Best sipped slowly over long periods of time
Contains 27 grams of sucrose, 70 mEq per liter of sodium, 20 mEq per liter of potassium, and 30 mEq per liter of bicarbonate. The final osmolarity is approximately 245 mOsm per liter
tbsp tablespoon, *tsp* teaspoon

Table 54.4 Common medicines for control of high output stomas

Medication	Starting dose	Maximum daily dose
Psyllium	1 tablespoon BID	1 tablespoon TID
Loperamide tab	2–4 mg PO QID	16 mg[a] (4–8 tabs)
Loperamide liquid	2–4 mg PO QID	80 mL (16 mg[a])
Diphenoxylate-atropine tab	2.5–5 mg PO QID	20 mg (4–8 tabs)
Diphenoxylate-atropine liquid	2.5–5 mg PO QID	40 mL (20 mg)
Codeine tab	15–30 mg PO QID	240 mg (60 mg PO QID)
Codeine elixir	15–30 mg PO QID	240 mg (80 mL)
Paragoric 0.4 mg morphine/1 mL paragoric (45% alcohol)	5 mL PO QID	37.5 mL PO QID (150 mL/day)
Opium tincture 10 mg morphine/1 mL opium (19% alcohol)	0.3–1 mL PO QID	1.5 mL PO QID (6 mL/day)

[a]Higher doses have been reported in off-label indications

pathology reports may merit endoscopic anastomotic evaluation to exclude cancer recurrence prior to stoma reversal. Endoscopic evaluation may be helpful prior to reversing stomas in IBD, ensuring that disease activity is controlled in the defunctioned bowel before attempting reversal; but the endoscopist must be aware that diversion colitis may grossly and histologically mimic IBD [84].

If a diverting loop stoma was used to protect a distal anastomosis, the authors prefer to use a lower gastrointestinal fluoroscopic contrast study to exclude anastomotic leak, stricture, and obstruction prior to stoma reversal. Similarly, for patients undergoing reversal of an end stoma, preoperative fluoroscopic and endoscopic studies are important to evaluate the remaining anatomy and quality of both distal and proximal segments of bowel – particularly when reversing another surgeon's stoma. Fluoroscopic abnormalities can be further examined with endoscopy allowing mucosal evaluation, tissue sampling, and anastomotic dilation, if needed. Coloanal, distal colorectal, and ileal pouch-anal anastomoses may be additionally assessed and gently dilated with digital rectal exam and exam under anesthesia, if required. Several groups espouse selective, rather than routine, use of lower GI contrast studies for anastomotic evaluation prior to stoma reversal and note that most anastomotic complications can be diagnosed without imaging [85–89]. Although intra- and postoperative surprises are not completely avoidable, the authors feel preoperative evaluation including record review, imaging, and endoscopy is the best way to avoid unexpectedly complex stoma reversals.

Timing

Timing of stoma reversal may impact the ease of the procedure. Diverting loop stomas are typically reversed within 2–3 months after creation once the surgeon is satisfied with the distal anastomosis (or pathology) that required diversion. Limited evidence over the years has suggested that loop ileostomy reversal performed less than 8.5 weeks following coloanal or ileoanal anastomosis may be associated with increased risk of complications [90]. Recently, several studies have challenged this notion. Most notably, a Scandinavian prospective randomized trial showed that loop ileostomy reversal at 8–13 postoperative days was as safe as late closure at 12 weeks after low anterior resection in selected patients without radiographic or endoscopic evidence of leak [94]. Not only was early closure as safe as late closure, but early closure patients experienced less complications than late closure patients, which largely arose from stoma-related complications.

Intriguingly, there were no differences in health-related quality of life between early and late ileostomy closure patients at 3, 6, and 12 postoperative months [95]. The study, although promising, was limited by the fact that this was a highly selected group of patients where nearly 70% of screened patients were not eligible to participate (13% with suspected leaks, 38% due to medical reasons, 13% due to unwillingness to participate). Until more rigorous evidence is available universally supporting safe early ileostomy closure, the authors recommend defaulting loop ileostomy closure until approximately 8–12 weeks postoperatively as dictated by the clinical situation. The authors concede that early ileostomy closure can be considered in highly selected and motivated patients that are thoroughly evaluated to exclude anastomotic leak.

The use of adjuvant chemotherapy introduces another consideration in the timing of stoma reversal. If adjuvant chemotherapy is planned, conventional wisdom dogmatically dictates keeping a diverting stoma through the duration of treatment to minimize postoperative reversal complications and diarrhea. Conversely, chemotherapy may further compound dehydration resulting in readmission for up to 11% of ileostomy patients [97], and ostomates must be mon-

itored carefully for dehydration during chemotherapy. A small retrospective study and subsequent meta-analysis showed that loop ileostomy reversal in the midst of colorectal cancer chemotherapy had comparable morbidity and cancer-related outcomes in select patients compared to post-chemotherapy reversal [98, 99], although this practice is not widely adopted at this time. Patient choice plays a large role in this situation, and a thorough discussion is helpful in choosing the ideal time for stoma reversal.

The optimal time for end stoma reversal remains a contentious issue with conflicting guidance in the literature [100]. It is generally considered that early postoperative adhesions become less tenacious and vascular with time, which may ease a challenging intra-abdominal dissection. Retrospective comparisons between early (<15 weeks) and late (>15 weeks) end colostomy reversal detail similar morbidity, but increased length of stay, subjective adhesion density scores, and small bowel injuries favor later surgery [101]. An older study associated early Hartmann's reversal (<3 months) with increased leaks, sepsis, and death compared to colostomy reversals took place after 6 months [102]. Although small series have shown no timing-dependent outcome differences [100, 103], the balance of low-level evidence suggests that delaying end stoma reversal for 3–6 months eases future surgery in patients having undergone open end colostomy creation.

Technical Consideration of Loop Stoma Reversal

Once the surgeon is satisfied with the quality of the protected distal anastomosis (or pathology) (see section "Stoma Reversal: Pre-operative Preparation"), loop colostomy or ileostomy reversal can typically be performed as a local procedure through a peristomal circular incision under general anesthesia. The entire abdominal midline should be included and prepared in the operative field, in the event an unplanned laparotomy is required. A circumferential skin incision is made just outside the mucocutaneous junction and sharply deepened until subcutaneous fat is seen (Fig. 54.22). Clamps may be placed on the skin rim to retract the stoma anteriorly to expose the interface between the serosal surfaces of the bowel limbs and the subcutaneous tissues. A cylindrical sharp dissection is performed on the serosal surfaces of the bowel limbs heading posteriorly until the anterior rectus sheath is encountered. If the patient is obese and the fascia is deep, clamps can be used to grasp and elevate the fascia; alternatively, radial 1–2 cm counter-incisions extending from the cut skin edge may allow better exposure. The rectus muscle is dissected from the bowel serosa and can be distinguished from the bowel by the longitudinal orientation of muscle fibers. Circumferential dissection continues until the abdomen is entered. Limited intra-abdominal adhesiolysis is performed to enable adequate mobilization of the bowel loop for eventual anastomosis and fascial closure. Care should be taken to avoid injury to the stoma mesentery during dissection, especially during loop colostomy reversal, since marginal artery injury can result in distal colonic ischemia.

If the stoma is everted, sharp adhesiolysis may be used to flip the everted bowel wall back into a normal configuration. The skin disk and mucocutaneous junction are excised and debrided back circumferentially to soft and supple bowel suitable for closure. Partial and full-thickness bowel injuries can rarely occur during loop stoma closure. Bowel assessment can be performed by injecting dilute povidone-iodine solution via a bulb syringe while digitally occluding each

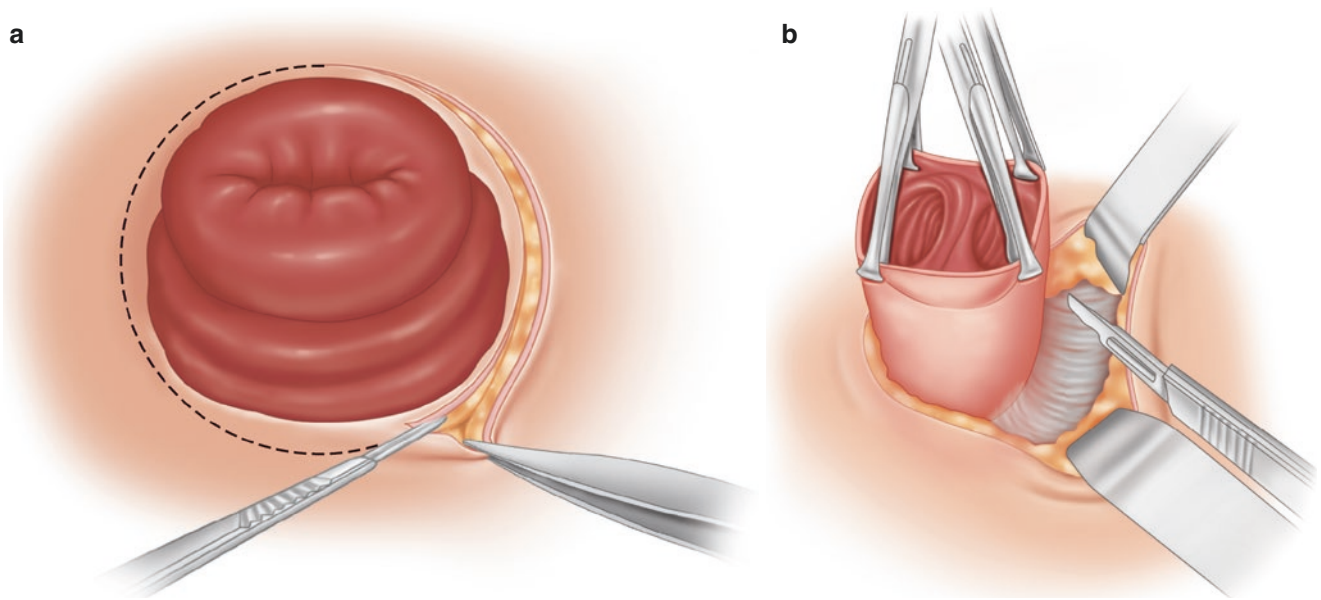

Fig. 54.22 (**a**) Incision of the stomal mucocutaneous junction. (**b**) Elevating the stoma with clamps to expose the subcutaneous stomal dissection performed assistance of clamps

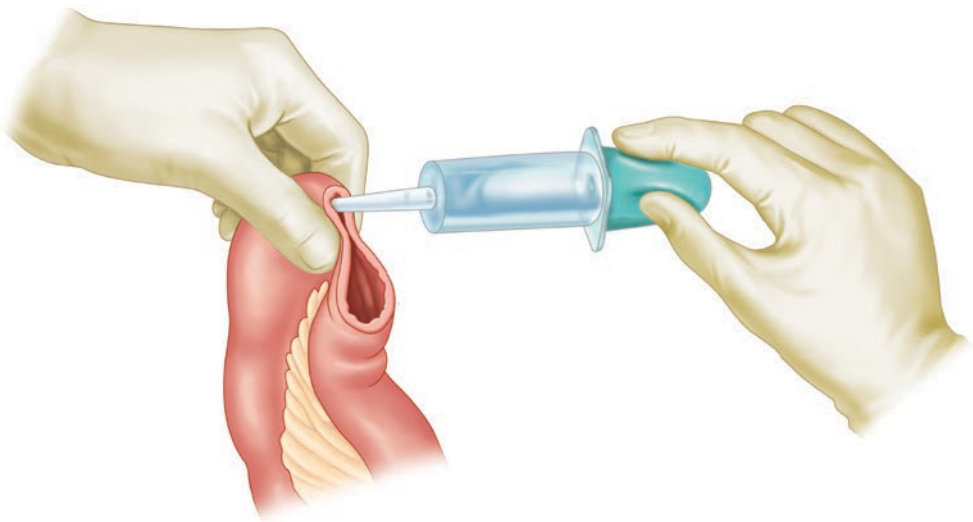

Fig. 54.23 Pressurized leak testing of injured bowel during loop stoma closure

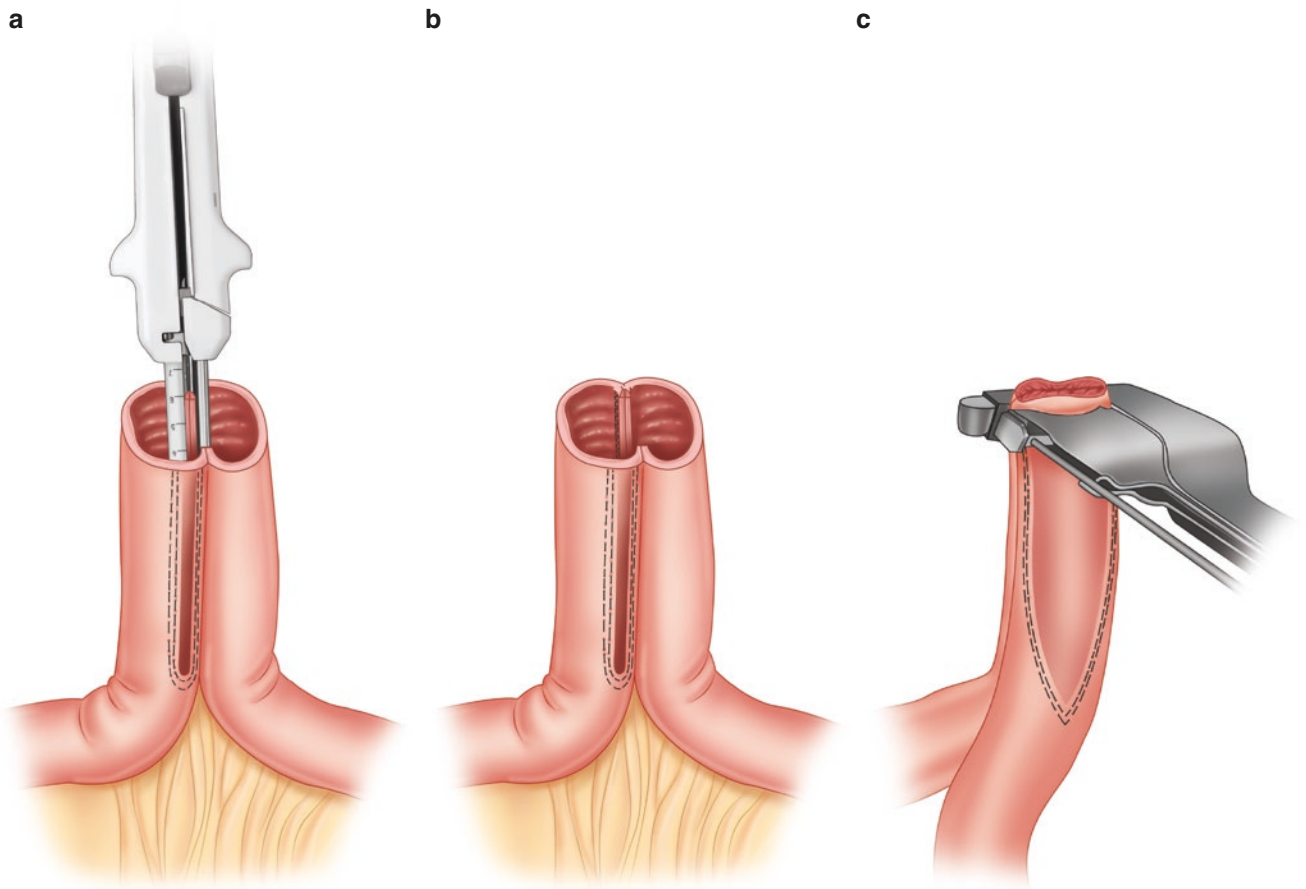

Fig. 54.24 (**a**–**c**) A stapled side-to-side anastomosis

bowel limb to pressurize the dissected bowel limbs and evaluate for injury (Fig. 54.23). Injuries can be suture repaired or resected depending upon the nature and location of injury. Rarely, tenacious adhesions or deep bowel injury may require a laparotomy for repair. The bowel portions that comprised the stoma can be resected or left in situ at the surgeon's discretion. Once the bowel is adequately mobilized and inspected, a stapled or handsewn closure is performed.

A side-to-side (functional end-to-end) stapled closure is performed by inserting the limbs of a linear cutter stapler (GIA type) into each limb of the loop stoma (Fig. 54.24). Care is taken to ensure the limbs are opposed along the anti-mesenteric surfaces prior to firing the stapler. The common portion of bowel

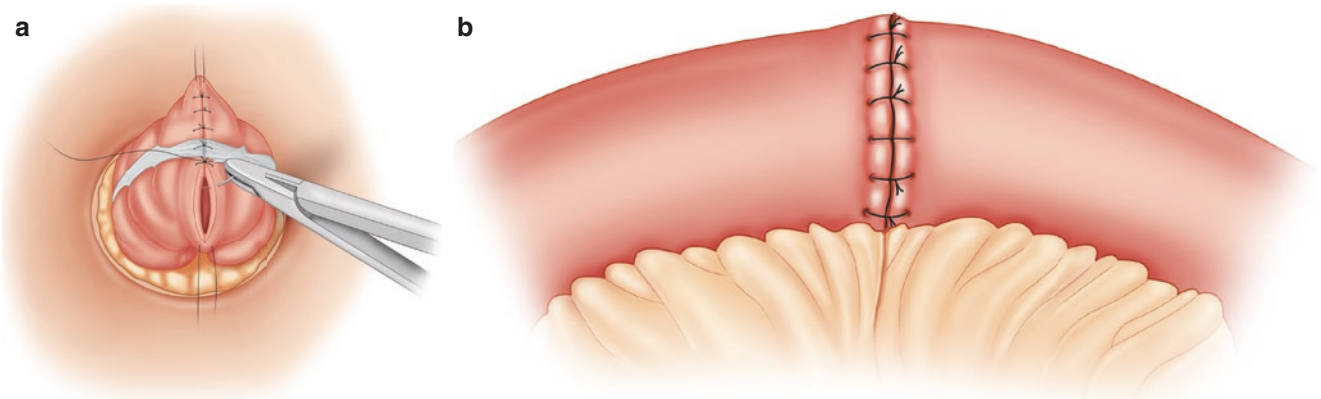

Fig. 54.25 Handsewn loop closure for (**a**) colostomy (**b**) ileostomy

wall that connects both bowel limbs may be divided or resected to improve antimesenteric opposition. The common enterotomy is then closed with either suture or an intersecting fire of another GIA or TA type stapler. The completed anastomosis may be oversewn at the discretion of the surgeon, and a suture may be placed at the confluence of the bowel limbs ("crotch stitch").

Alternatively, a handsewn anastomosis is performed with either running or continuous suture, in one or two layers to longitudinally close the defect (Fig. 54.25). The completed anastomosis is then reduced into the abdomen. Adequate intra-abdominal adhesiolysis must be completed prior to fascial closure to avoid injury to bowel adherent to peritoneum. The fascia is closed with interrupted or running suture. The skin can be closed with or without a drain, left partially open with wicks, or left completely open to heal secondarily.

Mode of loop ileostomy closure has long been a source of debate amongst surgeons based largely on preference and training pedigree. Several meta-analyses and three single-center prospective randomized control trials have shown that stapled and loop closures are equivalent with regard to anastomotic leakage, wound infection, overall complications, and cost; however, stapled closure was faster, caused less postoperative bowel obstruction, and was associated with shorter hospital stays [104–108]. It is postulated that the narrow luminal diameter produced with handsewn closure techniques is prone to edema and early obstruction compared to widely patent stapled anastomoses. Recently, a large multicenter trial showed stapled and handsewn anastomoses to have similar rates of postoperative bowel obstruction [109]. As a result, ASCRS Clinical Practice Guidelines (CPG) state that stapled and hand-sutured techniques are both acceptable for loop ileostomy closure [9].

Wound closure at the former stoma site is also a contentious issue that has been studied extensively. Several studies have compared various techniques including traditional linear wound closure, closure over a suction drain, and skin-level purse-string cerclage technique (which leaves a small opening at the center of the wound). Purse-string techniques are shown to have significantly lower wound infection rates and improved patient satisfaction [110, 111]. ASCRS CPG recommends stoma site skin reapproximation should be performed when feasible, and purse-string skin closure may have advantages compared with other techniques [9].

Technical Considerations of End Stoma Reversal

Undoubtedly, reversal of an end stoma can be a substantial surgical undertaking and may be a larger operation than the initial stoma creation. The patient and surgeon should be prepared for an extensive and potentially hostile operation. In addition to the preoperative preparation described above, the surgeon may selectively use ureteral stents to aid in identification of the ureters in a potentially hostile operative field. A fully prepared surgeon should have pelvic retractors, proctoscopes, EEA sizers, and vaginal retractors available in the operating room. Lastly, the surgeon should note the adequacy of the current stoma and site. If the current stoma site is in a poor location, the patient can be marked for a new stoma site should a temporary loop ileostomy be required.

Once the surgeon is satisfied with the quality of the protected distal anastomosis (or pathology), an end stoma can be reversed using open or laparoscopic approaches [112, 113]. The patient is typically placed in modified Lloyd-Davis (low lithotomy) or split-leg position allowing access to the anus. For open reversal of an end stoma, the stoma is prepared in the surgical field. A sterile, countable, gauze sponge, and adherent plastic drape can be used to limit colostomy contamination of the midline wound. The abdomen is entered sharply, and adhesions are lysed to identify the bowel conduit leading to the end stoma. The distal bowel conduit is identified, mobilized if necessary, and inspected for anastomotic suitability. In the case of a rectal stump, scarring and retraction may rarely require mobilization and resection of the previous rectal closure line; however, the anastomosis should be to the rectum and not sigmoid (see below). Once adequate intra-abdominal adhesiolysis is performed, the stoma is mobilized back into the abdomen by incising the stomal mucocutaneous junction and cylindrically dissecting

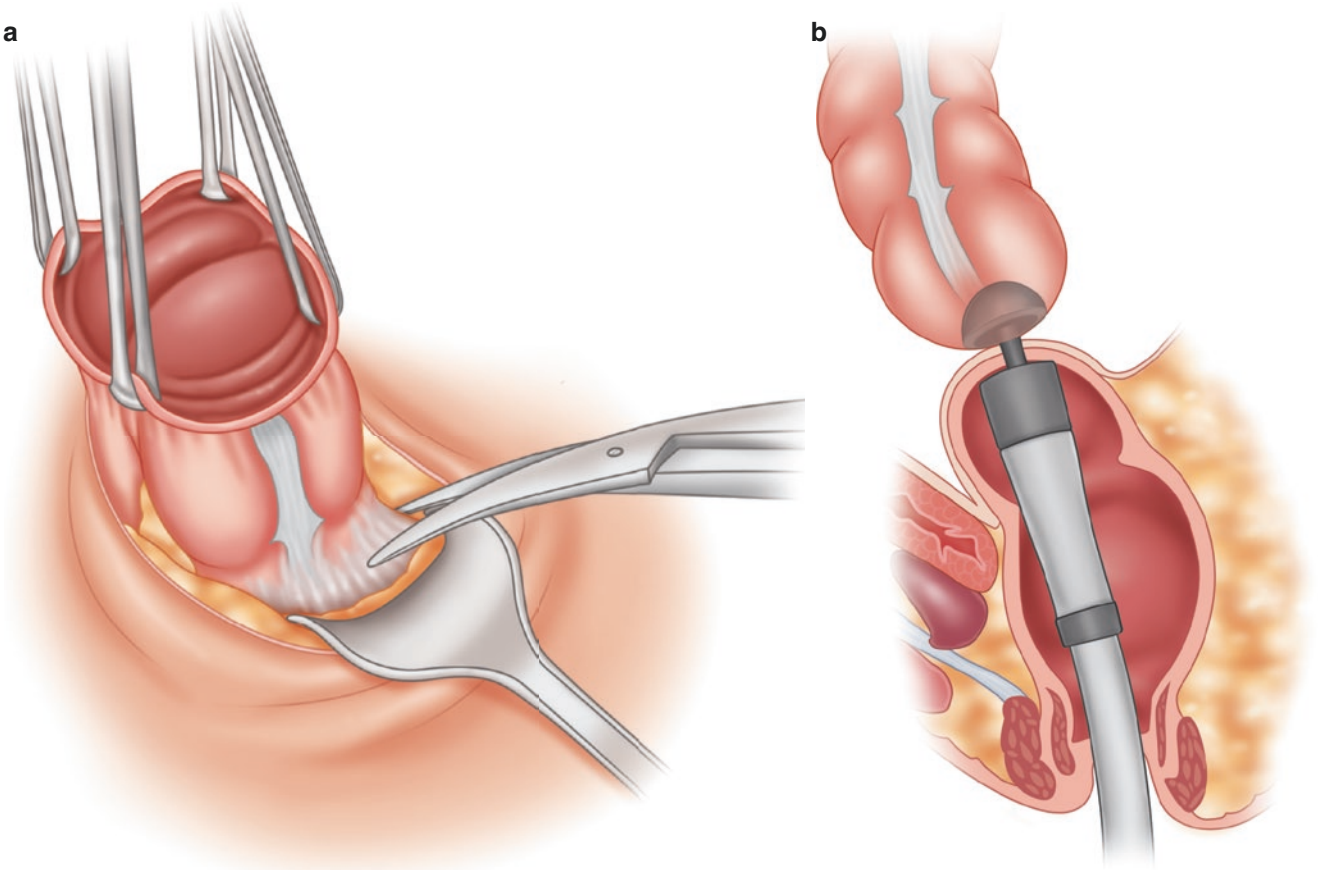

Fig. 54.26 (**a**) Mobilization of an end colostomy. (**b**) Stapled end-to-end colorectal anastomosis

subcutaneous adhesions until the abdominal dissection is met (Fig. 54.26a). Care is taken to avoid mesenteric injury and devascularization of the stoma since bowel length preservation may aid in creating low pelvic anastomoses.

After the end stoma is reduced into the abdomen, the surgeon may need to perform additional mobilization of the former stoma to obtain tension-free reach to the target distal bowel. For end ileostomy reversals, generous small bowel mobility does not typically require much additional mobilization. Colorectal anastomoses may require additional lengthening maneuvers including mobilization of the flexures and high vascular ligation to obtain tension-free reach into the pelvis. For an end colostomy reversal following sigmoid diverticulitis, the surgeon must ensure the adequacy of the initial resection at time of stoma reversal, with particular attention paid to previous resection margins. A surgeon may have left a sigmoid rather than a rectal stump during emergency surgery, and a completion sigmoid colectomy may be necessary at time of stoma reversal to ensure an adequate diverticular resection. Similarly for cancer, the oncologic adequacy of the initial resection must be assessed and remedied at time of stoma reversal, which may require additional bowel resection or lymphadenectomy.

Once the distal and proximal bowel conduits are adequately mobilized and prepared, an anastomosis is created with either stapled or handsewn techniques at the surgeon's discretion. For colorectal anastomoses following Hartmann's procedure, a stapled end-to-end anastomosis (EEA) is commonly performed (Fig. 54.26b). For stapled anastomoses, the surgeon must ensure the stapler can easily be passed to the transected rectal staple line. This may not always be easy or possible since the rectal stump can become corrugated, contracted, filled with clay-like desiccated mucus, entrapped, or lost in a hostile pelvis. Lighted deep pelvic retractors, proctoscopes, vaginal retractors, EEA-sizers, and copious lubrication may aid in identification of the rectal stump. If the stapler is unable to be advanced fully to the proximal rectal transection line, the end of the colon can be anastomosed to the side of the anterior rectal wall, but the end-to-side anastomosis must be several centimeters from the proximal rectal margin to avoid ischemia to the remaining bridge of rectal wall. Moreover, if an anterior end-to-side rectal anastomosis is performed, the surgeon must assure the vagina, and bladder is fully mobilized away from the intended rectal anastomotic site to avoid iatrogenic fistulas. An anastomotic air-leak test should be performed to interrogate anas-

tomotic quality. If a leak is discovered, the anastomosis can be resected and recreated, revised, or protected with a diverting loop ileostomy at the surgeon's discretion.

Laparoscopic and robotic end stoma reversal with colorectal or ileorectal anastomosis is predicated upon the same principles and techniques described above but are modified to reflect the nuisances of minimally invasive surgery. After similar preoperative workup and positioning, surgery typically commences with incision of the mucocutaneous stomal junction and subcutaneous stomal dissection. Once the stoma is completely freed from peritoneal attachments and un-everted, the anvil to an EEA stapler is secured in place, and the anvil-stoma combination is reduced into the abdomen. The former stoma site is occluded with an airtight, twisted plastic wound retractor or plugged with a balloon-tipped Hasson trocar as pneumoperitoneum is generated. Additional laparoscopic working ports are placed to complete the necessary adhesiolysis, pelvic dissection, and rectal mobilization exactly as performed for an open procedure. An intracorporeal EEA stapled rectal anastomosis is then completed as described above.

Stoma Reversal Complications

Loop stoma reversal is often considered a minor procedure when compared to the index operation; however complications may occur more frequently than most surgeons acknowledge (Table 54.5). Regardless of technique, loop ileostomy reversal is generally well tolerated with low risk of anastomotic leakage; however, early wound infections and late-term incisional hernias may occur. Reversal of an end stoma is associated with high morbidity, and stoma reversal is often more challenging than the initial operation. Given the gravity of some end stoma reversals, proper surgical planning is essential to assure the best surgical outcomes, while preoperative patient counseling can best manage perioperative patient expectations.

Table 54.5 Select published complications rates for stoma reversal [100, 109, 113, 114, 117, 126–128]

Stoma reversal type	Loop ileostomy reversal (%)	Loop colostomy reversal (%)	End colostomy reversal with colorectal anastomosis (%)
Superficial surgical site infection	3–13.5	5–20	14–43.8
Deep space infection/leak	2–4	2–4	1.5–21
Bowel obstruction/ileus	5–16	4	23
Hernia (clinically diagnosed)	0–50	2–38	3–31

Special Considerations

The Difficult Stoma

Increasing rates of obesity present a particular challenge to the colorectal surgeon. Unfortunately, obesity is associated with an increased risk of stoma-related complications [15]; as such, the patients who require the highest quality stomas paradoxically can have the most challenging stomas to create. Acutely inflamed and chronically foreshortened bowel mesentery also may hinder stoma creation, even in thin patients. Special tips and tricks can help the surgeon create difficult stomas in complex situations. Since stoma height has been identified as an independent risk factor for problematic stomas, it is not surprising that the majority of tips involve means of obtaining adequate, tension-free reach of an adequate length of the stoma conduit.

Simple measures are first employed when dealing with the difficult stoma. In obese patients with a thick abdominal wall, the surgeon will usually find the supraumbilical abdominal wall to be thinner, easing reach and minimizing tension on a stoma (Fig. 54.27). In the super morbidly obese, a subxiphoid loop transverse colostomy may be the easiest stoma to create if temporary diversion is necessary. If upper abdominal stoma sites are not plausible and the surgeon still strug-

Fig. 54.27 The abdominal wall may be thinner above the umbilicus in the obese patient, easing creation of a potentially difficult stoma

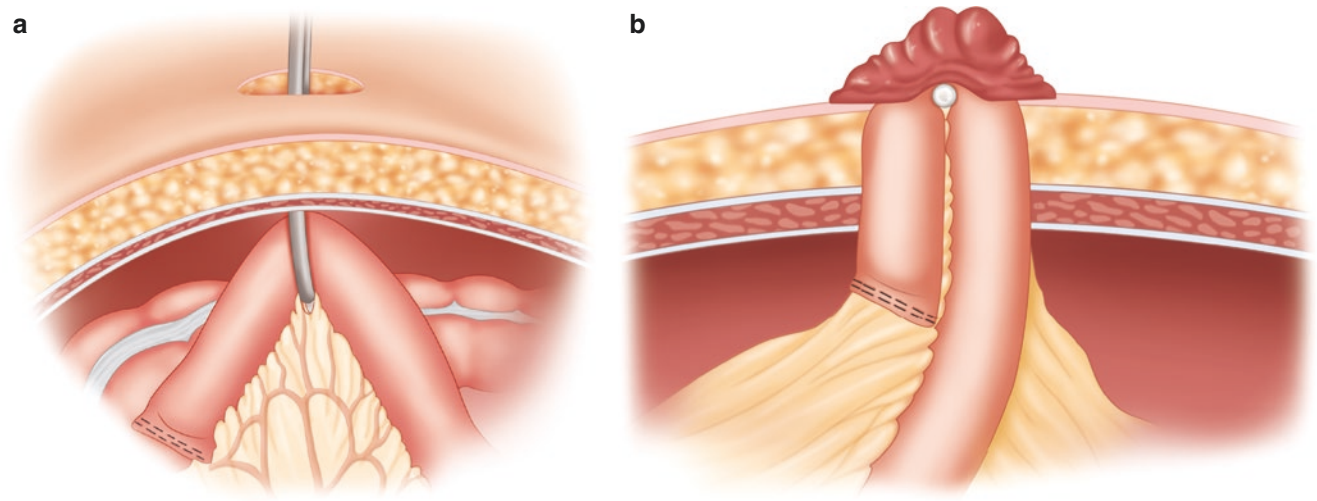

Fig. 54.28 (**a**, **b**) Loop-end ileostomy

gles to deliver bulky bowel through a thick abdominal wall, the stoma can be delivered in a stepwise fashion. First, the subcutaneous tissues can be completely elevated off of the anterior rectus sheath and the stoma delivered completely through the muscular layer. The stoma can then be delivered through the subcutaneous tissues and skin in a second step. Alternatively, the use of a plastic sleeve wound retractor with or without water soluble lubricant may provide a slick conduit to help deliver thickened bowel and mesentery through a challenging trephine. Some advocate performing subcutaneous lipectomy to minimize abdominal wall distance; however this may lead to a recessed stoma that is difficult to pouch and should be used judiciously, if at all.

A loop-end stoma is a unique ostomy configuration that may allow additional reach of an end ileostomy (Fig. 54.28) or colostomy (Fig. 54.29) in obese patients or those with a foreshortened mesentery. The loop-end stoma configuration is useful when the tip of the intended stoma conduit is tethered by the mesentery and the bowel immediately proximal to the end is more mobile. The loop-end arrangement preserves the mesentery to the entire stoma, assuring adequate perfusion. A loop-end stoma is created similar to a loop stoma, which is aided by passing a narrow Penrose drain through a mesenteric defect at the mesentery bowel interface to deliver the loop. The stoma is matured as a loop ileostomy or colostomy as detailed previously (see section "Technical Considerations of Stoma Creation").

Two to three centimeters of additional bowel reach can be obtained by sequentially scoring the peritoneal surface of the stoma mesentery perpendicular to the course of the vessels (Fig. 54.30). Such "pie crusting" should be carefully performed by only dividing the peritoneum while protecting the underlying vessels. In the case of a small bowel stoma, both peritonealized mesenteric surfaces may need to be scored to obtain maximum reach.

In the acute setting when it may be inadvisable to create an anastomosis, both segments of bowel may be exteriorized in a Prasad-style end-loop stoma (Fig. 54.31). This configuration is most commonly used when there is a bowel perforation related to diverticulitis or trauma but may be employed in any situation when primary anastomosis is inadvisable. The unique aspect of this stoma is that both bowel limbs are exteriorized and eventual reanastomosis may often be performed with a local procedure, without the need for laparotomy.

Challenging situations may require the surgeon to compromise on the tenets of stoma creation, and the ideal stoma at the ideal location with the ideal bowel segment may not be possible. If a surgeon is forced to decide between making a poor stoma in a good location versus making a good stoma in a poor location, a general consensus among stoma care professionals is that a poor stoma in a good location is the lesser of two evils [19]. Rarely, thickened bowel and mesentery may prohibit stoma eversion and maturation. In these cases where eversion and maturation are not possible, the stoma can be simply opened without maturation and secured to the skin well above skin level. While reactive serositis and late-term "bishop's collar" stricture may develop, this temporizing measure may get the patient through until the bowel is suitable for stomal revision or reversal.

Seldom, a remarkably hostile abdomen may prohibit stoma delivery through a traditional stoma trephine despite exhausting all lengthening maneuvers. In these rare situations, a stoma may be fashioned through the midline incision. Although a stoma placed in an incision is prone to wound infection and hernia, it may temporize or palliate an otherwise unsustainable surgical situation. Infrequently, a heavy mesentery or friable bowel may cause a stoma support rod to tear through the mesenteric aspect of a loop stoma. Instead, the bowel can be supported by two stoma rods placed alongside one another to distribute the tension over a

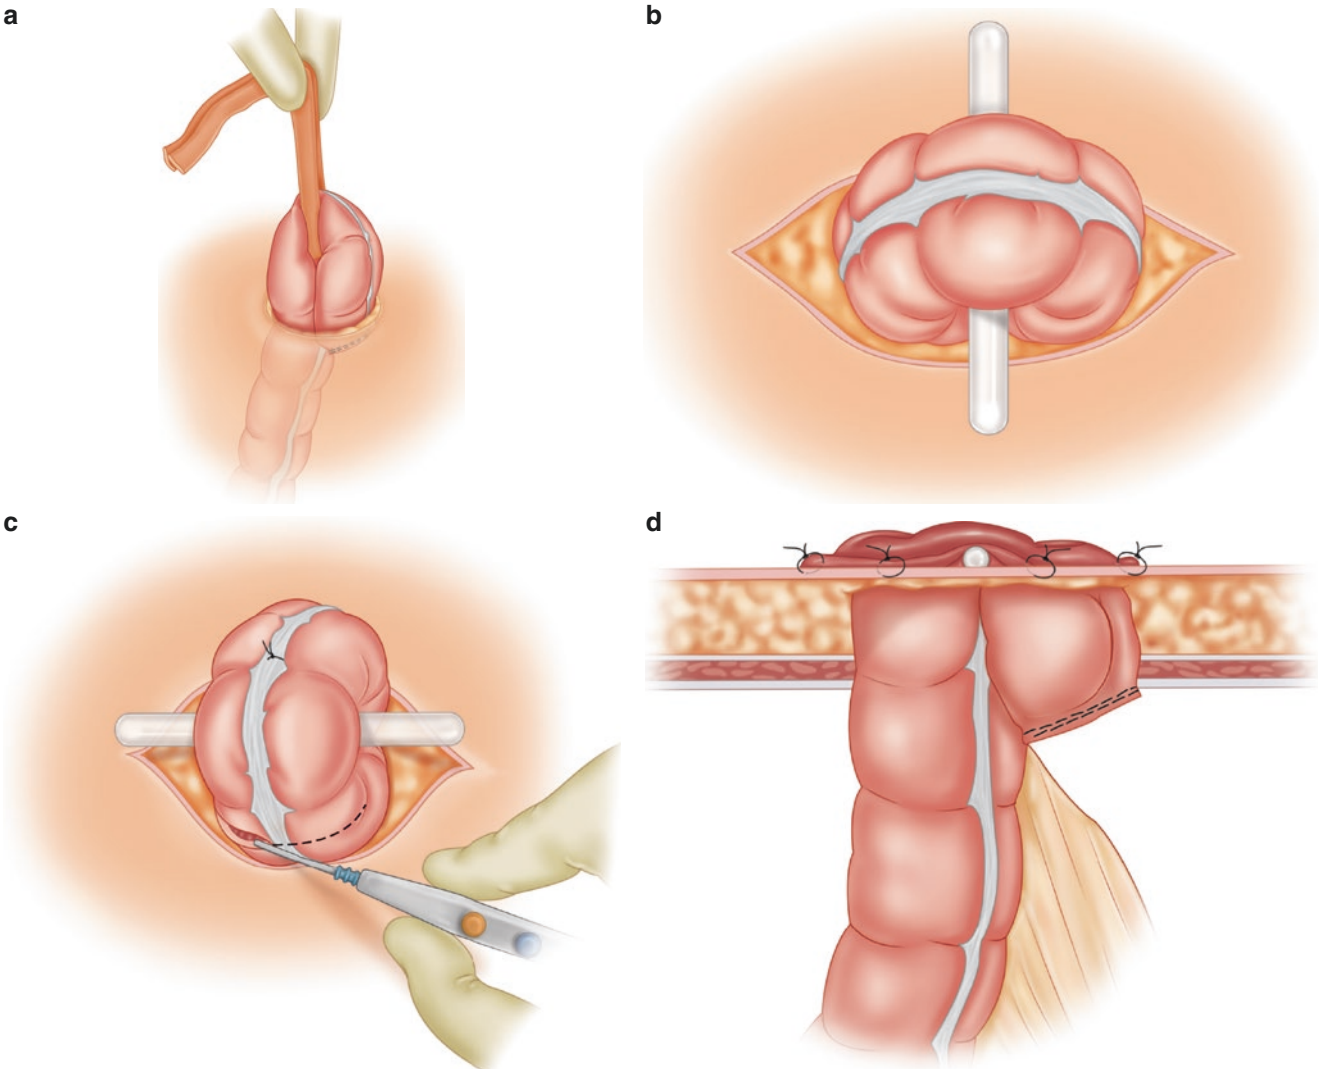

Fig. 54.29 (**a**–**d**) Creation of a loop-end colostomy

greater surface area. Alternatively, the mesentery can be braced at the fascia level rather than the skin level. In this method, a long malleable or pliable tube (e.g., thin chest tube, filiform, follower, plastic vascular tunneling device) is passed through a skin incision remote from the stoma site down to the anterior fascia of the abdominal wall where it pierces an avascular portion of the stoma mesentery before rising through the skin on the opposite side of the stoma (Fig. 54.32). This tube is subsequently removed in several days when the stoma and mesentery have adhered to the subcutaneous tissues and are at minimal risk for retraction.

Temporary Fecal Diversion: Loop Ileostomy Versus Loop Colostomy

The ideal level of temporary protective fecal diversion following colorectal or coloanal anastomosis has long been debated by colorectal surgeons. It is generally acknowledged that loop ileostomy and loop colostomy have similar complication rates but different complication profiles [9]. Clinical and patient-reported outcomes between temporary loop ileostomy versus loop colostomy have been compared in several recent trials and meta-analyses with inconsistent results [114–116]. Loop ileostomies, although more prone to dehydration, readmission, and post-reversal obstruction, are found to have less post-closure sepsis and less pre- and postoperative hernias and may offer improved quality of life compared to loop colostomy [117–119]. ASCRS CPG recommends loop ileostomy preferentially over transverse loop colostomy for temporary fecal diversion in most cases but acknowledges that there may be particular circumstances favoring a loop transverse colostomy [9]. For instance, a distal colorectal obstruction may best be treated with a transverse loop colostomy that allows both afferent diversion with efferent retrograde venting. Additionally, a transverse loop colostomy may be easier to fashion in the obese than a loop ileostomy (see section "Special Considerations: The Difficult Stoma").

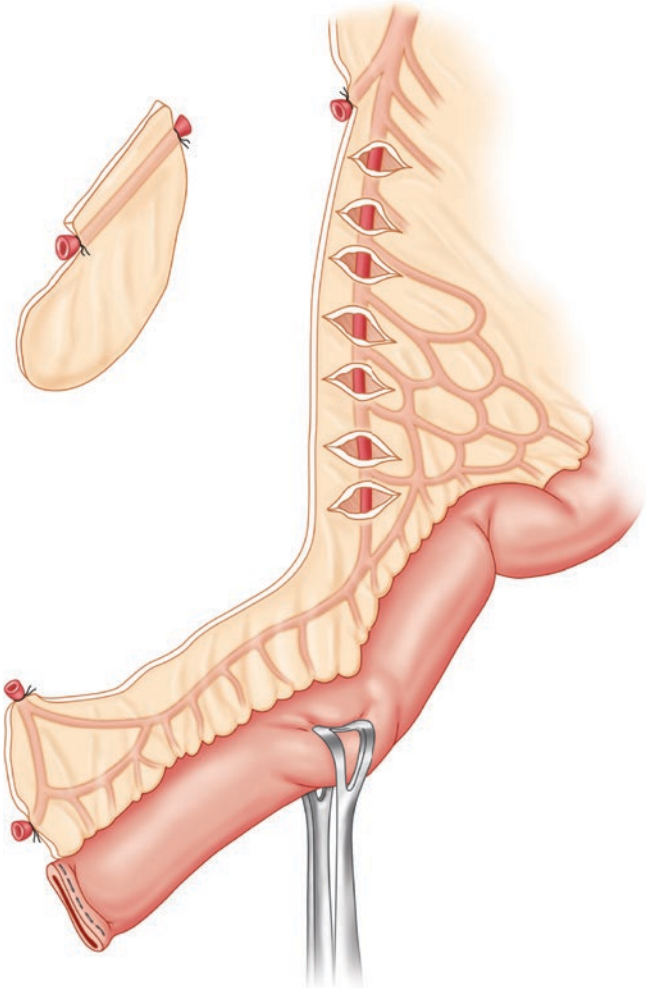

Fig. 54.30 "Pie crusting" of the bowel mesentery to obtain additional length prior to stoma creation. If a difficult end ileostomy is fashioned from the terminal ileum, the surgeon may find it helpful to ligate the ileocolic artery proximally to obtain reach

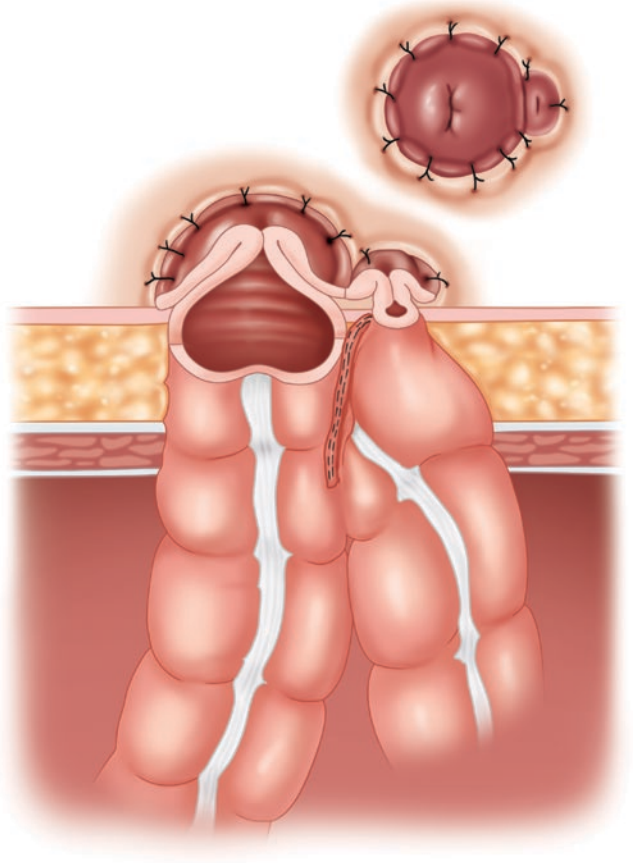

Fig. 54.31 A Prasad-type end-loop colostomy

Genitourinary Stomas

Although colorectal surgeons do not typically perform reconstructive genitourinary procedures, familiarity with such procedures is important for several reasons. First, a colorectal surgeon may be asked to help with stoma care and complications and assist with urinary stoma revisions. Additionally, a thorough understanding of urinary stoma construction and anatomy can prove invaluable during urgent and emergent reoperations on patients with previous genitourinary reconstructions. Moreover, genitourinary reconstruction may be necessary for patients with locally advanced pelvic malignancies that require multivisceral resection. Lastly, patients with neurogenic bowel and bladder may require synchronous urinary and fecal diversion, so understanding of the urologic aspects of a synchronous operation may be crucial.

The simplest reconstructive urinary diversion is the ileal conduit (Fig. 54.33) [120]. This procedure typically harvests a 10–15 cm segment of the ileum (typically at least 15–20 cm proximal to the ileocecal valve) to serve as a conduit between ureters and the skin. Enteric continuity is restored with an ileo-ileostomy, and the left ureter is tunneled through a sigmoid mesenteric defect. Both left and right ureters may be anastomosed separately (in a "Bricker" fashion) or sewn together and a single uretero-ileal performed ("Wallace" anastomosis). The proximal end of the conduit is usually oversewn to limit stone formation. The open end of the conduit is delivered through a stoma trephine and matured to the skin. The stoma is matured in either an end or loop-end configuration. The surgeon must be keenly aware of the left ureter's aberrant course during reoperation and left colon mobilization. Moreover, the tenuous ileal conduit mesentery must be preserved during reoperation, since inadvertent injury can result in conduit infarction and convert a simple adhesiolysis to an extensive and complex urinary reconstruction. The mesentery for the conduit will be inferior to the new ileo-ileostomy.

Urologic surgeons may augment or replace urinary bladders with harvested ileal segments for a myriad of indica-

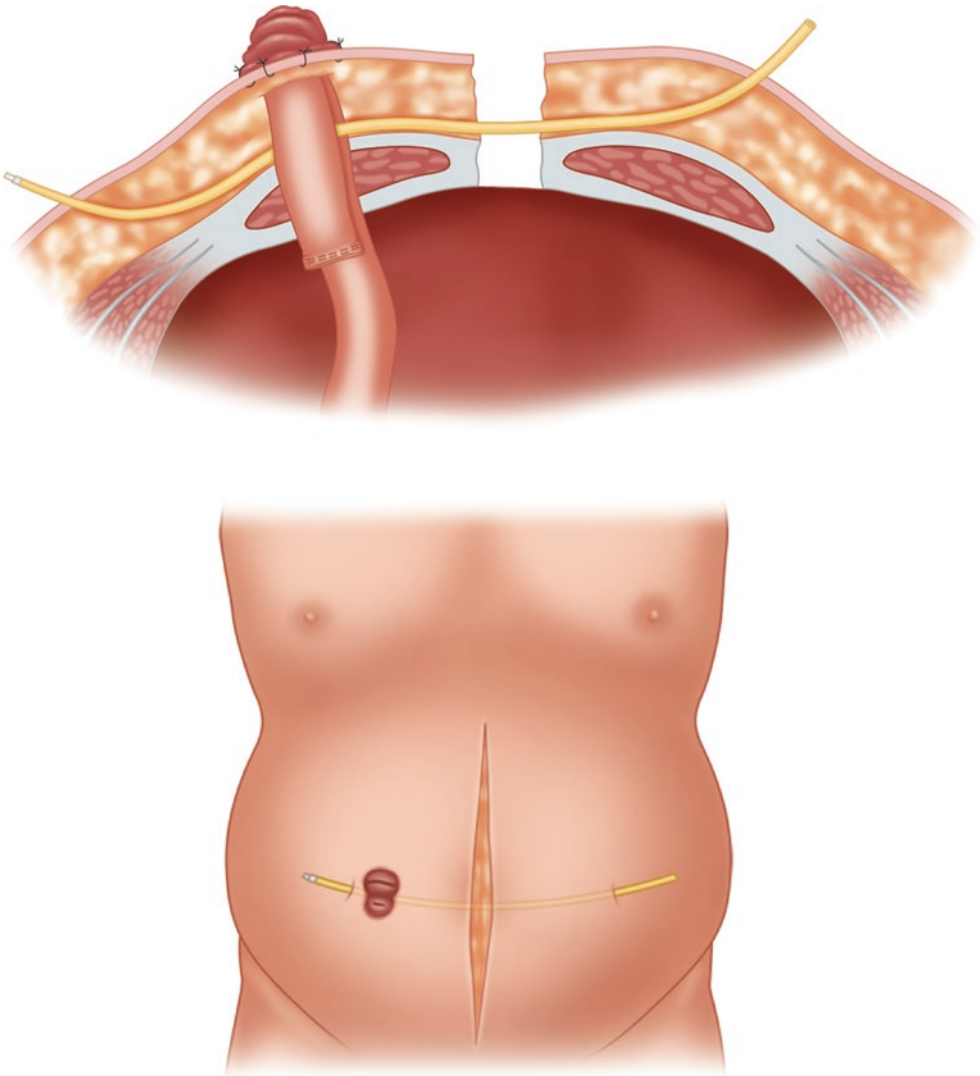

Fig. 54.32 Supporting a difficult loop enterostomy at the fascial level with a filiform catheter

tions [121]. Akin to the ileal conduit, a similar segment of mid ileum is harvested and configured as either a panel or pouch to augment or reconstruct the bladder and increase its capacity. Regardless of the ileal configuration, enteric continuity is restored with an ileo-ileostomy, and a mesenteric pedicle spans from the closed mesenteric defect to the pelvis. This ileal mesentery pedicle can be a nidus for obstruction and internal herniation, and extreme care should be taken to preserve the mesentery to avoid devascularization of the reconstructed urinary bladder.

Several types of catheterizable urinary stomas may provide appliance-free urinary continence to patients in need of genitourinary diversion. These catheterizable stomas are brought to the umbilicus or the right lower quadrant. Most pouches are created from the right colon with the appendix or the terminal ileum serving as the channel for catheterization. An Indiana pouch follows similar principles as the ileal conduit; however the right colon and ileum are harvested en bloc to create a large intra-abdominal urinary reservoir (Fig. 54.34) [122]. The ileocolic segment is anastomosed to the ureters, and a narrow, skin-level stoma is created that serves as a valve and permits intermittent catheterization. A Mitrofanoff appendicovesicostomy utilizes an appendiceal conduit to create a catheterizable stoma for the bladder or neobladder (Fig. 54.35) [123]. A Monti conduit is similar to the Mitrofanoff appendicovesicostomy but utilizes a pedicled segment of tubularized ileum to create a narrow, catheterizable urostomy (Fig. 54.36) [124].

The Turnbull Blowhole Colostomy

Rarely, difficult situations may arise where colectomy or proper fecal division is inadvisable due to prohibitively high operative risk. For example, gravid patients with fulminant colitis may be unsuitable for colectomy out of concern for patient or fetal demise. Occasionally, profound comorbidities such as sepsis or cardiovascular collapse may make a

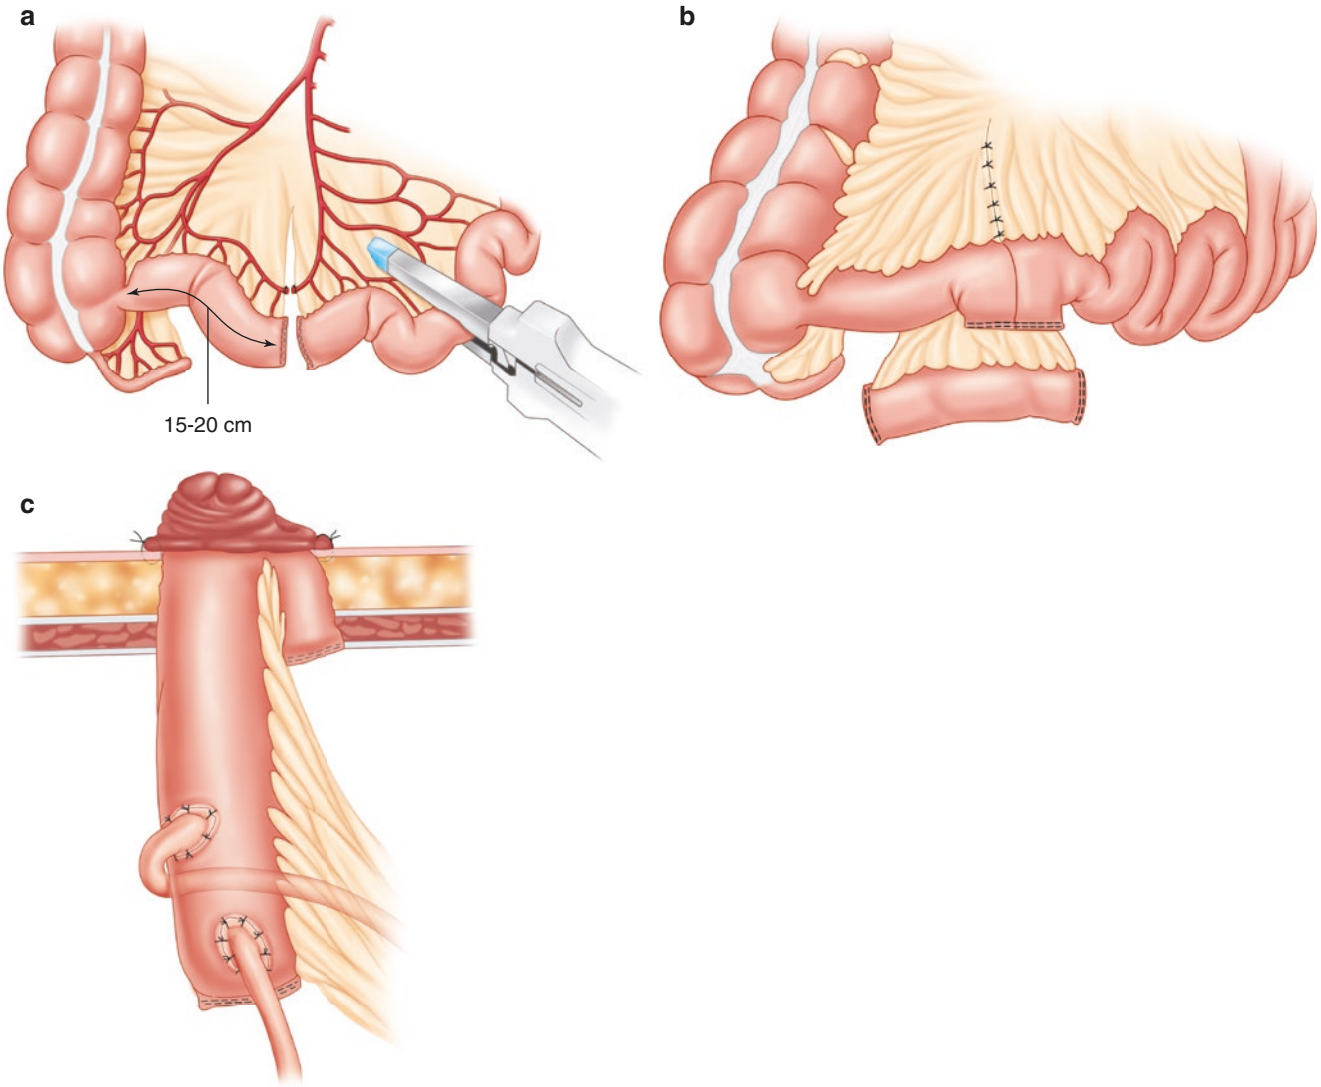

Fig. 54.33 The ileal urinary conduit: (**a**) A segment of mid ileum is resected, (**b**) an ileo-ileostomy is created, and (**c**) the harvested ileal conduit is anastomosed to the ureters and matured as a stoma

total colectomy inadvisable. In these situations, a limited upper midline laparotomy with loop ileostomy and Turnbull blowhole colostomy can be fashioned quickly to divert and decompress a toxic colon until the patient can sustain a proper resection (Fig. 54.37) [125]. In these challenging situations, a limited 10-cm supraumbilical laparotomy can be made to accommodate a hand to explore the abdomen. A loop ileostomy can be made through a separate stoma trephine, and the loop of transverse colon can be brought out through the midline incision. The midline fascia is closed around the bulge of the transverse colon loop and then a watertight seal is created between the seromuscular surface of the colon and the surrounding peritoneum with one or two layers of continuous suture (Fig. 54.38). Once the peritoneal cavity is sequestered from potential bowel spillage, the colon is incised, and the bowel edge is sutured to the skin. The ileostomy is then matured. The blowhole stoma is suboptimal due to prolapse and pouching difficulties owing to the flat nature of the stoma, but it can be a useful temporizing adjunct when no other options exist.

For rare patients too ill to tolerate a general anesthetic, the Turnbull blowhole colostomy can be performed under local anesthesia. A fluoroscopic projection of the upper abdomen is obtained with the patient supine on the operating table. The colon is identified by its characteristic bowel gas pattern, and a metallic coin is then used to mark the intersection of the transverse colon and the midline. The spot is then marked, and local anesthetic is infiltrated through the subcutaneous tissues, and a 4 cm midline incision is made directly over the colon. Local anesthetic is infiltrated layer by layer as the fas-

cia and peritoneum are carefully divided and the abdomen is entered. The anterior seromuscular surface of the colon is grasped through the incision and sutured circumferentially to the peritoneum to limit intra-abdominal stool contamination. A colotomy is made, and the stoma is sutured to the skin as described above.

Ileostomy and Foodstuff Bolus Obstruction

Early postoperative edema may cause transient ileostomy obstruction at the level of the rectus fascia. Such edema typically subsides before return of bowel function, but lasting edema can cause an obstruction. In the setting of obstructive symptoms, ileostomy obstruction may be suspected when there is peristomal pain with either thin, non-bilious, hydrops-type fluid ileostomy effluent or no output at all. Cross-sectional imaging may reveal an abrupt transition in bowel caliber as the stoma traverses the abdominal wall. If acute postoperative ileostomy obstruction is suspected, a 14–18-French Foley (or red rubber) catheter can be gently placed at the bedside to bypass the level of obstruction and decompress the bowel proximal to the ileostomy. To place a catheter, a two-piece stoma appliance should be used.

With the stoma flange in place and bag removed, a well-lubricated catheter is inserted into the stomal os as small aliquots of water are gently injected through the catheter with a Toomey syringe to create a water cushion ahead of the catheter tip. The catheter is advanced as long as resistance is not

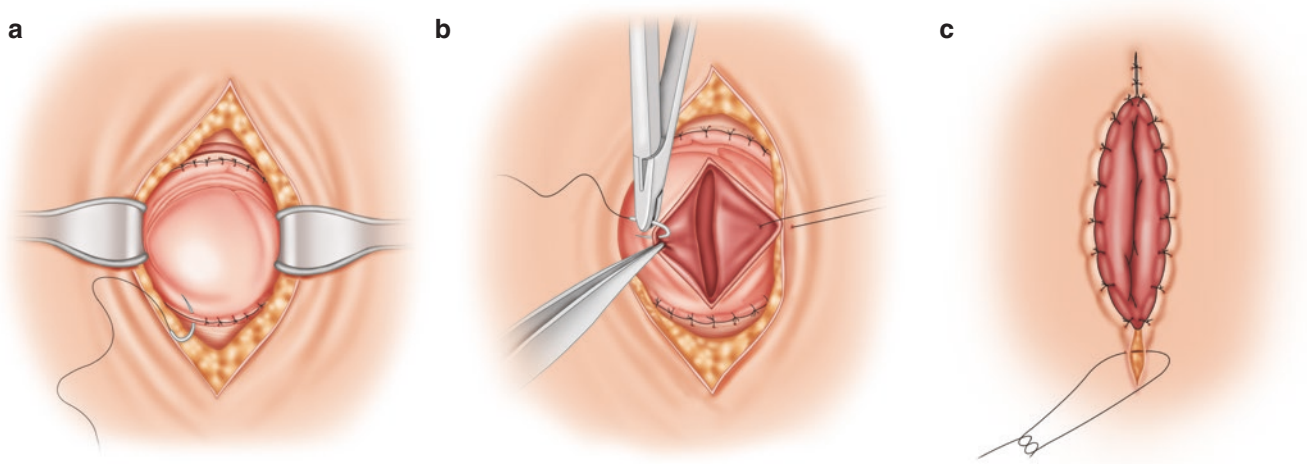

Fig. 54.38 (**a**–**c**) Creation of a Turnbull blowhole colostomy

met beyond the fascial obstruction and secured to the stoma appliance with suture or dental floss to hold the catheter in place. If a Foley catheter is used, the balloon should not be blown up out of concern of injuring the bowel. The catheter should be used cautiously, as both short- and long-term use of indwelling stoma catheters, can cause bowel perforation.

The relatively narrow luminal diameter of an ileostomy may occasionally cause bolus obstruction by nondigestible foodstuffs. High-residue foods such as nuts, seeds, shellfish, sausage casings, and raw produce are poorly digested and may pass through the ileostomy in large chunks. Rarely, such foodstuffs may become lodged within the ileostomy and require ileostomy irrigation to disimpact the food bolus. To irrigate an ileostomy, a Foley (or red rubber) catheter is placed as described above to a distance just beyond the fascia (typically <6 inches from the skin surface). A Toomey syringe is then used to slowly irrigate out the bolus obstruction with 30–50 mL aliquots of water until the bolus is dislodged. This process may take 1–2 hours.

Abdominal Wall Reconstruction and Parastomal Hernia Repair

55

Clayton C. Petro, Ajita Prabhu, and Michael J. Rosen

Key Concepts

- The precise incidence of parastomal herniation is largely based on criteria for diagnosis.
- A selective approach to repair of parastomal hernias is warranted owing to the high recurrence rates associated with surgical repair.
- Repair should generally be restricted to highly symptomatic patients with parastomal hernia.
- Laparoscopic Sugarbaker repair is the procedure of choice for most patients requiring surgery for parastomal hernias.
- Advanced abdominal wall reconstruction techniques may be indicated in complex defects.

Introduction

Parastomal hernias are a ubiquitous problem for both the general and colorectal surgeon alike. Experienced surgeons will admit that their repair is a humbling endeavor, and a thorough review of the literature for guidance reveals only anecdotal cohorts often with limited follow-up. As with all incisional hernias, repair of parastomal defects is impacted by the patient's comorbidities, the characteristics of the hernia itself, and the surgeons' experience or comfort level with various repair techniques. Here we review the available literature on repair options and attempt to provide a practical approach to surgical decision-making when presented with these difficult patients.

Incidence, Risk Factors, and Diagnosis

Conservatively, 120,000 ostomies are created yearly in the United States, and at any given time, approximately 800,000 Americans are living with a stoma [1]. Subsequent development of a parastomal hernia (PSH) – defined as an incisional hernia at the site of an ostomy – is one of the most common complications thereof [2]. The reported rates of PSH formation vary widely depending on the type of stoma, patient characteristics, the duration of follow-up, and definition or method of detection. Generally, rates are approximately 30% by 1 year and 40% by 2 years and can be greater than 50% with longer follow-up [3]. Some would even pessimistically contend that with long enough follow-up, PSH development is inevitable [4]. In addition to pain and potential obstructive symptoms akin to all incisional hernias, PSH bulging can also cause pouching dysfunction with a devastating impact on these patients' quality of life (QoL), not to mention the financial burden of additional supplies and frequent need for hospital readmission to break the cycle of appliance leakage and worsening skin excoriation [5, 6]. Consequently, both the American Society of Colon and Rectal Surgeons and the Association of Coloproctology of Great Britain and Ireland have identified PSH prevention and repair as a top research priority [7, 8].

As was previously alluded to, the precise incidence of PSH is a function of several important factors. Most rudimentary is the stoma type with the incidence ranges listed in Table 55.1 [9, 10]. In general, end colostomies have a higher incidence of PSH formation compared to the relatively similar rates identified in end ileostomies and loop colostomies.

Table 55.1 Parastomal hernia incidence

End ileostomy	2–28%
Ileal conduit [10]	17%
End colostomy	4–48%
Loop ileostomy	0–6%
Loop colostomy	0–31%

S. R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, https://doi.org/10.1007/978-3-030-66049-9_55

Loop ileostomies have the lowest incidence, likely owed to their transient presence. As was mentioned in the previous chapter, an enlarged trephine size at the time of creation has been associated with PSH formation and therefore minimizing the muscle defect without causing ischemia to the trespassing bowel is a delicate balance the surgeon hopes to achieve [11]. To account for some of the wide variability in PSH reporting, inconsistent definitions and variable patient characteristics often play a significant role. A review of the literature by Israelsson points out the frequent absence of parastomal definitions in clinical reports as well as the hindrance of this weakness on comparing repair techniques. In addition to emphasizing the importance of following stoma patients at least 1 year to monitor for PSH occurrence, he proposed the following definition that provides some practical specifics during clinical assessment – "any palpable defect or bulge adjacent to the stoma detected when the patient is supine with legs elevated or while coughing or straining when the patient is erect" [12]. Still, inter-observer reliability among staff surgeons is more disappointing that one would expect [13]. Regarding patient characteristics, advanced age, diabetes, surgical site infection, malnutrition, immunosuppression, malignancy, and emergent presentation have all been implicated as risk factors for PSH development. That said, obesity and waist circumference seem to carry the strongest association supported by clinical data [14–16]. While not entirely reflective of an American patient population, the Swedish National Colorectal Cancer Registry and National Patient Register of over 6300 patients with a permanent colostomy identified body mass index (BMI) >30 kg/m^2 as the only risk factor for PSH development [13]. Furthermore, the patient's particular body habitus may be an even more specific predictor, as a waist circumference > 100 cm has a 75% probability of budding a PSH [15]. For this reason, preoperative weight loss before embarking on PSH repair is something that should be taken seriously whenever possible.

Next, the timing and methodology of diagnosis deserve some additional discussion. Data from large prospective series tend to demonstrate that PSH occurrences start to plateau after the first two postoperative years [3, 17, 18]. Specifically, a large cohort of 202 parastomal hernias analyzed by the French federation of ostomy patients found a median time of 18 months until presentation but with a range of up to 27 years [19]. The aforementioned diagnoses were self-reported by those patients who were educated on the signs and symptoms of a PSH. The authors acknowledge that self-observation could underestimate the true rate of PSH in their patients. However, 76% of the PSH patients identified by patients themselves had symptoms, and 56% had undergone operative repair (Table 55.2) suggesting that self-observation is at least a good way to identify a clinically significant PSH. Alternatively, while CT scan findings can be useful to identify a concomitant incisional hernia, PSH interpretation can be challenging. Some have suggested that CT scans can overestimate the presence of a clinically significant PSH bulge by misinterpreting redundant bowel in the subcutaneous tissue, while others have found that a traditional supine image with reduced hernia contents may not adequately demonstrate a clinically significant parastomal bulge that would be present in the standing/prone position or with Valsalva [20, 21]. So while CT scans can provide a lot of useful information for operative planning – specifically the presence of a concomitant incisional hernia, bowel obstruction, or size of a PSH defect that may dictate the need for re-siting – the importance of the patient's self-assessment in non-urgent scenarios should not be underrated as their symptoms correlate with required operative intervention more often than not [19].

Table 55.2 Parastomal hernia symptoms and complications

Symptom	
Pain	35%
Appliance difficulty	28%
Leakage	27%
Skin irritation	22%
Irrigation difficulty	24%
Complications	
Prolapse	18%
Obstruction	15%
Hemorrhage	2%

Classification

Several PSH classification schemes have been proposed, though none has been validated or gained wide adoption. While their systems have less clinical value in regard to operative decision-making, colorectal surgeons should at least be familiar with the historical definitions by Rubin, Bailey and Devlin summarized in Table 55.3A [22, 23]. The definitions proposed by the European Hernia Society (EHS) in 2014 reflect multinational collaboration and somewhat formalized the systems proposed by Gil, Szczepkowski and Moreno-Matias (Table 55.3B). Modern pragmatic systems incorporate two of the most important variables that impact surgical decision-making – the size of the parastomal defect and the presence of a concomitant incisional hernia.

Operative Indications

Before we discuss repair techniques and strategies, we should set the stage by discussing the implications of operative endeavors in the context of a PSH. First, data from the Abdominal Core Health Quality Collaborative (ACHQC)

Table 55.3 Parastomal hernia classifications

Rubin and Bailey		
I: "True" parastomal hernia	Hernia sac penetrates a dilated stomal canal	
II: Intrastomal hernia	Stomal sac formed by serous membrane of prolapsed intestine	
III: Subcutaneous prolapse	Excess bowel forms a loop in the subcutaneous tissue	
IV: Pseudohernia	Enervation of the lateral abdominal wall	
Devlin		
I: Interstitial hernia	Hernia sac between layers of the abdominal wall	
II: Subcutaneous hernia	Hernia sac penetrating into the subcutaneous layers	
III: Intrastomal hernia		
IV: Peristomal hernia	Associated with stomal prolapse	
Gil and Szczepkowski		
Parastomal hernia w/o coexisting cicatricial hernia and w/o abdominal wall deformation		
Parastomal hernia with cicatricial hernia w/o abdominal wall deformation		
Large, isolated parastomal hernia w/o coexisting cicatricial hernia w/ abdominal wall deformity		
Large parastomal and coexisting cicatricial hernias with abdominal wall deformity		
Moreno-Matias		
Ia	Bowel forming the colostomy with a sac <5 cm	
Ib	Bowel forming the colostomy with a sac >5 cm	
II	Sac containing omentum	
III	Intestinal loop other than bowel forming the stoma	
EHS parastomal hernia classification		
I	<5 cm parastomal hernia, no concomitant incisional hernia	Primary or recurrent
II	<5 cm incision hernia, yes, concomitant incisional hernia	
III	>5 cm parastomal hernia, no concomitant incisional hernia	
IV	>5 cm parastomal hernia, yes, concomitant incisional hernia	

found that only 22% of stomas were reversible at the time of their hernia repair [24]. So while reversal of a temporizing stoma simplifies reconstruction techniques akin to an incisional hernia, in the vast majority of situations, the surgeon is going to have to deal with the trespassing bowel again. Second, while the success of each technique is somewhat variable and will be discussed in more detail shortly, no PSH repair is tremendously successful. Recurrences again depend on risk factors, the length of follow-up, and diagnostic technique, but can still be >50% when long-term follow-up is available, even when a mesh reinforcement is utilized [19, 25]. Finally, with each additional repair that includes prosthetic reinforcement, the next operation typically becomes more complex, with reports of sobering complication rates >50% and re-operation rates of 12% [26]. So in the absence of symptoms that warrant repair, it is not surprising that up to 70% of patients living with a PSH do not pursue an operation, a preference no doubt shared by their surgeon [27]. While there is no good evidence to describe the consequence of watchful waiting, the results of operative intervention are certainly not celebrated enough to appeal to the asymptomatic or minimally symptomatic patient, and there are at least anecdotal reports of safe non-operative practices by surgeons [28]. Unlike descriptions of pain that can be widely variable, patients with pouching issues or intermittent obstruction typically have an impaired QoL sufficient enough to pursue surgical repair – *see incidence in* Table 55.3. A standardized QoL measure – Patient-Reported Outcomes after Parastomal HErnia tReatment (PROPHER Study) – is in the midst of development by the European Society of Coloproctology to help guide this discussion and give patients feedback on realistic expectations after their operation [26]. To date, repair should be offered to those patients with a history of PSH complications – most commonly bowel obstruction and prolapse – or symptoms causing significant limitation in their QoL. An honest discussion should be had about the real risk of recurrence and the optimization techniques that can help prevent both recurrence and wound morbidity discussed next.

Preoperative Optimization and Planning

Given the tenuous results of surgical repair, every effort should be made to optimize these patients before their operation. In the absence of an emergent presentation, an emphasis should be placed on weight loss, smoking cessation, and diabetes control. In addition to the association of BMI with wound morbidity and an increased length of stay, the aforementioned association of PSH recurrence with BMI and waist circumference underscores the importance of preoperative weight loss specifically in this context [29, 30]. Most experts agree on the extremes – that surgery should be offered to those with a BMI <30 kg/m^2 and that a BMI >50 kg/m^2 should be considered prohibitive [31]. However, recommendations on those patients between a BMI of 30 and 50 mg/m^2 are ambiguous, and prospective evidence on the benefits of weight loss in this setting is lacking. Intuitively, retrospective data from the AHSQC regarding incisional hernias found that surgical site infection and those requiring an intervention progressively decreased with a lower BMI, but a safe "cutoff" could not be determined [32]. The authors suggest that the surgeon counsel patients on weight loss and monitor the patient's progress in 3-month intervals [33]. We typically aim for a BMI <35 kg/m^2, or < 40 kg/m^2 if a sincere attempt has been made and the severity of the patient's symptoms is escalating. Likewise, active smoking and poorly controlled diabetes have similar correlations with wound morbidity [34–36]. Data supports the effectiveness of smok-

Table 55.4 Parastomal hernia repair preoperative optimization

BMI	<35–40 kg/m^2
Smoking cessation	≥4 weeks
Hemoglobin A1C	<7–8
Stoma marking	All patients
Bowel prep	No

ing cessation for at least 4 weeks before surgery and a hemoglobin A1C <7–8 [36, 37].

Briefly, there are two additional points to discuss regarding preoperative planning – the importance of stoma marking and role of a bowel prep. Preoperative stoma marking of a PSH patient should be done even when not planning to re-site a stoma in the uncommon case where it is necessary. Certainly the insight of an enterostomal therapist has been found to be helpful in regard to reducing postoperative adverse events and improving patients' postoperative quality of life and independence [38, 39]. Finally, there is actually not evidence to support the use of a routine bowel prep during PSH repair [2]. Practically, this can increase the leakage of watery stool during a repair that may require manipulation of the bowel. Furthermore, data from the ACHQC has found that a routine bowel prep does not impact wound morbidity and may increase the impact of wound morbidity requiring a procedural intervention in contaminated cases [40].

The outlined optimization approaches – summarized in Table 55.4 – seem straightforward. However, some of the most challenging and emotional discussions with patients are those without an urgent operative indication who resist the recommended optimization efforts, most typically weight loss and smoking cessation. Often surgeons feel compelled to intervene when a patient "gives up," concerned that an emergent presentation would be viewed as their failure to intervene in an elective setting. Here, the authors encourage strict adherence to the aforementioned optimization efforts at all costs, emphasizing to the patient that they too are responsible for the consequences of non-adherence that include potential emergent presentation and a non-definitive primary repair.

Repair Techniques and Associated Outcomes

To date there are no randomized controlled trials comparing repair techniques for parastomal hernias with mesh reinforcement. As such we will summarize the findings of large or significant series for each approach.

Primary Repair

Primary repair has mostly fallen out of favor due to unacceptable recurrence rates as high as 80% [12, 41–43]. Relocation of the stoma without mesh reinforcement – typically requiring a midline laparotomy – likewise has recurrence rates as high as 86% with the added risk of a midline incisional hernia or hernia at the previous stoma site, again as high as 52% [44, 45]. Additionally, ipsilateral and multiple re-siting procedures further potentiate these recurrences [44, 46]. These maneuvers should be reserved for patients in extremis or for sub-optimized patients presenting for urgent repair – typically for an associated bowel obstruction.

Onlay Mesh Repair

Using an incision at least 10 cm away from the stoma to avoid interactions with the appliance, an extraperitoneal dissection is achieved in the anterior rectus sheath, external oblique aponeurosis, hernia sac, and stoma circumferentially to allow for sufficient mesh overlap (5–10 cm) [12]. Next the hernia sac can either be excised or reduced. The fascial edges are then approximated with permanent suture, working toward the stoma to create a desired aperture of two finger breaths. Next uncoated polypropylene is placed in the onlay position and fixated with either suture or a skin stapler [47, 48]. If the stoma is left in situ, a keyhole slit can be made in the mesh and the tails secured around the bowel with permanent suture. If the stoma is mobilized from the skin and subcutaneous tissue, then a cruciate incision can be made in the mesh sufficient for the bowel caliber. Benefits are the avoidance of a laparotomy for high-risk patients with small- to medium-sized defects. Disadvantages are that concomitant incisional hernias will not be addressed and the raising of skin flaps poses potential wound ischemia and subcutaneous seroma formation, though most authors acknowledge this can be managed with the use of closed suction drains [49].

Using the aforementioned keyhole technique, Ho et al. report 1 recurrence (7%) in 15 patients over the span of 19 years with an average follow-up of 15 months [50]. De Ruiter et al. supplemented the onlay technique with a solid polypropylene ring reinforcement in 46 patients. While their 15% recurrence rate at 51 months appears favorable, 26% of patients ultimately required removal of the prosthetic – two for infection, five for recurrence, and five during another operation [51]. Steele and colleagues subsequently described another modification to the cruciate mesh repair – the "stove pipe hat" – in which an additional piece of polypropylene mesh is secured to the bowel circumferentially and then separately to a piece of onlay polypropylene. They reported a more modest 26% recurrence rate at 51 months. While 16% of patients had complications, only one patient developed a mesh erosion with this modification [52]. Pooled analysis by Hansson et al. in 2012 of these 3 trials and 3 other small series of onlay PSH repair culminates in 149 patients with at least 1-year follow-up (median 3 years) and an overall recurrence rate of 19%. Importantly, they also summarized rela-

Table 55.5 Onlay parastomal hernia repair: key reports

PP Polypropylene, * mean

tively low rates of surgical site infection (2%) and mesh infection (2.6%), tempering theoretical concerns regarding devascularized skin flaps [43]. Since that analysis, Warwick and colleagues have provided an important addition to the literature, describing the high failure rate of keyhole biologic mesh as a supplement for polypropylene in this setting. With a median follow-up of 3 years, 26/30 (90%) patients developed a recurrence, and the median time to that event was 10 months (Table 55.5) [53].

Open Intraperitoneal Mesh Repair

In the setting of an open PSH repair – following closure of the parastomal defect – intraperitoneal mesh with at least 5 cm of overlap can be placed in one of two orientations relative to the bowel leaving the peritoneal cavity. One is a keyhole or cruciate mesh reinforcement and like the onlay description depends on whether the bowel is left in situ or re-sited respectively [43]. Alternatively, Sugarbaker described lateralizing the bowel as it exits the peritoneal cavity, placing a mesh reinforcement directly over the hernia site and allowing the loop of intestine to drape between the abdominal wall and the prosthetic, creating a "valve" effect with increased abdominal pressure. Sugarbaker's initial description of seven patients resulted in no recurrences after an average of 5 years [54]. While the Sugarbaker technique allows for more of an interface between the exiting bowel and the prosthetic, raising concern for erosion, this alternative overcomes a limitation of cruciate and keyhole repairs that are subject to mesh shrinkage and enlargement of the orifice leaving these patients more prone to recurrence [55]. While some of the initial descriptions were with uncoated polypropylene, contemporary repairs utilize anti-adhesive/barrier-coated synthetic mesh or expanded polytetrafluoroethylene (ePTFE).

Five series exist for these repairs, none with more than 20 patients. Pooled analysis by Al Shakarchi and Williams totaled 65 patients with a 9% recurrence rate at a mean follow-up of 38 months, as well as a 3% surgical site infection rate and 1 report of mesh infection [56]. The largest single study consisted of 20 repairs with ePTFE in the Sugarbaker orientation, reporting a 15% recurrence rate with a mean follow-up of 42 months [55]. The keyhole repairs totaled a slightly lower recurrence rate (7%) but with less follow-up (median 28 months) (Table 55.6) [43].

Laparoscopic Intraperitoneal Mesh Repair

The paucity of literature on open intraperitoneal mesh repair is likely because of the rapid adoption of laparoscopic intraperitoneal mesh repair. The principles of repair are similar to an open approach with use of three or four trocars for peritoneal access, reduction of the hernia contents, optional closure of the parastomal defect, and placement/fixation of mesh in either the keyhole (Fig. 55.1) or Sugarbaker orientation (Fig. 55.2) [43]. When technically feasible, the benefits of most laparoscopic alternatives remain true for these repairs compared to their open counterparts in regard to reduced pain, morbidity, length of stay, and earlier return to work [57]. Given the need for 5 cm of fascial overlap in all directions, small- to medium-sized defects without a concomitant fascial defect are ideal candidates for a minimally invasive approach.

A meta-analysis by DeAsis et al. pooled 15 studies from 2005 to 2015 with at least 5 patients and a minimum 1-year follow-up. There was no difference in morbidity rates among techniques. Specifically, rates of surgical site infection (4%), infected mesh (1.7%), and obstruction requiring re-operation (1.7%) were relatively low. The overall recurrence rate was 17–10% for the 191 laparoscopic Sugarbaker repairs and 28% for the 231 laparoscopic keyhole repairs [58]. This comprehensive analysis would suggest that the laparoscopic Sugarbaker is the more durable repair compared to the keyhole technique (Table 55.7).

Open Retromuscular Repair and Abdominal Wall Reconstruction

While technically challenging, the versatility of open retromuscular repair with sublay mesh placement offers numerous benefits. When attempted, the surgeon should first consider whether a retrorectus dissection alone will suffice. This technique involves dissection of the posterior rectus sheath from the rectus muscle to the semilunar line bilater-

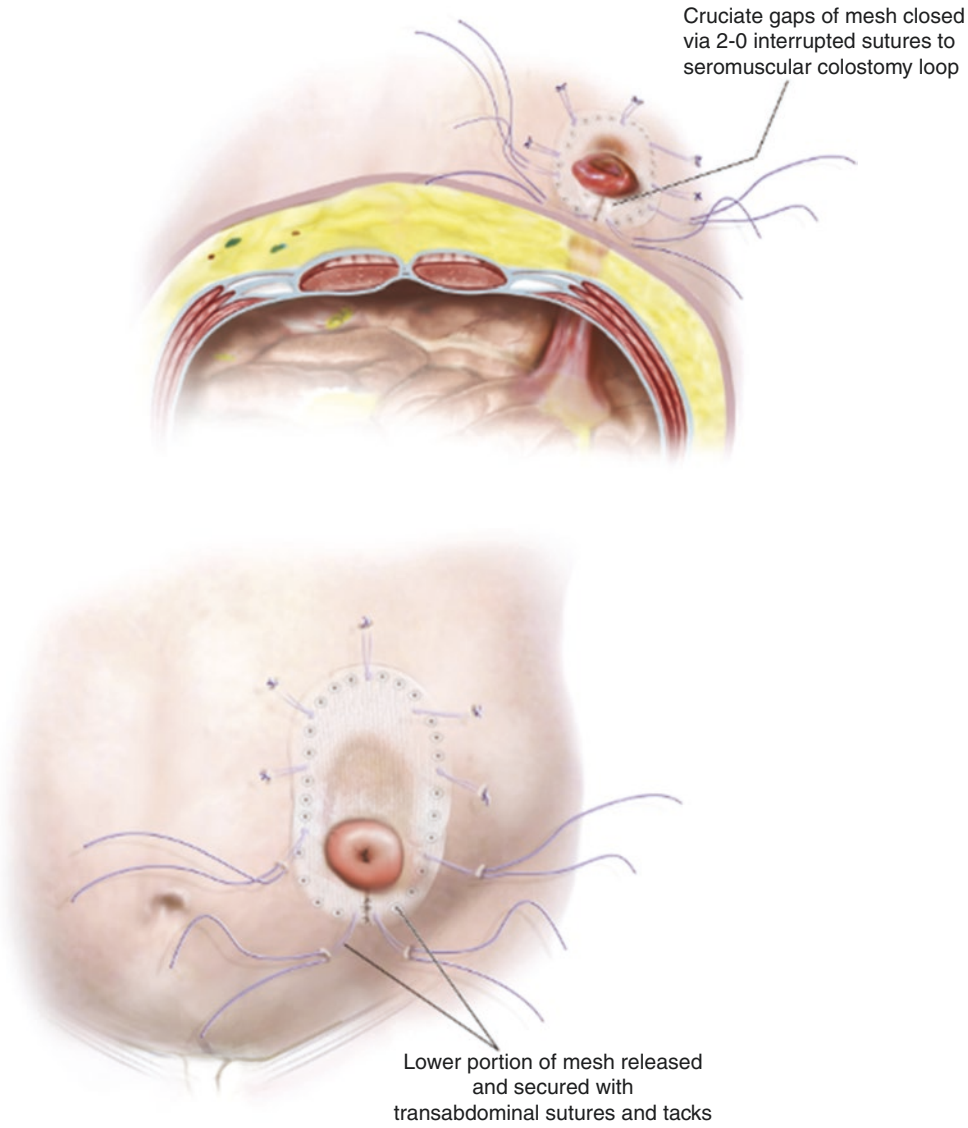

Fig. 55.1 Intraperitoneal mesh repair – keyhole (Reused with permission from Rosen [81]. Copyright © 2017 Elsevier)

ally. When possible, the stoma should be re-sited to the contralateral side before approximating the posterior rectus sheaths to isolate the viscera from the retrorectus pocket. Placement of mesh in the retrorectus position not only allows for prophylactic mesh reinforcement of the new stoma site, but mesh repair of the prior stoma site and reinforcement of the midline when necessary [27]. This technique is favorable when a concomitant midline defect is present or after several alternate methods have failed. It also allows for the usage of uncoated polypropylene, which is less expensive than its intraperitoneal barrier mesh alternatives. Early reports of retromuscular repair with polypropylene mesh have shown favorable results. The pooled analysis of 4 studies including 76 patients found an 8% recurrence rate with a mean follow-up of 24 months [56]. While they also report an overall infection rate of 4%, there were no mesh infections or reports of mesh excision (Table 55.8).

Often, a large parastomal defect or concomitant large midline defect makes re-approximation of the posterior rectus sheaths impossible after an isolated retrorectus dissection. Furthermore, with large lateral parastomal defects, a retrorectus dissection to the semilunar line will often not allow for sufficient mesh overlap to prevent a recurrence. It is in these cases where an abdominal wall reconstruction with a posterior component separation/transversus abdominis release (TAR) allows for several additional advantages. At the lateral extent of either retrorectus dissection, division of the transversus abdominis muscle just medial to the laterally perforating neurovascular bundles allows for extension of the retrorectus dissection to the lateral preperitoneal plane above the arcuate line. This preperitoneal plane can be matured bilaterally to the psoas muscles, cephalad to the central tendon of the diaphragm, and inferiorly to the space of Retzius. Liberation of the peritoneum from its surround-

Pauli	44	TAR/Sugarbaker	10	4.5%

ing attachments allows for a large visceral sac and even wider retromuscular pocket for prosthetic reinforcement with wide overlap in all directions. Again, a large mesh placement allows for reinforcement of the previous stoma site, midline, and stoma – which is typically brought through the mesh in a keyhole or cruciate orientation (Fig. 55.3).

Several cohorts exist of parastomal hernia repair with an abdominal wall reconstruction and keyhole/cruciate mesh reinforcement. Raigani et al. report our experience with 46 repairs using this technique, and we found a 46% surgical site infection rate but with only 1 re-operation for mesh erosion. At a mean follow-up of 13 months, five (11%) patients developed a recurrence, and three required repair. In a separate report of 46 retromuscular PSH repairs, Beffa et al. required the addition of a TAR in 2/3 of cases. Their overall surgical site infection rate was lower (17%) but increased dramatically (40%) when the stoma was re-sited. Their recurrence rate was 22% with a more meaningful follow-up

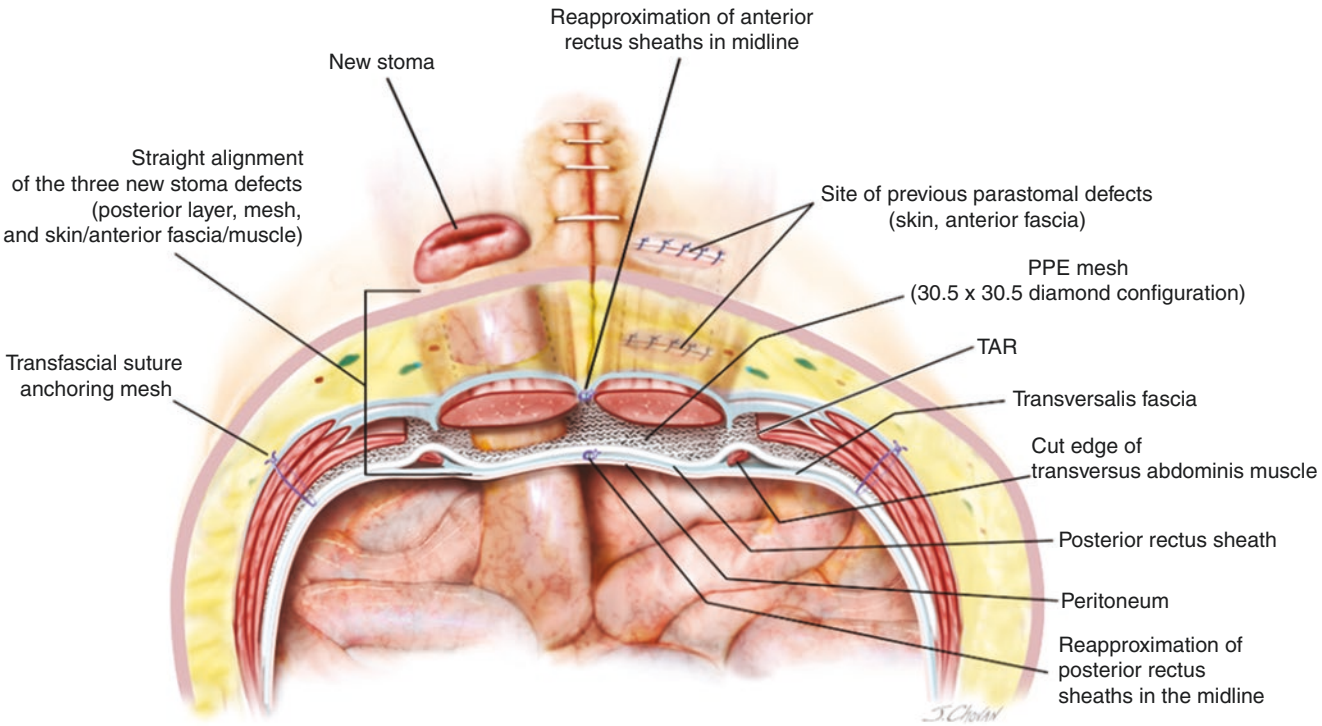

Fig. 55.3 Retromuscular mesh repair – keyhole (Copyright © 2017 Elsevier)

of 22 months [59]. Several descriptions of an adjunct to retromuscular keyhole mesh have also been described – both of which use a 28 mm EEA stapler to secure the retromuscular mesh to both the anterior and posterior rectus sheaths. The use of Stapled Transabdominal Ostomy Reinforcement with Retromuscular Mesh (STORRM) in 12 patients identified 2 (17%) recurrences with a mean follow-up of 13 months [60]. Likewise, a report of the Stapled Mesh stomA Reinforcement Technique (SMART) procedure identified four (18%) recurrences with a median follow-up of 21 months [61].

Recently, Pauli and colleagues reported their results of a novel technique for parastomal hernia repair at the 2018 International Hernia Congress with exciting early results. As was previously described, they utilized a bilateral transversus abdominis release and placement of a retromuscular mesh reinforcement. However, rather than bringing the stoma through a keyhole or cruciate defect in the mesh, it is draped over the mesh in the retromuscular space akin to a Sugarbaker repair (Fig. 55.4). Six surgeons reported their results of 44 patients with a mean follow-up of 10 months, and they currently have a 4.5% ($n = 2$) recurrence rate, with no reports of mesh erosion or stoma necrosis [62]. Our institution's experience with the technique was humbling, as early results demonstrated mesh erosion into the bowel in 3/38 (8%) patients [63]. We have since modified the technique to no longer fixate the mesh adjacent to the stoma and are currently enrolling patients in a randomized controlled trial of open retromuscular PSH repair with either keyhole/cruciate or Sugarbaker mesh reinforcement (NCT03972553).

Algorithm

Each of the abovementioned repairs has advantages and disadvantages and should be part of the armamentarium of the surgeon attempting to make PSH repair part of their routine practice. While there is certainly room for variability based on the surgeon's comfort level with each technique, we propose the following algorithm to utilize in surgical decision-making (Fig. 55.5).

Mesh Options

While a comprehensive discussion of mesh options is beyond the scope of this chapter, surgeons choosing from an ever-expanding menu of synthetic, biosynthetic, and biologic prosthetics should have a basic understanding of what evidence exists, particularly due to the cost implications. Despite the almost exclusive use of permanent synthetic mesh in the aforementioned studies with low rates of mesh-associated complications – findings supported by numerous randomized controlled trials of prophylactic mesh reinforcement of stomas – the use of synthetic mesh in contaminated

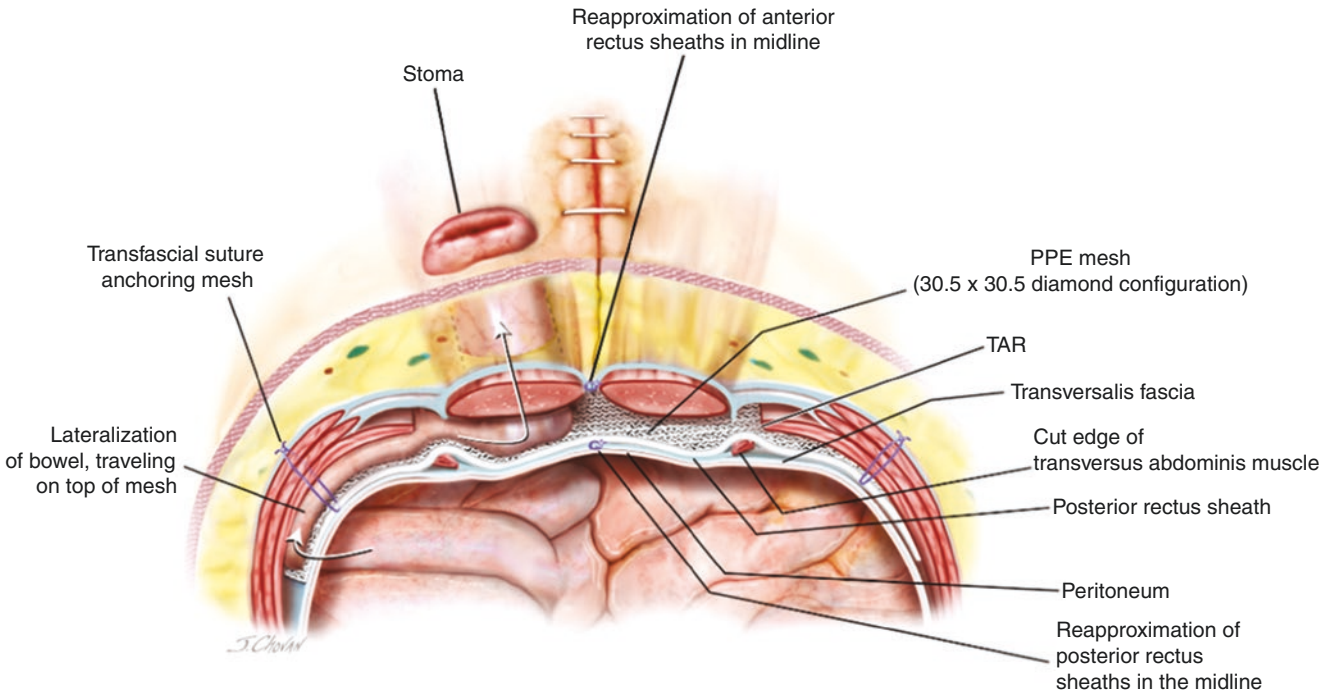

Fig. 55.4 Retromuscular mesh repair – Sugarbaker (Copyright © 2017 Elsevier)

fields remains a surgical faux pas, and use of non-synthetic alternatives remains commonplace [64–67]. Several factors have tempered the concern of using permanent mesh in these scenarios, and an understanding of these concepts can help to demystify why such an evolution in this thinking has occurred in the past 10 years. First, a contemporary understanding of favorable mesh characteristics has taught surgeons to avoid multifilament or barrier-coated meshes in contaminated settings, as animal studies have demonstrated that macroporous, monofilament, uncoated polypropylene is most resilient to a bacterial burden [68, 69]. This fact underscores the importance of minimizing contamination when using a barrier-coated mesh for intraperitoneal repairs and explains why uncoated polypropylene was the mesh of choice for prophylactic stoma reinforcement studies. Next, a better understanding of patient optimization techniques outlined earlier has narrowed the usage of synthetic mesh in contaminated fields to optimized patients in an elective setting (Centers for Disease Control and Prevention {CDC} wound classes II–III), as opposed to early reports of synthetic mesh in damage control laparotomies where staged mesh excision was essentially planned [70, 71]. Finally, popularization of retromuscular techniques including TAR has allowed for a large retromuscular pocket with well-vascularized tissue at each interface to accommodate the ideal polypropylene prosthetic without concern for interaction with the underlying viscera or exposure of the prosthetic to potential superficial wound morbidity [72]. So to summarize, usage of the right mesh, in the right myofasciocutaneous plane, and in the right patient, offers a much more thoughtful utilization of synthetic mesh in contaminated scenarios than what promulgated most of the negative conceptions among surgeons.

The largest series to date of synthetic mesh in contaminated fields was recently published by Warren et al. in 2020. They describe a complex group of 402 patients with a 30% active smoking history, moderate-sized defects (mean 9 cm), and significant levels of contamination (CDC II 53%, III 42%, IV 6%). With a median follow-up of 21 months, they were able to overcome a 14% surgical site infection rate with mesh excision in 2.4% of cases and recurrences in 10% [73]. Regarding biologic and biosynthetic alternatives, there actually only exist three prospective series in which any of these materials were studied and none had a control arm. The RICH study evaluated the effectiveness of porcine dermis collagen matrix in a very complex group of 80 patients with large hernias (mean width 16 cm) and a 9% rate of enterocutaneous fistula (ECF) takedown. While 19% of these patients had a bridged repair, they were able to overcome a 35% surgical site infection rate with no mesh excisions. At 2 years their recurrence rate was 28% [74]. The COBRA study evaluated the long-active resorbable mesh Bio-A (GORE®) in a group of patients with moderate-sized hernias (mean width 9 cm) but with high degrees of contamination (CDC II 23%, CDC III 77%). They overcame a surgical site infection rate of 18%, again with no

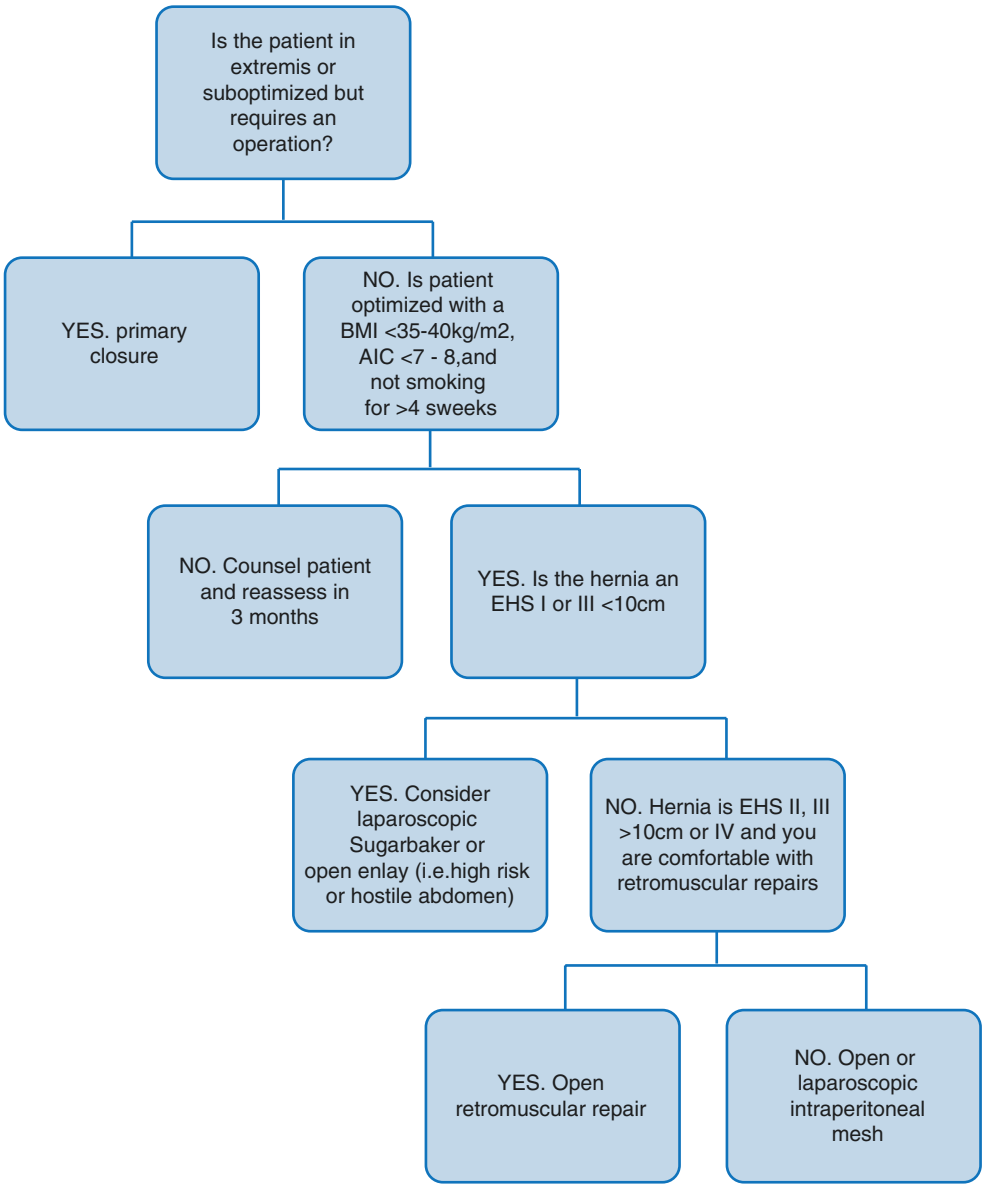

Fig. 55.5 Parastomal hernia surgical decision-making

mesh excisions, but ultimately had a recurrence rate of 17% at 2 years [75]. Finally, a study by Roth et al. evaluated poly-4-hydroxybutyrate mesh – another long-active resorbable mesh (Phasix – Bard) – in a relatively less complex cohort of comorbid patients with medium-sized defects in clean cases. They reported a 9% surgical site infection rate and no mesh excision, with a 9% recurrence rate at 18 months [76].

Taken together, the results summarized in Table 55.9 demonstrate that biologic and biosynthetic prosthetics appear to have rates of wound morbidity that correlate with long-term recurrence. That said, mesh excision is an exceedingly rare event for those patients. Alternatively, while synthetic mesh still allows for relatively acceptable wound morbidity and a seemingly durable repair with lower long-term recurrence, the tradeoff is a slightly higher risk of mesh excision.

Conclusion

Parastomal hernia repair is a humbling endeavor with little evidence-based guidance. Surgeons should make every effort to optimize their patients preoperatively and familiarize themselves with the repair techniques that have a place in the operative armamentarium. While advanced abdominal wall reconstruction techniques utilizing a posterior component separation have promising results and are growing in popularity, open onlay, as well as both open and laparoscopic use of intraperitoneal mesh, also has very reasonable results and should not be dismissed.

Part V

Pelvic Floor Disorders

Functional Disorders After Colorectal Surgery/IBS

56

Hiroko Kunitake and Kyle Staller

Key Concepts

- Irritable bowel syndrome (IBS) is defined by the Rome IV criteria and divided into three subtypes (diarrhea-predominant (IBS-D); constipation-predominant (IBS-C); mixed bowel habits (IBS-M)) defined by stool form. The diagnosis is one of exclusion.
- Surgery for IBS is not indicated, but patients with IBS frequently have undergone one or more surgical procedures in an attempt to alleviate chronic pain.
- Treatment of IBS depends on the subtype.
- There are three subtypes of chronic anal pain defined by Rome IV criteria: levator ani syndrome, unspecified functional anorectal pain, and proctalgia fugax. These subtypes are distinguished by differences in the duration of pain and the presence or absence of anorectal tenderness.
- Coccygodynia is defined as pain or discomfort at or around the coccyx and may be related to trauma, but also an idiopathic variant exists.
- Pudendal neuralgia produces knifelike pain in the anus, vagina, or perineum. It is felt to be produced from pudendal nerve entrapment in Alcock's canal or in the infrapiriformis canal.

Definitions

Despite being one of the most commonly diagnosed digestive illnesses worldwide, irritable bowel syndrome (IBS) remains a diagnostic and therapeutic dilemma for many clinicians. The high prevalence estimates for IBS are based on formal criteria alone, but IBS is invoked commonly by many medical providers even when a patient does not meet simple, symptom-based criteria. Some of the confusion arises in the absence of reliable biomarkers for what is undoubtedly a heterogeneous disease process, encompassing many pathophysiologic mechanisms [1]. Therefore, we depend on symptom-based criteria which are useful but only modestly differentiates IBS from organic disease. [2] Further confusion arises with the continued updating of the symptom-based criteria as our understanding of the disease improves. The most recent iteration is the Rome IV criteria. IBS is currently defined as recurrent abdominal pain occurring at least weekly in the last 3 months associated with ≥2 of the following: (1) relationship to defecation, (2) change in frequency of stooling, and/or (3) change in stool form. These criteria must be fulfilled for the previous 3 months with onset at least 6 months prior (Fig. 56.1) [3]. Previous definitions have included abdominal pain or discomfort and *improvement* with defecation, but fundamentally IBS remains a disease of abdominal pain and altered bowel habits.

IBS subtypes (diarrhea-predominant (IBS-D); constipation-predominant (IBS-C); mixed bowel habits (IBS-M)) are defined by stool form (Fig. 56.2). More than 25% of bowel movements with loose stools (Bristol types 6 or 7) or hard, lumpy stools (Bristol types 1 and 2) define IBS-D and IBS-C, respectively, while >25% of bowel movements with both stool forms defines IBS-M [3] . Beyond mere classification purposes, the Bristol stool form is a useful surrogate for colonic transit time [4] that can help guide treatment selection to augment or slow down colonic motility.

Diagnosis and Clinical Workup

Even with the limitations of the symptom-based Rome criteria, a diagnosis of IBS is associated with a specificity and positive predictive value as high as 100% in the absence of red flag symptoms [5]. Nevertheless, many feel that the cur-

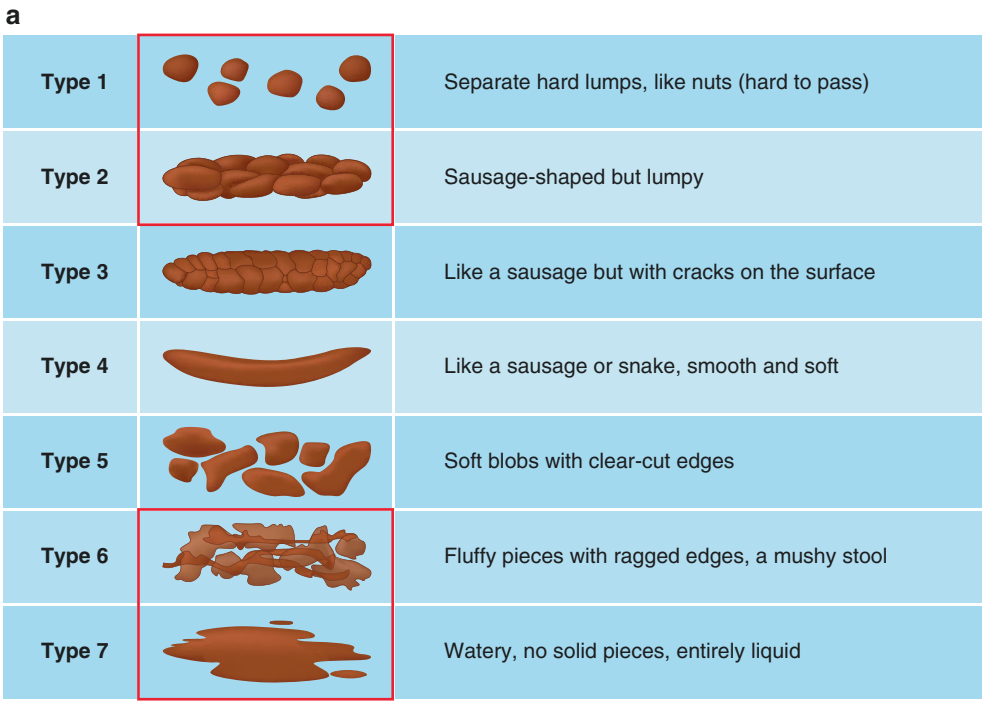

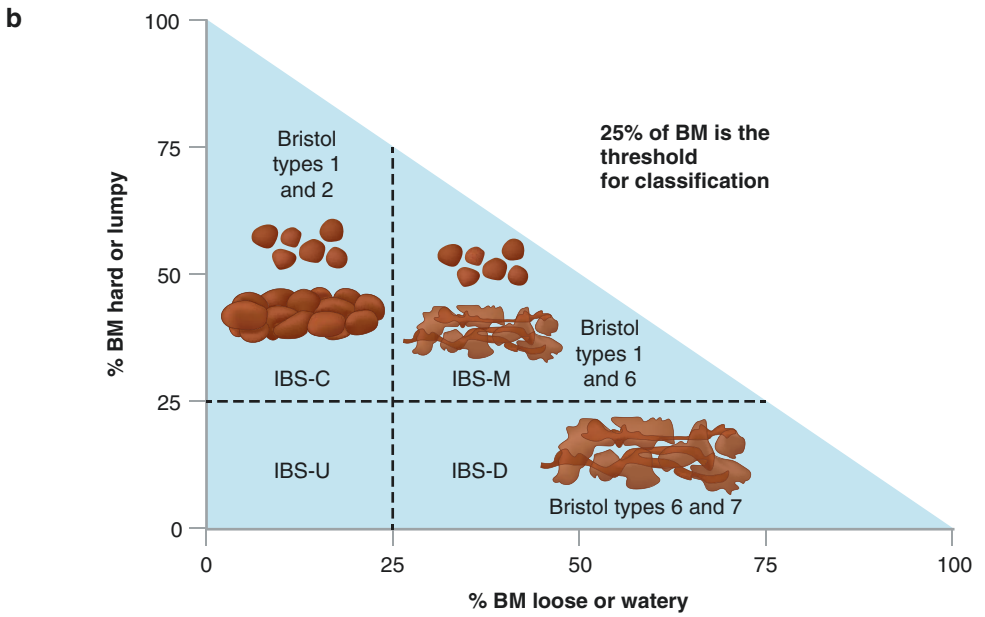

Fig. 56.2 (**a**, **b**) IBS subtype definitions according to stool consistency

rent symptom-based criteria continues to be inadequate for many patients, who ultimately get a positive diagnosis a mean of 6.6 years after the onset of symptoms [6]. Red flags either suggestive of another diagnosis or meriting further diagnostic workup include an abnormal exam, recent antibiotic use, documented weight loss, nocturnal symptoms, bloody stools, or family history of colon cancer. Most analysis suggest that patients with IBS are no more likely than controls to have organic GI disease on symptom criteria alone [7, 8]. All patients will nonetheless benefit from a limited workup guided by the results of a careful history and physical exam in order to avoid unnecessary diagnostic testing and its attendant risks [9].

The diagnostic workup is best understood by IBS subtypes (Fig. 56.3). The differential diagnosis for patients with IBS-D is the broadest, though historical pearls can be helpful. For most alternative diagnoses causing diarrhea, the likelihood of an entity other than IBS is low, with controversy as to whether these diseases have increased prevalence in the IBS population. The most widely accepted workup includes celiac serologies using a tissue transglutaminase (TTG) IgA with an IgA level, C-reactive protein (CRP), and ideally a fecal calprotectin level [10]. Testing for *Giardia* and bile acid diarrhea (where available) should be considered as well [11]. Patients with IBS-M generally undergo the same workup as those with IBS-D.

Two diagnostic entities that deserve special mention include bile acid diarrhea and microscopic colitis. Bile acid diarrhea either due to ileal resection or more commonly malabsorption in an anatomically normal small bowel is increasingly recognized as a cause of diarrhea in patients that would otherwise be labeled as IBS-D (up to 28.1%) [12]. Testing remains difficult with reliance on measurement of fasting serum C4, 48-hour stool collection, or the gold standard—the SeCHAT nuclear medicine test—limited to certain countries and academic centers currently [13]. Empiric use of bile acid sequestrant medications continues to be the most common diagnostic and therapeutic test used in everyday practice. However, tolerance of these drugs is poor due to palatability, and dose titration is often required to reach therapeutic levels [14].

Microscopic colitis is a frequent cause of diarrhea overlooked frequently by nongastroenterologists, presenting as watery diarrhea in older patients with a female predominance. As its name implies, the mucosa of the colon appears endoscopically normal, and biopsies are required for diagnosis [15]. The yield of colonoscopy for diagnosing microscopic colitis in patients with IBS is thought to be slightly higher than controls (2.3%) among patients ≥45 years old [16]. This suggests that diagnostic colonoscopy in the older IBS-D population, especially women, should be a consideration.

The approach to IBS-C is much more straightforward, in that the possible alternative diagnoses are limited. Therefore, testing may be used to better define the physiology of constipation.

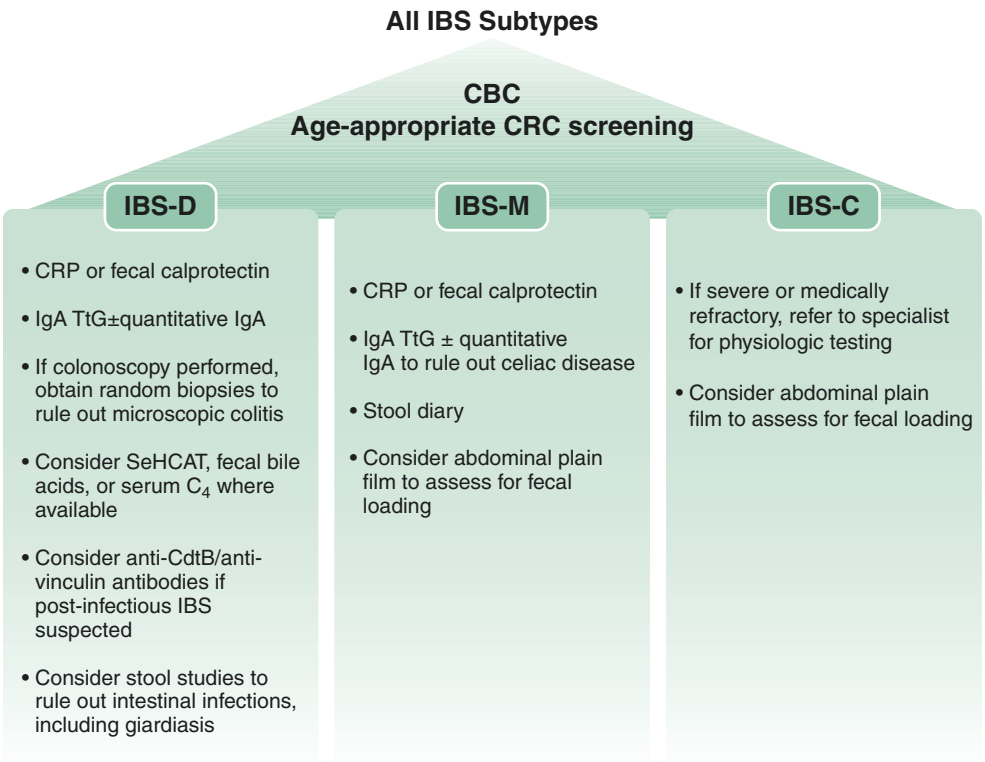

Fig. 56.3 Medical workup for IBS symptoms according to subtype: CRC colorectal cancer, CBC complete blood count, TTG tissue transglutaminase IgA antibody, SeHCAT 23-seleno-25-homotaurocholic acid, selenium homocholic acid taurine, or tauroselcholic acid, C4 serum 7α-hydroxy-4-cholesten-3--one

IBS and the Relationship to Surgery

Although surgery has no role in the treatment of IBS, patients with IBS are much more likely to undergo surgical procedures including cholecystectomy, [17–19] hysterectomy [17, 18], and appendectomy [17]. In many cases, these procedures represent preoperative misdiagnoses in an attempt to search for the etiology of chronic pain symptoms [20]. Extensive workups for an organic disease that an IBS diagnosis may mimic are essential. Because severe IBS can severely impact a patients' quality of life, they frequently call or are seen in their primary care doctor's office, go to the emergency room, or are referred to other specialty caregivers. Their ongoing complaints lead to further testing that can culminate in frequently unnecessary surgical procedures [20].

Colorectal surgical diagnosis is not immune to this phenomenon with diverticular disease, the prototypical example. Diverticulitis leads to acute abdominal pain with associated imaging findings. The associated inflammation can sensitize vulnerable visceral afferent nerves of the affected section of colon through damage followed by regrowth and altered function with resultant hypersensitivity to normal stimuli [21]. Low-grade inflammation can persist in many patients with diverticulosis [22] and is thought to be associated with symptomatic uncomplicated diverticular disease (SUDD). SUDD is a controversial entity that may not be entirely separate from IBS [23]. It is characterized by recurrent abdominal symptoms frequently associated with loose stools in the presence of localized diverticular disease [22, 24]. Like IBS, SUDD is associated with increased somatization [25]. Due to its association with diverticular disease, SUDD skews toward an older population [26].

Patients with functional complaints similar to IBS prior to an elective resection for diverticular disease are less likely to have satisfactory outcomes such as relief of abdominal pain or normalization of altered bowel habits [27]. Persistent symptoms after sigmoid resection for diverticulitis are present in up to 25% of patients, and these symptoms closely mirror those of IBS despite the presence of inflammation in resected specimens [28]. Alternatively, surgery may be a precipitating factor for IBS, with new IBS symptoms found to occur in a significant number of patients after abdominal surgeries [29–31]. A possible mechanism is surgical alteration of gastrointestinal function producing symptomatic IBS in susceptible individuals [18].

IBS Treatment Approach

Assigning a diagnosis of IBS can be unsatisfying for the patient and provider since the disease is mostly a diagnosis of exclusion without a lab or radiology test that is characteristic for this problem. Instead, patients should be reassured about the benign natural history of the disease, and focus should be directed toward symptom-directed treatments [3]. Taking the time to explain the rationale behind the treatment approach can pay long-lasting dividends with a therapeutic patient-provider relationship, an independent predictor of improvement in health status [32]. Many IBS patients come to clinical visits with preexisting negative experiences from previous providers and seek someone to listen, support, and provide hope in addition to comprehensive information about their disease and answers to their questions [33]. Education and reassurance provide the foundation for much of effective IBS treatment with pharmacotherapy, psychological treatments, and multidisciplinary care added in a graded approach for those with more moderate or severe symptoms (Fig. 56.4) [34].

Conservative measures benefit many patients with mild symptoms, and these interventions tend to be agnostic to

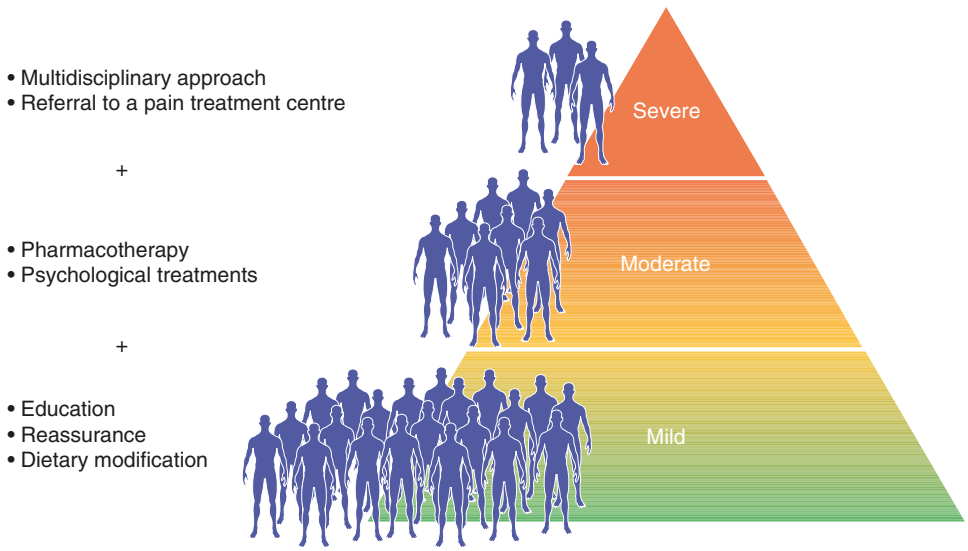

Fig. 56.4 Graduated treatment approach to IBS

IBS subtype, which is particularly useful among patients with mixed bowel habits (IBS-M). Exercise is associated with mild improvements in symptom severity and is associated with overall maintenance of physical and mental health [35]. Probiotics similarly provide a mild benefit for IBS symptoms, though the quality of supporting evidence is quite low. Individual probiotic preparations vary substantially in preparation, strain, and dose—making firm recommendations difficult. Moreover, the more rigorous studies have shown modest treatment effects, [36] with the highest-quality studies demonstrating benefit with *Bifidobacterium infantis* [10]. Peppermint oil also provides a modest benefit in IBS, [37] though a recent well-done randomized trial demonstrated no benefit to either small intestinal- or colonic-release peppermint oil formulations when subjected to rigorous European Medicines Agency (EMA) or US Food and Drug Administration IBS endpoints [38]. Peppermint oil likely acts as an antispasmodic, of which there are several pharmacologic varieties available with limited evidence suggesting a benefit compared to placebo in improving IBS symptoms [35]. The authors prefer to use antispasmodics as either on-demand or as prophylactic agents rather than as a regularly scheduled medication. Such dosing allows for patients to use these agents in response to abdominal pain or cramping or in anticipation of events where abdominal pain and/or cramping would be especially inconvenient (i.e., before meals at a restaurant, for car rides, while using public transportation).

Fiber

Fiber has been a mainstay recommendation for IBS treatment for years and is associated with global improvement in IBS symptoms [39]. Although the reasons for its benefits in IBS are poorly understood, fiber can serve as a bulking agent and a substrate for colonic fermentation and production of beneficial short-chain fatty acids that affect colonic motility and sensation [40]. Fiber should not be thought of as monolithic. Insoluble fibers are generally thought to increase stool bulk and water-holding capacity. Soluble fibers are generally associated with higher fermentability—serving to produce byproducts such as short-chain fatty acids and gas [41]. Soluble fiber (psyllium, ispaghula, calcium polycarbophil) has consistently shown greater benefit in IBS than insoluble fiber (corn, wheat, bran) [39, 41, 42]. Overall, psyllium is the most evidence-supported fiber supplement in IBS, providing both laxation effect and fermentation with some risk of increased gas/flatus [43]. However, patients with IBS-C who suffer from bloating primarily may not tolerate any gas formation and would be better served by insoluble, non-fermentable agents such as cellulose or methylcellulose. Thus, knowing the solubility and fermentability of various fiber supplements can allow personalization based on the predominant IBS symptoms.

Dietary Treatments

Dietary treatments for IBS have emerged as important tool in the arsenal of weapons against the symptoms of IBS. Their growing popularity can be explained by the following: (1) 60–70% of IBS patients' symptoms are worsened by meals, (2) more than 70% of IBS patients believe that food causes their symptoms, [40] and (3) up to 90% of IBS patients exclude or avoid certain foods to prevent or minimize GI symptoms [44]. True food allergies are not more prevalent in IBS patients compared to the overall population, but food intolerances are common and are unrelated to the IBS subtype [40].

Lactase deficiency occurs in approximately 30% of Caucasians and 70% of Asians and deserves special discussion. Most individuals worldwide will develop lactase non-persistence which is a decrease of intestinal lactase expression in the first two decades of life leading to lactose malabsorption and GI symptoms over time. The risk of symptoms in response to lactose ingestion in those with lactase deficiency is thought to be increased in IBS patients [45].

Our understanding of dietary treatment for IBS has evolved over time with earlier literature focusing on a population of patients developing worsening of IBS symptoms in response to ingestion of wheat in the absence of celiac disease or allergy. Among IBS patients without celiac disease, a double-blind, placebo-controlled dietary study demonstrated worsening of symptoms with blinded reintroduction of gluten to the diet [46]. The field has since shifted to embrace the use of a diet low in fermentable oligosaccharides, disaccharides, monosaccharides, and polyols (FODMAPs). These are carbohydrates that are poorly or partially absorbed in the small intestine resulting in an increased osmotic load (water is drawn into the intestinal lumen) and excess bacterial fermentation in the colon [47]—all leading to symptoms in IBS patients but not normal controls. Wheat is just one of the many FODMAPs, and the relationship between wheat ingestion and a low-FODMAP diet is well demonstrated by another dietary intervention trial from the same research group [48]. Patients with self-reported non-celiac wheat sensitivity and IBS were given a 2-week low-FODMAP diet with improvement in all GI symptoms before being randomly assigned a no-gluten, low-gluten, or high-gluten diet. In all cases, symptoms worsened in patients no longer on the low-FODMAP diet despite exclusion of gluten in some groups.

In principle the low-FODMAP diet has broad appeal, but execution and adherence is difficult. The initial phase of the diet requires elimination of many types of food followed by

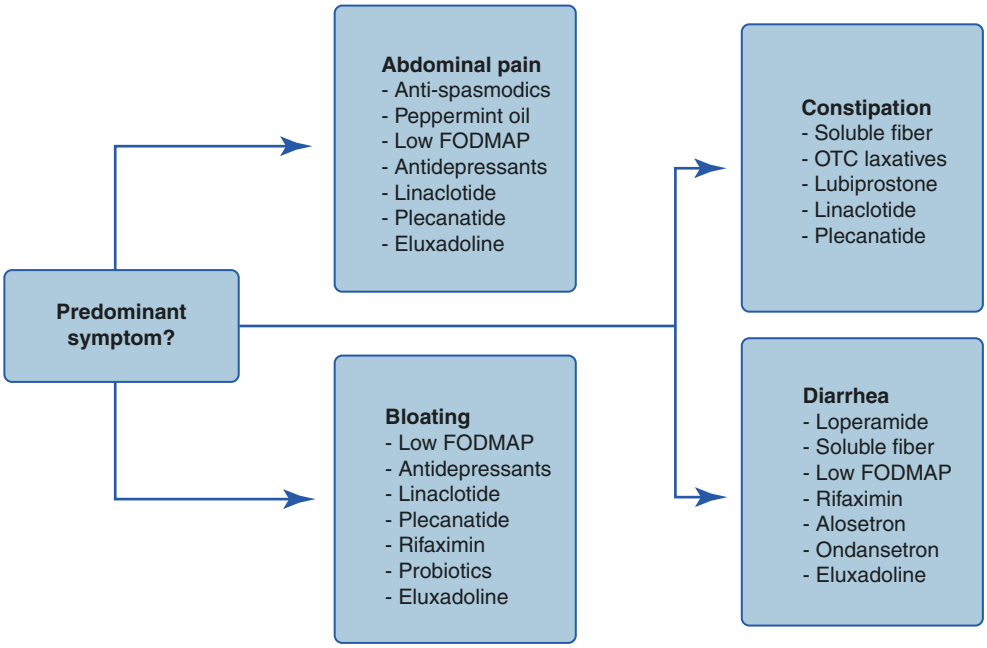

Fig. 56.5 Matching pharmacotherapy choice to predominant symptom complaint

systematic reintroduction of the eliminated foods to test which classes of foods cause symptoms. Because of its complexity, nutritional consultation and management is key but limited by availability of trained practitioners and payment issues. The "FODMAP-gentle" diet is an alternative bottom-up approach that limits the dietary restriction to some of the highest-yielding foods and may be more practical for many patients to follow [49].

Most FDA- or EMA-approved treatments for IBS target symptoms related to the predominant IBS subtype or symptom (Fig. 56.5). Several over-the-counter agents similarly have isolated use in IBS-D or IBS-C. Newer arrivals to the market have been subjected to clinical trials utilizing rigorous IBS-specific endpoints so that the quality of evidence is higher for these agents. Older agents are frequently used successfully but robust data is lacking. A strong placebo effect has been noted in trials examining functional GI disorders like IBS, with response to an active treatment over placebo often around 10%.

IBS-D Treatments

Loperamide is a synthetic mu-opioid receptor agonist with specificity for peripheral receptors to decrease colonic transit allowing increased water absorption in the colon. Many IBS-D patients will use over-the-counter loperamide prior to seeking care for their symptoms. While there it appears that loperamide can improve urgency and stool consistency, [3] its effect on global symptoms and pain is less well established [35]. The authors do find loperamide useful as an adjunctive agent in IBS-D, primarily given as prophylaxis for patients who know they will be in situations with limited bathroom access but rarely as monotherapy for those with consistent, bothersome symptoms.

Because of the increasing recognition of bile acid diarrhea as a driver of IBS-D symptoms, bile acid sequestrants can play an important role in the treatment of these patients when bile acid malabsorption is present. Cholestyramine is the usual first choice treatment given its presumed efficacy and ability to be easily titrated. Its use is heavily limited by poor palatability and GI side effects. More data is available in the form of small pilot studies for the newer agents colesevelam and colestipol, which are better tolerated but also more expensive [50]. In our practice, we often start with cholestyramine to demonstrate proof of principle with aggressive uptitration in dosing should a noticeable but inadequate effect be seen. Once the presence of bile acid diarrhea and response to treatment is established with cholestyramine, we often switch over to the newer agents for long-term treatment.

Rifaximin is a minimally absorbable, gut-specific antibiotic approved for treatment of IBS-D as a 14-day course. Initially, large trials demonstrated an approximate 10% improvement in adequate relief of global IBS symptoms over placebo with minimal adverse effects and no discernable increased risk of *Clostridium difficile* infection or emergence of bacterial resistance [10]. A more recent study evaluating multiple treatment courses of rifaximin demonstrated similar improvement rates over placebo that were sustained with retreatment after reemergence of symptoms. This has led rifaximin to currently be approved in the USA for up to three treatments [51].

Eluxadoline is a combined mu- and kappa-opioid agonist and delta-opioid antagonist approved in the USA for treat-

ment of IBS-D. In two large, phase 3 trials, eluxadoline conferred a clinical benefit over placebo using the FDA and EMA IBS endpoints [52]. Initial clinical experience demonstrated that the medication is overall well tolerated, but severe pancreatitis and Sphincter of Oddi dysfunction has occurred primarily in patients without a gallbladder. Alosetron is a 5-HT_3 antagonist approved in the USA for women with refractory IBS-D, demonstrated to reduce abdominal pain, discomfort, stool frequency, and urgency [10]. Like eluxadoline, its early use was concerning due to reports of severe constipation and ischemic colitis; however, these concerns have been mitigated with a lower initial starting dose and by limiting use to women with severe IBS-D with inadequate response to conventional therapy. Ondansetron and ramosetron are other 5-HT_3 antagonists with efficacy in IBS-D, though traditionally used off-label (ondansetron) or with limited geographic distribution (ramosetron) for this purpose. A recent meta-analysis found ramosetron and alosetron to be more effective than rifaximin and eluxadoline in patients with IBS-D and IBS-M [53].

IBS-C Treatments

IBS-C lies on a spectrum with functional constipation in that both entities are frequently associated with constipation symptoms: hard or lumpy stools, straining during defecation, a sense of incomplete evacuation, fewer than three bowel movements per week, a sense of anorectal blockage, and manual maneuvers to facilitate defecation [3]. For patients with mild to moderate symptoms, the distinction between functional constipation and IBS-C may be academic, as first-line therapy for both includes fiber (20–30 g/day) supplementation. Over-the-counter laxatives are frequently employed as well with polyethylene glycol (PEG), the most common choice. Constipation symptoms typically improve with fiber and/or PEG. However, IBS-C crucially requires abdominal pain in addition to bowel symptoms, and the importance of pain control is likely to be more important in patients with moderate to severe symptoms. In the limited literature for use of PEG in IBS-C, this agent was found to be more effective than placebo for constipation symptoms (i.e., bowel movement frequency, straining, and stool consistency), but there was no improvement in abdominal pain [54].

Since 2006, several new prescription laxative agents have been introduced onto the market with indications for both IBS-C and functional constipation. In most cases, these agents have been rigorously studied in placebo-controlled clinical trials using FDA- and EMA-mandated endpoints incorporating improvements in both stool consistency and abdominal pain. The three "secretagogues" vary in their exact mechanism of action but share an ability to drive net chloride secretion into the GI tract with water following. Lubiprostone dosed at 8 μg bid, linaclotide dosed at 290 μg daily, and plecanatide dosed at 3 mg daily all demonstrated improvement in global IBS symptoms and were all well tolerated. Diarrhea is the most commonly reported adverse event with all of these agents, [35] but lubiprostone is known to be associated with nausea as well [55]. None of these agents have been compared in a head-to-head fashion, and a recent meta-analysis suggests similar efficacy [56]. Our own experience is that there is individual patient variation as to which agent works best, but this does not occur with any discernible pattern. Thus, the decision on which agent to use is frequently dictated by payer coverage and regional availability.

Treating Abdominal Pain with Neuromodulation

IBS likely lies on a pathophysiologic spectrum with chronic abdominal pain, which is now most properly called centrally mediated abdominal pain syndrome (CAPS). CAPS is associated with frequent, almost continuous abdominal pain in the absence of changes in bowel habits—distinguishing this entity from IBS [57]. Chronic pain is a central feature of moderate to severe IBS, generally mediated by visceral hypersensitivity. With chronic stimulation, peripheral gut sensory nerves become increasingly sensitized to normal stimuli. Peripheral sensitization may progress to sensitization of central pathways, which is more common in the setting of comorbid emotional distress or a history of trauma. Thus, these patients are faced with an imbalance of amplified peripheral gut pain sensations and reduced central pain inhibitory mechanisms. Stress amplifies this maladaptive central pain response, a likely explanation for the frequent association between stress and IBS symptom exacerbations [58]. For IBS patients at the more severe end of the spectrum, central nervous system pain dysregulation likely plays a greater role in symptom generation—accompanied by shifting demographics and a greater degree of somatic symptoms (Table 56.1).

Neuromodulators are an underutilized tool in the treatment of IBS and have a well-developed rationale for their use: (1) downregulation of incoming visceral pain signals in the central nervous system, (2) reduction of maladaptive psychological processes (catastrophization, hypervigilance, anxiety), (3) treatment of comorbid psychiatric illness, (4) harnessing of ability to accelerate or slow GI transit, and (5) ability to treat frequent concomitant GI symptoms such as nausea and dyspepsia [60]. We frequently use these agents as monotherapy, in combination with peripheral motility agents (as outlined above for IBS-D and IBS-C) or in combination with behavioral therapies (Fig. 56.6).

Table 56.1 Spectrum of IBS disease severity and associations with predominant pathophysiology and patient characteristics

Clinical feature	Mild (40%)	Moderate (35%)	Severe (25%)
Physiological factors	Primarily bowel dysfunction	Bowel dysfunction and CNS pain dysregulation	Primarily CNS pain dysregulation
Psychosocial	None or mild psychosocial distress	Moderate psychosocial distress	Severe-high psychosocial distress, catastrophizing, abuse history
Sex	Men = women	Women > men	Women >>> men
Age	Older > younger	Older = younger	Younger > older
Abdominal pain	Mild/intermittent	Moderate, frequent	Severe/very frequent or constant
Number of other symptoms	Low (1–3)	Medium (4–6)	High (≥7)
Health-related quality of life	Good	Fair	Poor
Healthcare use	0–1/y	2–4/y	≥5/y
Activity restriction	Occasional (0–15 days)	More often (15–50 days)	Frequent/constant (>50 days)
Work disability	<5%	6%–10%	≥11%

Adapted from Drossman [59]

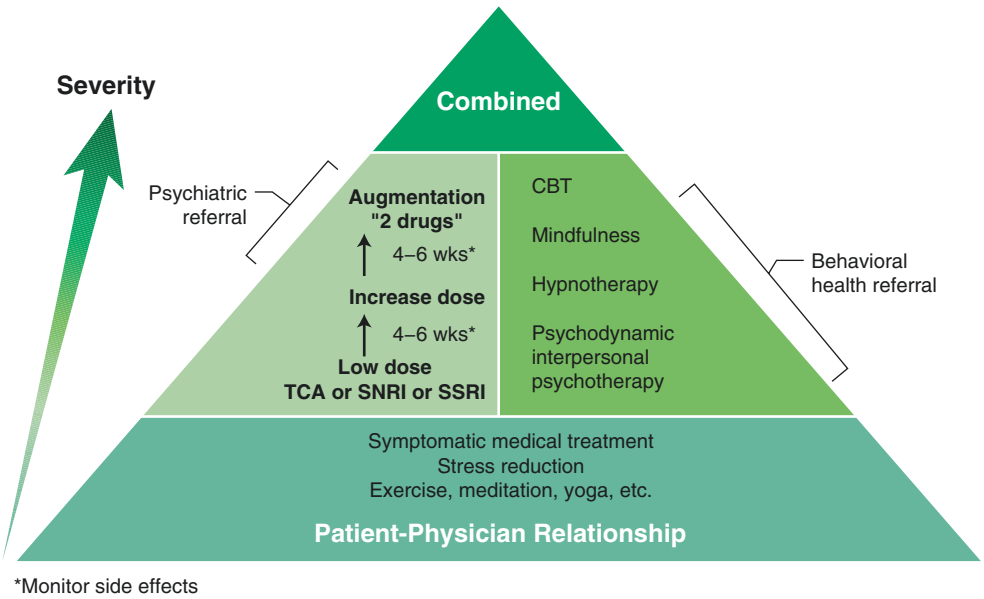

Fig. 56.6 Graduated treatment approach to addressing disordered brain-gut interaction in IBS

We approach neuromodulator agent selection based on the predominant IBS bowel habit (Table 56.2). For those with IBS-D, we favor tricyclic antidepressants (TCAs)—the most effective agents for the treatment of pain [57]. They are used at low doses well below the doses used for treatment of psychiatric disease and thus without the well-known side effects seen at those higher doses. Anticholinergic side effects are responsible for some of the benefit in patients with diarrhea, and we find significant improvements in patients' perception of urgency as well. The mantra of "start low and go slow" is key: using the lowest possible dose of the best tolerated agent. Although the tertiary amine amitriptyline (and to some extent imipramine) is the most well-known TCA for IBS, we prefer the secondary amines, nortriptyline and desipramine, which are much better tolerated with fewer anticholinergic side effects [60]. Patients are encouraged to take the TCAs for at least 2 weeks, as any anticholinergic side effects will wane over time.

Selective serotonin receptor inhibitors (SSRIs) are frequently used in IBS patients, though their ability to treat pain is diminished compared to TCAs [58]. We find these agents are more useful as an adjunct to the TCAs in patients with comorbid anxiety and depression than as a primary treatment agent for IBS. The selective serotonin and norepinephrine reuptake inhibitors (SNRIs), which we employ frequently for patients with IBS-C or IBS-M, are less likely to slow GI transit than the TCAs. Most of the evidence for their use is derived from other chronic pain conditions such as fibromyalgia. Duloxetine and milnacipran are favored over venlafaxine because the latter requires higher doses to achieve noradrenergic effects (useful for pain) and is more commonly associated with nausea and withdrawal side effects [60]. We also use the α2δ ligands gabapentin and pregabalin in both IBS-C and IBS-M, with the latter agent demonstrating some benefit in a recent small randomized, clinical trial [61].

Table 56.2 Neuromodulator/antidepressant treatment options in IBS and centrally mediated abdominal pain syndrome

	Tricyclic antidepressants	Selective serotonin reuptake inhibitors	Serotonin-norepinephrine reuptake inhibitors
Treatment targets	Pain, depression	Pain, depression, panic, anxiety, obsessive compulsive disorder	Pain, depression
Adverse events	Sedation, hypotension, constipation, dry mouth/eyes, arrhythmias, weight gain, sex dysfunction	Insomnia, agitation, diarrhea, night sweats, headache, weight loss, sex dysfunction	Nausea, agitation, dizziness, sleep disturbance, fatigue, liver dysfunction
Risk from overdose	Moderate	Low	Minimal
Dose adjustment	Yes	Not usual	Not usual

Adapted from Keefer et al. [57]

Psychological interventions have a clear role in the treatment of IBS symptoms either as monotherapy or in combination with neuromodulators. There is increasing evidence for cognitive behavioral therapy, relaxation therapy, hypnotherapy, and multicomponent psychological therapy in IBS, though connecting patients with these interventions is limited by the lack of psychological providers experienced in treating IBS and the time intensiveness of these modalities [35].

Chronic Pelvic Pain

Chronic pelvic pain is usually described as lower abdominal pain that has lasted ≥6 months and is unrelated to pregnancy. Chronic pelvic pain syndromes affect up to 11% of the population and are associated with a multitude of factors, both physiologic and psychological, which can make caring for these patients challenging [59]. This section will address the diagnosis, evaluation, and treatment of the following types of pelvic pain disorders: IBS-associated pelvic pain, functional anorectal pain, coccygodynia, and pudendal neuralgia.

IBS and Pelvic Pain

Although IBS is primarily associated with abdominal pain, there is also a strong association between IBS and chronic pelvic pain. IBS symptoms are reported by up to 40% of women with chronic pelvic pain and these two disease entities are similar in terms of symptoms, psychosocial factors, and healthcare utilization [62–64]. A study of 987 women attending a pelvic pain clinic investigated the overlap of IBS and chronic pelvic pain and found that muscular back pain, age > 40, depression, 6 to 8 pain sites, higher symptomatic distress scores (Symptom Checklist-90 Global Score), and a history of adult physical abuse were associated with an IBS diagnosis among chronic pelvic pain patients [63].

For IBS patients, chronic pelvic pain is treated with neuromodulators, similar to the aforementioned treatment of chronic abdominal pain. The selection of neuromodulators is based on minimizing their diarrhea or constipation symptoms. Tricyclic antidepressants are used in IBS-D, and selective serotonin reuptake inhibitors and norepinephrine reuptake inhibitors are favored in IBS-C or IBS-M.

Pelvic floor dyssynergia symptoms including strain and incomplete emptying are also prevalent in IBS patients and likely contribute to chronic pelvic pain. It should be noted, however, that these same symptoms can be seen among many patients with chronic constipation who do not have evidence of pelvic floor dysfunction. We perform anorectal manometry testing on any patient in whom pelvic floor dyssynergia is suspected. In a study of female non-IBS-D patients, over 50% experienced anal pain which was correlated with abnormal anorectal physiology including absent relaxation or paradoxical contraction on strain (91%), inadequate straining rectal pressure (53%), and prolonged balloon expulsion time (47%) [65]. Biofeedback therapy is a suggested treatment approach for these IBS patients with pelvic floor dyssynergia in addition to the use of neuromodulators.

Functional Anorectal Pain

The Rome IV criteria describes three subtypes of functional anorectal pain: (1) levator ani syndrome, (2) unspecified functional anorectal pain, and (3) proctalgia fugax. These three subtypes are primarily distinguished by differences in the duration of pain and the presence or absence of anorectal tenderness [66]. Levator ani syndrome is defined as chronic or recurrent rectal pain or aching lasting at least 30 minutes with tenderness on traction of the puborectalis muscle and the exclusion of other structural or systemic disease that can result in rectal pain. Unspecified functional anorectal pain is also defined as chronic or recurrent rectal pain or aching lasting at least 30 minutes but without tenderness to palpation of the puborectalis muscle. Proctalgia fugax is comprised of recurrent episodes of rectal pain unrelated to defecation which can last from seconds to up to 30 minutes in the absence of anorectal pain between episodes. Each set of criteria must be fulfilled for the last 3 months with symptom onset at least 6 months before diagnosis.

Levator Ani Syndrome

Levator ani syndrome is hypothesized to result from spasm of the pelvic floor muscles and elevated anal resting pressures. It has also been attributed to inflammation of the arcus tendon of the levator ani muscle where the muscle inserts into the pubic ramus. The onset of levator ani syndrome may be associated with pelvic injury, childbirth, a history of pelvic and spinal surgery, psychological stress, anxiety, and depression [67]. Diagnosis is based on the Rome IV criteria which includes the clinical finding of tenderness to palpation of the puborectalis muscle on rectal examination, which is usually greater on the left side than the right side. Pain is typically worse when sitting compared to lying down or standing. Imaging or anorectal physiology studies add little to the diagnosis other than to rule out other causes of anorectal pain.

Treatment of levator ani syndrome aims to relax the pelvic floor muscles and includes digital massage of the levator muscles, biofeedback, electrogalvanic stimulation (EGS), and trigger point injections with botulinum toxin or steroids. Treatment with digital massage of the puborectalis sling is the oldest described treatment and in conjunction with hot sitz baths and oral diazepam was able to relieve symptoms in up to 68% of patients with this type of chronic anorectal pain [68]. Digital massage continues to be a staple in the treatment of levator ani syndrome and is usually undertaken prior to other more invasive therapies.

A prospective randomized trial of 157 patients allocated patients to one of the three common treatments for levator ani syndrome: biofeedback to teach relaxation of the pelvic floor muscles, EGS, and digital massage of the levator muscles [69]. Biofeedback was shown to be superior to EGS and digital massage for pain relief in addition to restoration of the appropriate anal canal relaxation with straining (94% successful) and ability to defecate a water-filled balloon (97% successful). The mechanism for improvement in rectal pain was thought to be related to improvement in the overall mechanics of defecation described above. Similarly, biofeedback demonstrated the greatest benefit in another retrospective cohort of patients with levator ani syndrome, outperforming tricyclic antidepressants, Botox injections, and sacral nerve stimulation. The response to biofeedback was greatest in patients reporting difficulty with defecation. In this group 65% described improvement in their pain compared to only 35% of those without defecatory difficulties [67].

A prospective study comparing local steroid injection with a mixture of triamcinolone and lidocaine into the maximal point of tenderness on the arcus tendon in the levator ani muscle versus EGS showed better short-term results in the local injection group than the EGS group. However, there was no difference between pain scores at 12 months [70]. Studies of Botox injection for levator ani syndrome have been less promising. Twelve patients with levator ani syndrome received anal intra-sphincteric injections of 100 units of botulinum toxin A and placebo at 90-day intervals using EMG guidance in a randomized, placebo-controlled, crossover study. The mean frequency, intensity, and duration of pain were unchanged after Botox injection compared with baseline [71]. Botox injection combined with biofeedback was slightly more successful in reducing levator ani pain [72].

Proctalgia Fugax

There are several proposed etiologies of proctalgia fugax, the most widespread is that it is due to abnormal smooth muscle contraction of the anal sphincter complex. It has been shown that proctalgia fugax is associated with a higher mean internal anal sphincter thickness and resting pressure than chronic proctalgia [67]. A familial form of proctalgia fugax has been described which is associated with hypertrophy of the internal anal sphincter and comorbid constipation. In these patients, internal anal sphincter strip myomectomy improves the constipation but is not as effective in resolving pain [73–75]. Pudendal nerve neuralgia is another reported cause of proctalgia fugax which is supported by a study of 68 patients with proctalgia fugax, where 55 had tenderness along the pudendal nerve. In this study, a nerve block relieved symptoms completely in 65 percent of patients and decreased symptoms in 25 percent of patients suggesting that the pathogenesis of proctalgia fugax may be neuralgia of the pudendal nerve [76].

Attacks of proctalgia fugax are often precipitated by stressful life events or anxiety. Changing a patient's position, reassurance, warm baths, sublingual nifedipine or topical nitroglycerin, passing flatus, or a bowel movement with the help of an enema often stops the episode [76]. In a randomized double-blind, placebo-controlled, crossover trial, inhalation of albuterol was reported to shorten the onset of pain relief from 14 minutes to 5 minutes [77]. However, the mechanism of benefit of albuterol is unclear as it has no significant effect on anal resting tone, sphincter relaxation, or rectal compliance when patients are asymptomatic.

In persistent cases, biofeedback therapy, local anesthetic blocks, or Botox injections can be considered. Botulinum toxin was used in a study of five patients versus controls with resolution of symptoms for up to 2 years with 25 units of Botox (and with a further 50 units in 1 patient with persistence of symptoms) [78]. These patients had an increased mean resting pressure on anal manometry compared to controls which returned to normal values after treatment. Internal anal sphincterotomy has also been described when more conservative measures are not successful [79].

Coccygodynia

Coccygodynia is defined as pain or discomfort at or around the coccyx including the sacrum, anorectum, and perineum which is usually aggravated by prolonged sitting on hard surfaces. When the pain lasts longer than 2 months, it is considered chronic. There are two principle subtypes: [1] coccygodynia related to trauma and [2] idiopathic which is commonly attributed to pelvic floor spasm, inflammation of the coccygeal bursa, degenerative joint disease, and hypermobility or hypomobility of the sacrococcygeal joint. Obesity and female gender are considered predisposing factors due to the resulting pelvic rotation and a more posterior location of the coccyx which makes it more vulnerable to injury.

Reproduction of the pain by pressure or manipulation of the coccyx externally or during digital transrectal palpation is key to the diagnosis. Pain is usually worse when leaning back while sitting and may be triggered by moving from sitting to standing. Symptoms improve with relief of pressure when standing or walking. Spasm or tenderness of the pelvic floor muscles may also be seen. Most patients do not require imaging studies. However radiological evaluation using lateral sacral radiographs and dynamic X-rays comparing sitting and standing allows classification of the shape of the coccyx according to its inclination and evaluation of bony pathology. MRI is useful to exclude degenerative spine disease, tumors, or metastatic bone disease as the source of pain [80].

The vast majority of patients (90%) improve with nonoperative treatment including rest, protection of the area with a donut or wedge cushions, nonsteroidal anti-inflammatory drugs, and heat or ice [81]. Coccyx manipulation, ganglion impar blockade, and biofeedback therapy have also been successful in treating coccygodynia.

Coccyx manipulation via the rectum relaxes the muscles attached to the coccyx. Since these muscles may be in spasm, this treatment may make a stiff coccyx more mobile. In a randomized trial of 102 patients with chronic coccygodynia comparing coccygeal manipulation (three 5-minute sessions of intrarectal manipulation over a period of 10 days) and external magnetic field physiotherapy, the group that received coccygeal manipulation was more likely to have decreased pain compared with the placebo group (36% versus 20% at 1 month), but neither group had a large improvement [82].

Ganglion impar blockade using fluoroscopy or CT guidance is another treatment option for coccygodynia. The addition of corticosteroids further enhances the efficacy of the nerve block. In a prospective, randomized, double-blind study of chronic coccygodynia involving over 70 patients, ganglion impar block with local anesthetic plus corticosteroid decreased pain and also depression at 1 and 3 months compared with local anesthetic alone [83].

For those patients who fail nonoperative treatment, surgery may be considered. Coccygectomy has been found to provide good or excellent pain relief in up to 85% of cases [80]. A retrospective cohort study comparing coccygectomy and nonsurgical care in 109 patients with an average 4 year follow-up showed that surgically treated patients had significantly less pain and better health status than nonsurgical patients [84]. The most common reported complication of coccygectomy is wound infection, which can be seen in up to a quarter of patients.

Pudendal Neuralgia

The pudendal nerve derives from sacral roots S2, S3, and S4 and is composed of both motor and sensory fibers which innervate the anogenital area and pelvic muscles. The pudendal nerve passes between the sacrospinous ligament and sacrotuberous ligament close to the ischial spine before entering Alcock's canal. The most common etiology of pudendal neuralgia, also called Alcock's canal syndrome, is pudendal nerve entrapment between the sacrospinous ligament and sacrotuberous ligament, in Alcock's canal or in the infrapiriformis canal (Fig. 56.7).

Pudendal neuralgia may be described as a knifelike pain or a foreign-body sensation in the rectum, vagina, or perineum. The pain usually worsens during the day and may be unilateral. The ischial spine may be tender to palpation, and defecation can trigger pain, generally several minutes to an hour later. Making the diagnosis of pudendal neuralgia is difficult, and patients may suffer for many years before the diagnosis is reached.

In 2006, a multidisciplinary working group in Nantes, France, defined five required criteria for the diagnosis of pudendal neuralgia by pudendal nerve entrapment [85].

1. Pain is in the anatomical territory of the pudendal nerve which extends from the anus to the clitoris or penis.
2. Pain is worsened by sitting due to excessive pressure on the nerve.
3. The patient is not woken at night by the pain.
4. There is no objective sensory loss on clinical examination. A superficial perineal sensory deficit is more suggestive of a sacral nerve root lesion.
5. Pain is relieved by an anesthetic pudendal nerve block. This criterion is not specific as it indicates that the pain is situated in the territory of the pudendal nerve.

The exclusion criteria were purely coccygeal, gluteal, or hypogastric pain which does not correspond to the territory of the pudendal nerve: exclusively paroxysmal pain, exclusively pruritus, and presence of imaging abnormalities able to explain the symptoms.

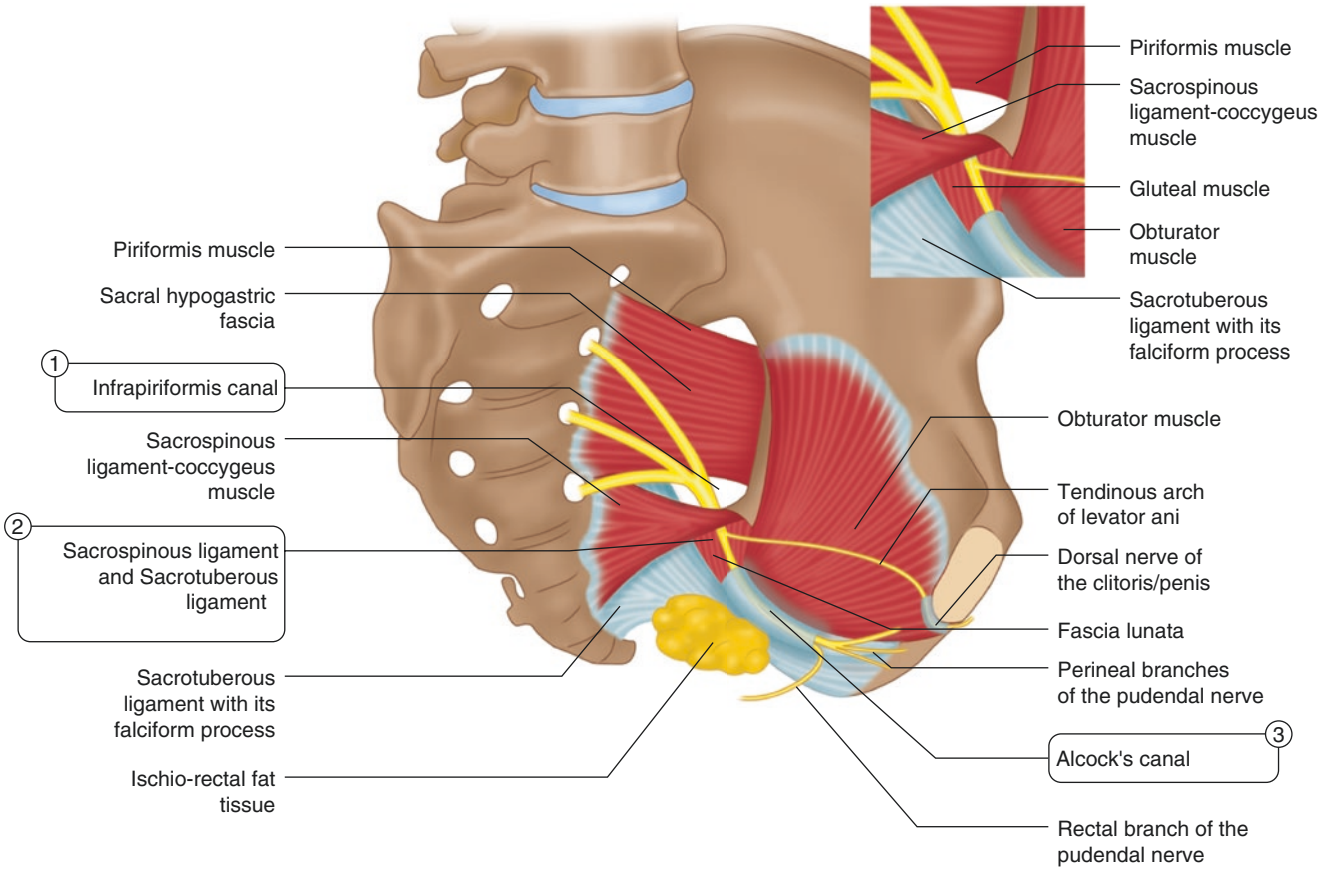

Fig. 56.7 Demonstration of the anatomical course of the pudendal nerve showing different levels of possible pudendal nerve entrapment: (1) in the infrapiriformis canal; (2) between the sacrospinous ligament and sacrotuberous ligament; (3) in Alcock's canal

Only the operative finding of nerve entrapment and postoperative pain relief can formally confirm the diagnosis of pudendal neuralgia due to nerve entrapment. However magnetic resonance neurography is now gaining an increasing role in the diagnosis and management of pudendal neuralgia [86].

Pudendal neuralgia can be treated medically with rehabilitation, psychobehavioral approaches, nerve injection, nerve ablation, or neuromodulation. Patients may undergo multiple treatments, yet achieving sustained improvement is challenging. Surgical decompression of the pudendal nerve may be recommended for patients who fail nonsurgical treatments.

Pudendal Nerve Block

Pudendal nerve block can be performed in the operating room using landmarks to palpate the course of the pudendal nerve either transvaginally or transanally. However, we prefer CT-guided pudendal nerve blocks with injection into the sacrospinous ligament and Alcock's canal. A retrospective review of 95 patients who underwent CT-guided injection of both locations using a combination of lidocaine hydrochloride, ropivacaine chlorhydrate, and cortivazol demonstrated clinical success as defined by at least a 50% reduction in baseline pain scores in 63% of patients at 1-month postprocedure, 50% of patients at 3 months, and 25% of patients at 6 months with no major complications [87]. The efficacy of using steroids in nerve injection was investigated in a randomized, double-blind, controlled study comparing CT-guided pudendal nerve blocks with a local anesthetic versus local anesthetic and corticosteroid. Corticosteroids provided no statistically significant improvement in pain, functional criteria, or quality of life compared with local anesthetic alone [88].

Neuromodulation

In addition to sacral neuromodulation, which has some reported success, pudendal neuromodulation and conus medullaris stimulation have also been used [89–91]. A retrospective review included 19 patients who underwent pudendal neuromodulation with a quadripolar lead (InterStim, Medtronic, Minneapolis, MN, USA) placed at the pudendal

nerve. At the end of a 2-week test period, just prior to implanted pulse generator placement, pain relief was complete in three patients, almost complete in three, significant/remarkably improved in ten patients, and three reported a small/slight amount of relief. Pudendal neuromodulation was felt to be more effective than nerve block. Of the four patients who had previously experienced sacral neuromodulation, three rated pudendal neuromodulation as more effective [90].

Another study included 27 consecutive patients who underwent conus medullaris stimulation for refractory pudendal neuralgia following pudendal nerve decompression surgery. The electrode (Lamitrode TM S8 or TM 44C electrode, St. Jude Medical, Inc., or three column electrode, Medtronic, Inc.) was initially tested for an average of 13 days. Twenty patients had positive tests. The zone of paresthesia was confined to the perineal zone in one quarter of patients, while the other patients also reported paresthesia in the lower limbs (essentially affecting the L4, L5, and S1 dermatomes). One hundred percent of implanted patients remained long-term responders. Mean sitting time tripled and mean estimated percent improvement was 55.5%. Additionally, the effect of conus medullaris stimulation appeared to remain stable over time, as no reduction of the analgesic effect experienced by the patients was observed after a mean follow-up of 15 months after implantation [91].

Nerve Ablation

Nerve ablation can also be used to relieve pudendal neuralgia pain. CT-guided cryoablation was reported to be effective in durably reducing pelvic pain in 9 of the 11 patients (82%) included in a study over a 6-month follow-up period with no procedure-related complications [92]. In a case report, transgluteal pulsed radiofrequency ablation was reported to be successful for at least 6 weeks in a 51-year-old woman who had only transient relief with prior nerve injection [93].

Fat grafting has been considered to alleviate neuropathic pain. The precise mechanism is not clear, but there may be some anti-inflammatory effects of adipose-derived stem cells and mechanical cushioning by fat. In a study of 15 women who underwent pudendal nerve lipofilling with adipose tissue into Alcock's canal, 10 were pain-free at 12 months [94].

Operative Approaches

Pudendal nerve decompression surgery is recommended after failure of medical treatment and ideally should treat all possible entrapment levels including (1) the space between the piriformis muscle and the sacral hypogastric fascia, (2) the interligamentary space, (3) Alcock's canal, and (4) the subpubic dorsal nerve canal [95]. The success of surgery is predicted by a positive response to nerve infiltration. Therefore, surgery is not recommended for patient with a negative response to nerve infiltration. Pudendal nerve decompression and transposition was shown to be superior to nonsurgical treatment at 3 months and 6 months in a randomized controlled trial of 32 patients [96]. The majority of patients (8/10) who had successful surgical decompression at 1 year remained so at 4 years, demonstrating the possibility of a long-term successful outcome with surgical decompression.

Multiple surgical approaches for surgical nerve decompression have been recognized; transgluteal, transperineal, transischiorectal fossa, and laparoscopic. New hybrid techniques including endoscopic assistance are now being investigated to improve visualization and surgical safety.

Laparoscopic pudendal nerve decompression and transposition with omental flap protection of the nerve (Istanbul technique) was performed in 27 patients by Erdogru et al. [97] This technique involved complete division of the sacrospinous ligament and splitting of the inner side of the levator ani muscles to reach the fatty tissue in front of the canal entrance. The aponeurosis of the internal obturator was opened, and an omental flap was used to wrap the decompressed nerve. At 6 months 80% of patients reported a > 80% reduction in pain scores. Quality-of-life scores also improved and were sustained up to 12 months.

A new technique adding an endoscope to a transperineal approach ("operative pudendoscopy") aimed to improve visualization in what was otherwise historically a blind transperineal procedure. With the patient in lithotomy position, a skin incision was made between the ischial tuberosity and the anal margin. Using the endoscope, the surgeon was able to visualize each decompression step, the different levels of entrapment and cut the sacrospinous ligament under visual control. This technique was used in 113 patients with improvement in pain in 73% of patients and a 50% reduction in pain in 42% [95]. A learning curve of 60 interventions was noted and a larger decrease in pain was seen for patients treated by the more experienced surgeon.

In patients who experience failure of surgery, repeat surgery, though technically challenging, can be offered with improvement of symptoms in the majority of patients and minimal postoperative complications as described by Hibner et al. [98]. Using a transgluteal incision, a nerve monitoring system was used to aid in identifying the pudendal nerve. Adhesiolysis was performed from the piriformis muscle to the distal aspect of Alcock's canal with the aid of a surgical microscope. The nerve was enclosed in NeuraWrap Nerve Protector (Integra, Plainsboro, NJ, USA) and coated with active platelet-rich plasma. An On-Q PainBuster (Halyard Health, Alpharetta, GA, USA) catheter was placed along the nerve in Alcock's canal, and the sacrotuberous ligament was

repaired using an Achilles or gracilis cadaver ligament. Mean follow-up was 23 months. Eight of nine patients reported global improvement with two patients reporting complete resolution of symptoms. No patient experienced worsening of symptoms.

Conclusion

Irritable bowel syndrome, chronic abdominal pain and chronic pelvic pain have complex physiologic and psychosocial roots. Patients often experience a delay in diagnosis and may undergo multiple attempts at treatment before achieving resolution of their symptoms. Colorectal surgeons should be well versed in the management of these typically nonoperative chronic conditions, and realistic expectations should be set regarding their management and expected outcomes.

Common Tests for the Pelvic Floor

57

Amy J. Thorsen and Leslie Roth

Key Concepts

- Disorders of anorectal function are common and have a significant impact on individual's quality of life.
- Anal manometry allows assessment of anorectal motor and sensory function to delineate contributing factors leading to symptoms of obstructed defecation, anal pain, and fecal incontinence.
- Ultrasound, fluoroscopic defecography, and MR defecography provide anatomic and dynamic assessment and the impact of anatomy on function in evaluating patients with fecal incontinence, obstructed defecation, and pelvic organ prolapse.

Introduction

Alterations of anal continence and defecation can have a devastating effect on quality of life [1]. Community-based studies suggest fecal incontinence affects 8.4–14.4% of the population [2, 3]. Evacuation disorders are more common, affecting 12–19% of North Americans [4]. Up to one half of all parous women will have some degree of clinical pelvic organ prolapse; 10–20% of these women will have symptoms [5, 6]. Given affected individuals may avoid work and social activities, appropriate evaluation and treatment can have significant impact on patients' lives.

The etiology of these conditions can be quite variable and multifactorial. Serious underlying pathology, such as colonic malignancy or inflammatory bowel disease, should be excluded in patients with new onset of symptoms. Multispecialty evaluation may be indicated to evaluate and treat functional bowel and neurologic issues, as well as concomitant urologic and vaginal symptoms. Pelvic floor testing is indicated in patients who fail first-line conservative management such as optimizing stool consistency and lifestyle modification.

This chapter will focus on the evaluation of patients experiencing fecal incontinence, obstructed defecation, and the spectrum of posterior compartment pelvic organ prolapse. Pelvic floor assessment includes evaluation of motor and sensory function, structural anatomic assessment, and dynamic imaging.

Manometry

Equipment

The first studies of anorectal manometry were done in 1877 by Gowers [7], who measured anal canal resting tone and was reportedly the first to explore the rectoanal inhibitory reflex. The first attempt at measuring colorectal pressures with rectal tubing was described by Joltain et al. in 1919 [8]. Using procedures learned by performing cystometry, White et al. further refined the technique in the evaluation of patients with neurologic injury in 1940 [9]. The various anorectal manometry systems presently used all consist of a pressure sensing probe, an amplifier/recorder which translates the pressure signals, a video monitor to display these signals, and a computer with software to analyze and store data. Present-day probes can be water perfused, air charged, or microballoon [10]. A nonlatex balloon is attached to the end of the catheter where a pressure transducer is located to measure rectal pressure and reflexes.

Water-perfused catheters consist of thin plastic tubing with a central channel connected to a pneumohydraulic pump. Nitrogen gas is used to pump water out of a reservoir through the catheter and out of four to eight side holes spaced 0.5–2.0 cm apart. Water-perfused catheters indirectly measure intraluminal pressures using the resistance pressure of

water flow out of the catheter as picked up by transducers [11, 12]. The pressure in each tube is sensed and converted to an electrical signal by a volume displacement transducer. The frequency of the amplifier/recorder should be at least 8 Hz. The recorded pressure rises when the flow of water through the side hole of a tube is impeded by anal contraction.

Prior to beginning a study, the reservoir needs to be filled with water, and the pneumohydraulic pump is started. Water perfusion should be set at a rate of 0.2–0.4 mL/minute at a pressure head of 10 psi. The transducers located on the pump and on the catheter need to be at the same level during calibration and when placed in the patient when performing the study [10]. Conventional manometry probes containing few sensors are incapable of acquiring the pressures of the entire anal canal simultaneously. Therefore, they required pull-through maneuvers or rotation to sample the entire area of interest. This prevents a continuous measurement of pressures throughout the entire anal canal. Radial sensors require a pull-through procedure that may introduce motion artifacts [13]. Water-perfused catheters are low cost and simple but cannot be used in an upright position; tracings can be impacted by anatomic and technique-induced artifact [14].

Solid-state catheters consist of a linear array of miniature, solid-state strain gauge transducers spaced at regular intervals along a flexible tube. Outputs from the strain gauges are passed to an amplifier and then to a computer [15]. Solid-state catheters have much higher frequency- response characteristics, making them able to accurately record the much faster pressure transients produced by striated muscle. Calibration of these catheters is straightforward and does not require the probe and transducers to be at the same level. Solid-state devices require less technical expertise and are less cumbersome to use, but they are fragile and more expensive than water-perfused catheters.

Air-charged catheter technology uses an air column from a balloon to an external transducer which allows circumferential area readings that are gravity independent. Air-charged catheters are low cost and disposable; they avoid the need for high-level disinfection which results in decreased personnel time. Air-charged catheters have been shown to have reproducible results compared with water-perfused and solid-state microtransducers when evaluating intrauterine [16], intraurethral [17], esophageal, and anorectal pressures (Fig. 57.1a, b) [18].

Further advancements in manometry catheters and software have led to the development of high-resolution manometry (HRAM) in 2008, which was soon followed by high-definition 3D manometry and topography (HDAM). The HRAM catheter consists of two sensors in the rectal balloon and ten sensors at 6-mm intervals along the anal canal. Each sensor is able to record pressure changes in excess of 6000 mmHg/s with an accuracy within 1 mmHg of atmospheric pressure. The recording unit and software can accommodate data at 35 Hz frequency. The catheters are susceptible to thermal drift. Thermal compensation is applied during analysis to compensate for temperature changes during prolonged studies [19].

The HDAM probe is a large-diameter (10.75 mm) catheter with 256 pressure sensors that are arranged in 16 rows with each row having 16 circumferentially oriented sensors (Fig. 57.2). Although pressure is sensed at 4-mm intervals, the software linearly interpolates the space between sensors to provide measurements at 1-mm spacing with negligible error. The amplifier and recording system attached to the catheter utilize specialized software to display topographic images. Recording frequency is at >20 Hz with a resolution of 0.1 mmHg. Thermal compensation is also applied similar to HRAM probes [20].

The additional sensors at close intervals on HRAM and HDAM solid-state probes provide a continuum of data acquisition without loss of information. A tool called the eSleeve (Sierra Scientific Instruments, Los Angeles, CA, USA) reduces the data from a number of sensors into a single

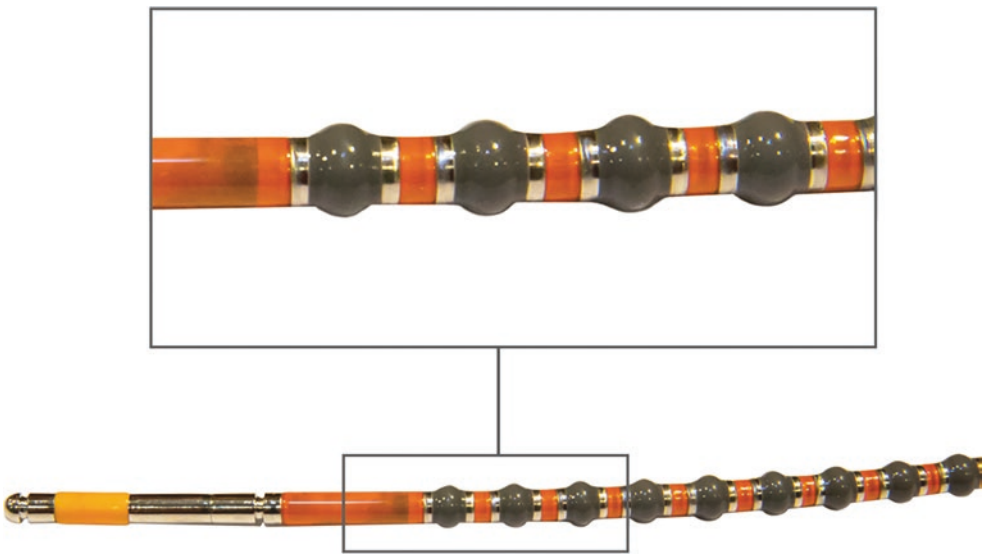

Fig. 57.2 HDAM manometry catheter (Images courtesy of Laborie Medical Technologies, Corp.)

maximum value at each time point. Color topography provides a continuous and dynamic display of the large amount of data gathered by the sensors, allowing simpler and more comprehensive interpretation of the data compared to the linear plots of conventional manometry [21].

Indications

Diagnostic manometry may be indicated in the evaluation of patients with fecal incontinence [22], constipation and obstructed defecation [23, 24], anal pain [25], anal fissure [26], and Hirschsprung's disease [27]. Manometry has been used as a preoperative assessment of anorectal function if intervention is associated with risks to continence (e.g., fistulotomy [28]and lateral sphincterotomy [29]) or ability to evacuate (e.g., rectopexy [30]). Assessment of anorectal function in patients after obstetric injury/traumatic birth may be useful if the clinician and patient wish to quantify anal sphincter function prior to future deliveries [31]. Biofeedback protocols using anal manometry have been developed for the treatment of fecal incontinence [32] and obstructed defecation [33].

Technique

Bowel preparation is optional; however, tap water or Fleets™ phospho-soda enema is indicated if digital rectal exam reveals the rectum is full of stool. Patients are not required to fast but should empty their bowels at least 30 minutes prior to testing for optimal results. The patient should lie in the left lateral position with the knees and hips at 90 degrees flexion. A digital exam is performed noting any local pathology, tenderness, blood, or stool present. The patient's understanding of instructions such as "squeeze" or "push" should be noted. The manometry probe is lubricated with a non-anesthetizing agent and then placed into the rectum and orientated such that the most distal sensor is external to the anal verge. Any rectal balloon attached to the catheter should be 3–5 cm above the upper border of the anal canal to avoid impingement upon inflation. A minimum longitudinal recording length of 6 cm is required.

After probe placement, a rest period of 3–5 minutes should be allowed to give the subject time to relax and the sphincter tone to return to basal levels. Ultraslow wave activity consisting of phasic pressure activity at 1–1.5 cycles/min with amplitude >= 40 mmHg may be noted [11]. Low-amplitude slow waves are more common and occur at a frequency of 10–20/minute. They are frequently seen in the lower anal canal and may promote anal continence by causing an upward movement of rectal contents [34].

There are several techniques to perform manometry with water-perfused and air-charged catheters. The stationary technique involves leaving the catheter in one position during recording. With the stationary pull-through method, the catheter is replaced within the anal canal. The resting pressure and the squeeze increase at 6, 5, 4, 3, 2, and 1 cm from the anal verge are measured by extracting the probe in increments of 1 cm from the rectum to the anal verge. With the continuous pull-through technique, the catheter is moved through the lower rectum and the anal canal at a constant speed (often 1 cm/second) with a specialized puller, and the pressures are simultaneously recorded [35]. The stationary pull-through technique is today the recommended method of choice since the continuous pull-through technique creates a reflex sphincter contraction due to the stimulation generated by the probe resulting in higher anal pressures [36].

The multiple sensors of HRAM and HDAM probes allow for a stationary exam to be performed after probe placement.

This allows for a shorter exam time, which in theory may lead to more patient comfort. Although studies have not suggested a greater comfort with HRAM than with a water-perfused manometer of a similar diameter and stiffness, HDAM was felt to be somewhat more comfortable compared to HRAM [37].

Resting Pressure

The resting tone created by the internal and external anal sphincter, and to a lesser extent the hemorrhoidal plexus, contributes to resting anal pressure. Up to 80% of resting tone may depend on internal sphincter tone. Resting anal pressures should be recorded approximately 3 minutes after probe insertion to allow reflex contractions from probe placement to abate. Resting pressure is generally recorded for 20–30 seconds. Mean resting pressure represents the averaged pressure recorded over this time, whereas the maximum resting pressure is the highest pressure measured at any instant. The high-pressure zone (HPZ) represents the length of anal canal over which the pressures are greater than half the maximum resting pressure. Resting anal pressures are lower in women than in men [38, 39] and decrease in women as they age [39–41]. Hypotonic resting pressures may be associated with passive fecal incontinence [42–44]. Hypertonic pressures at rest may be seen with anal fissure [45–47] or constipation [48].

Squeeze Pressure

The squeeze anal pressure measures voluntary contraction of the external anal sphincter muscle. Anal squeeze pressure is usually measured for 30 seconds after the patient is asked to maximally squeeze as hard as possible as long as he/she can. Squeeze endurance can also be assessed. A short 5-second squeeze can be measured by asking the patient to squeeze as hard as possible as if avoiding to pass flatus or stool. Similar to resting pressures, squeeze pressures or the squeeze increment (mean squeeze pressure minus mean resting pressure) are lower in women than in men and lower in older compared to younger women [38–41]. HDM can distinguish the contribution of the squeeze pressure from the puborectalis muscle [39, 49], but has not yet been shown to be better in identifying injury to the puborectalis or external sphincter than simpler forms of manometry [50].

Cough Reflex

The cough reflex assesses the response of the anal canal to a sudden increase in intraabdominal pressure. The patient is requested to perform a single cough, and this is repeated 30 seconds later. The rapid rise in intraabdominal pressure with a cough should cause a reflex contraction of the external anal sphincter. This reflex assesses the integrity of the sacral reflex arc. The reflex is preserved in patients with spinal lesions above the sacral level but is absent in patients with cauda equina lesions or pudendal neuropathy [51, 52].

Push/Simulated Evacuation

Evacuation requires an adequate propulsive force, measured as an increase in rectal pressure, with simultaneous anal canal relaxation noted as a decrease in anal pressure. The patient is requested to push down as if she is trying to pass a bowel movement. Three pushes are performed for 15 seconds at 30-second intervals with the catheter in place. The rectal balloon does not need to be inflated. The best attempt is used for analysis.

Dyssynergic defecation was initially thought to be caused by paradoxic anal canal contraction or involuntary anal spasm during defecation [53]. A prospective study by Rao et al. [54] revealed that most patients with dyssynergic defecation demonstrate the inability to coordinate the abdominal, rectoanal, and pelvic floor muscles to facilitate defecation. This may be due to inadequate pushing force, paradoxical anal sphincter contraction, impaired anal sphincter relaxation, or a combination of these mechanisms (Fig. 57.3a, b). Based on these features, at least four types of reproducible dyssynergic defecation [55, 56] have been recognized:

- *Type I:* The patient can generate an adequate push (rise in intraabdominal pressure) along with a paradoxical anal sphincter contraction.
- *Type II:* The patient is unable to generate an adequate push but displays a paradoxical increase in anal sphincter pressures.
- *Type III:* The patient can generate an adequate push, but either has absent or incomplete (<20%) reduction in anal sphincter pressure.
- *Type IV:* The patient is unable to produce an adequate push and demonstrates an absent or deficient anal sphincter relaxation.

Manometry alone cannot diagnose dyssynergic defecation, given some studies have suggested up to 90% of asymptomatic controls and patients with proctalgia without constipation can exhibit dyssynergic patterns [57, 58]. This may be due to the nonphysiologic positioning of the patient in the left lateral position, as well as the lack of rectal con-

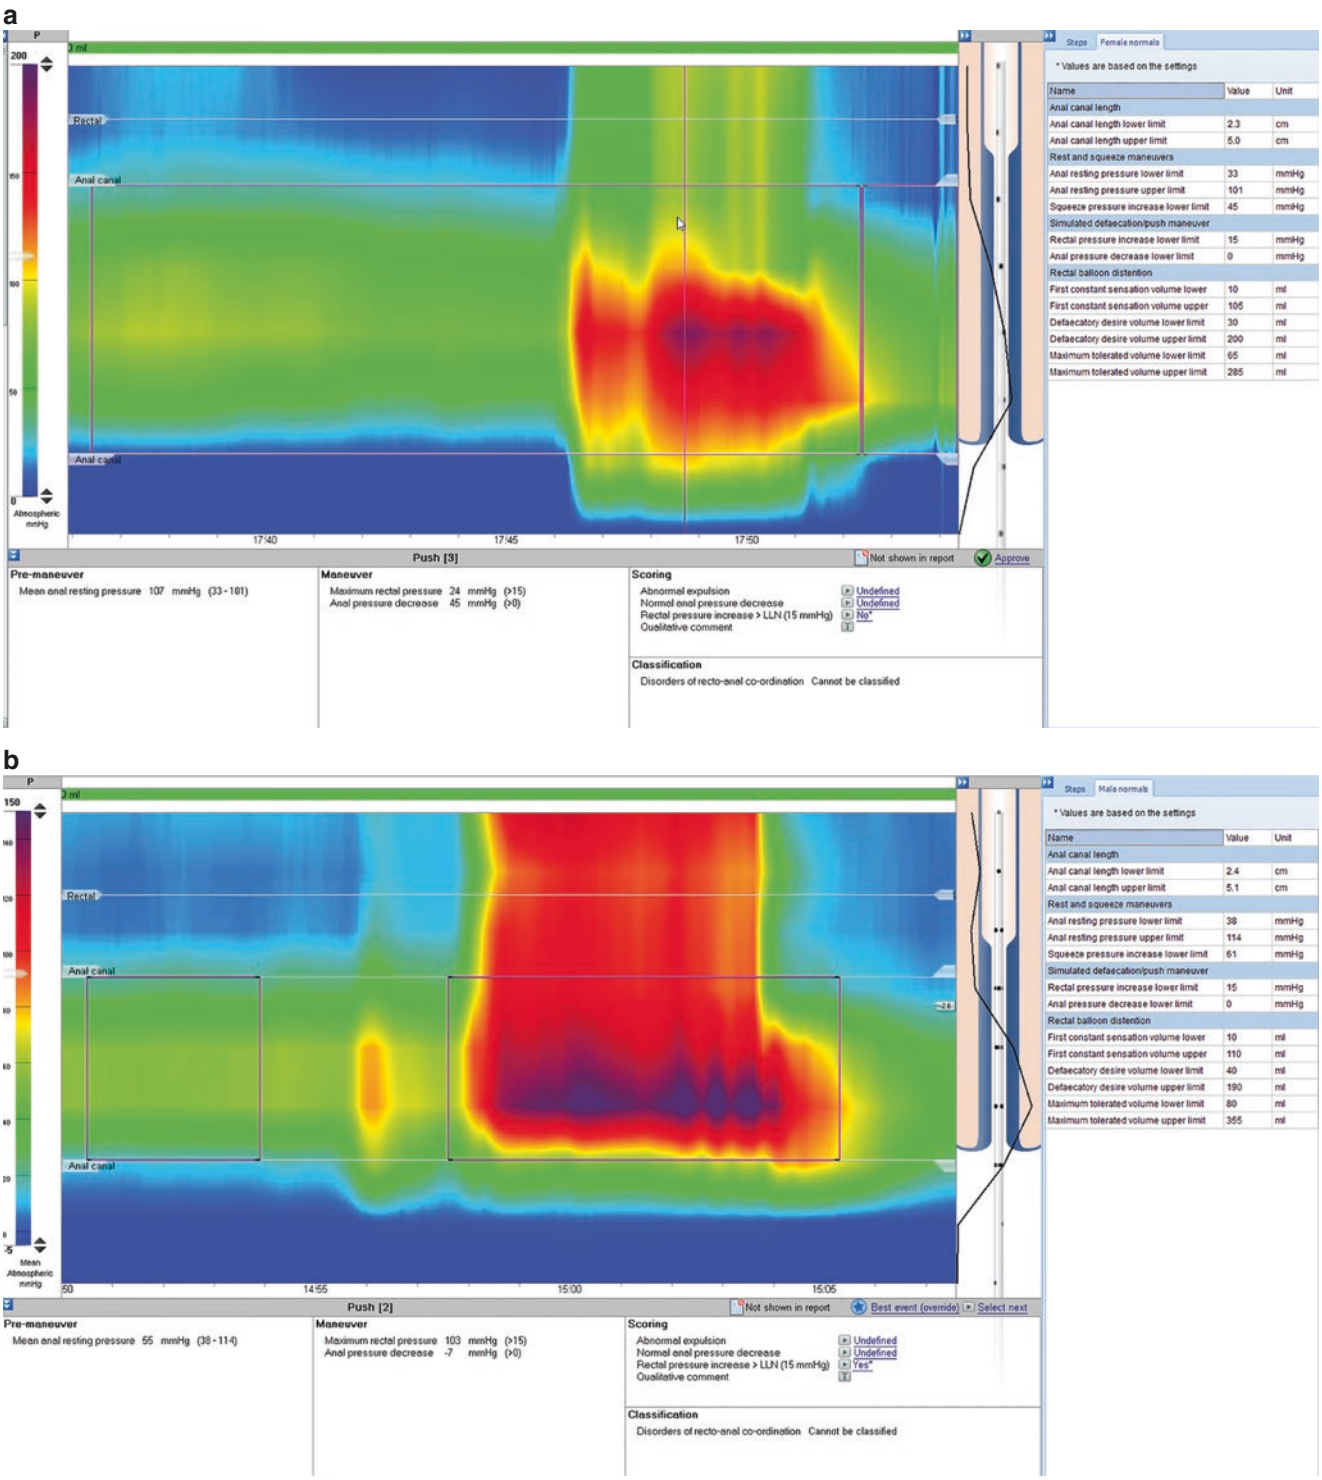

Fig. 57.3 (**a**) Normal response with push on HDAM. (**b**) Paradoxic contraction of the anal canal with push on HDAM (Images courtesy of Laborie Medical Technologies, Corp.)

tents when the patient is asked to simulate defecation [59]. The rectoanal gradient, which is the difference between rectal pressure and anal pressure during simulated evacuation, is negative in a majority of asymptomatic women, undermining the utility of a negative gradient for diagnosing defecatory disorders by HRM [40]. The defecation index (normal >= 1.2), which is the ratio of maximal intrarectal pressure and anal sphincter residual pressure, is a simple and useful quantitative measure of rectoanal coordination during defecation [54, 60].

Rectoanal Inhibitory Reflex (RAIR)

Gowers [7] first noted that distension of the rectal wall leads to first a reflexive contraction of the external sphincter followed by relaxation of the internal sphincter (Fig. 57.4). This rectoanal inhibitory reflex (RAIR) is mediated by the myenteric plexus. The RAIR is performed by inflating the rectal balloon with at least 30 mL air. Failure to elicit the RAIR may be seen with low distending volumes in a large capacity rectum; therefore the test should be repeated with increasing balloon volumes if megarectum is suspected. A RAIR may also be very difficult to detect in the setting of very low resting pressures. The RAIR reflex may be absent in Hirschsprung's disease [61], in the presence of acquired myenteric neuropathies [62, 63], and after rectal reconstruction [52].

Rectal Sensation

Rectal sensitivity to distension is measured by utilizing a rectal balloon placed at least 3–5 cm proximal to the upper border of the anal canal. Either ramp (continuous 1–2 cc/s) or phasic air insufflation can be performed with a hand-held syringe or pump [12]. The volume of the balloon is recorded for three sensory thresholds: (1) first sensation, the first time the patient constantly feels sensation from the balloon pressure; (2) first urge/desire to defecate, the volume the patient feels the persistent urge to defecate; and (3) maximum tolerated volume, when the volume in the balloon causes the patient to feel too uncomfortable to continually tolerate. Intra-balloon volumes and intrarectal pressures are recorded concurrently, allowing rectal compliance to be calculated from the derived pressure–volume curve. Rectal capacity can also be measured.

Rectal sensation volumes can be normal, reduced (hypersensitive), or elevated (hyposensitive) in both chronic constipation and fecal incontinence [64–66]. Rectal hypersensitivity can be seen with urge fecal incontinence [67], radiation proctitis, ulcerative colitis, IBS-D [68], and low anterior syndrome [69]. Improvement of symptoms after behavioral therapy [70], pharmacological therapy [71], or surgical therapy [72] may occur with improvement in sensory thresholds.

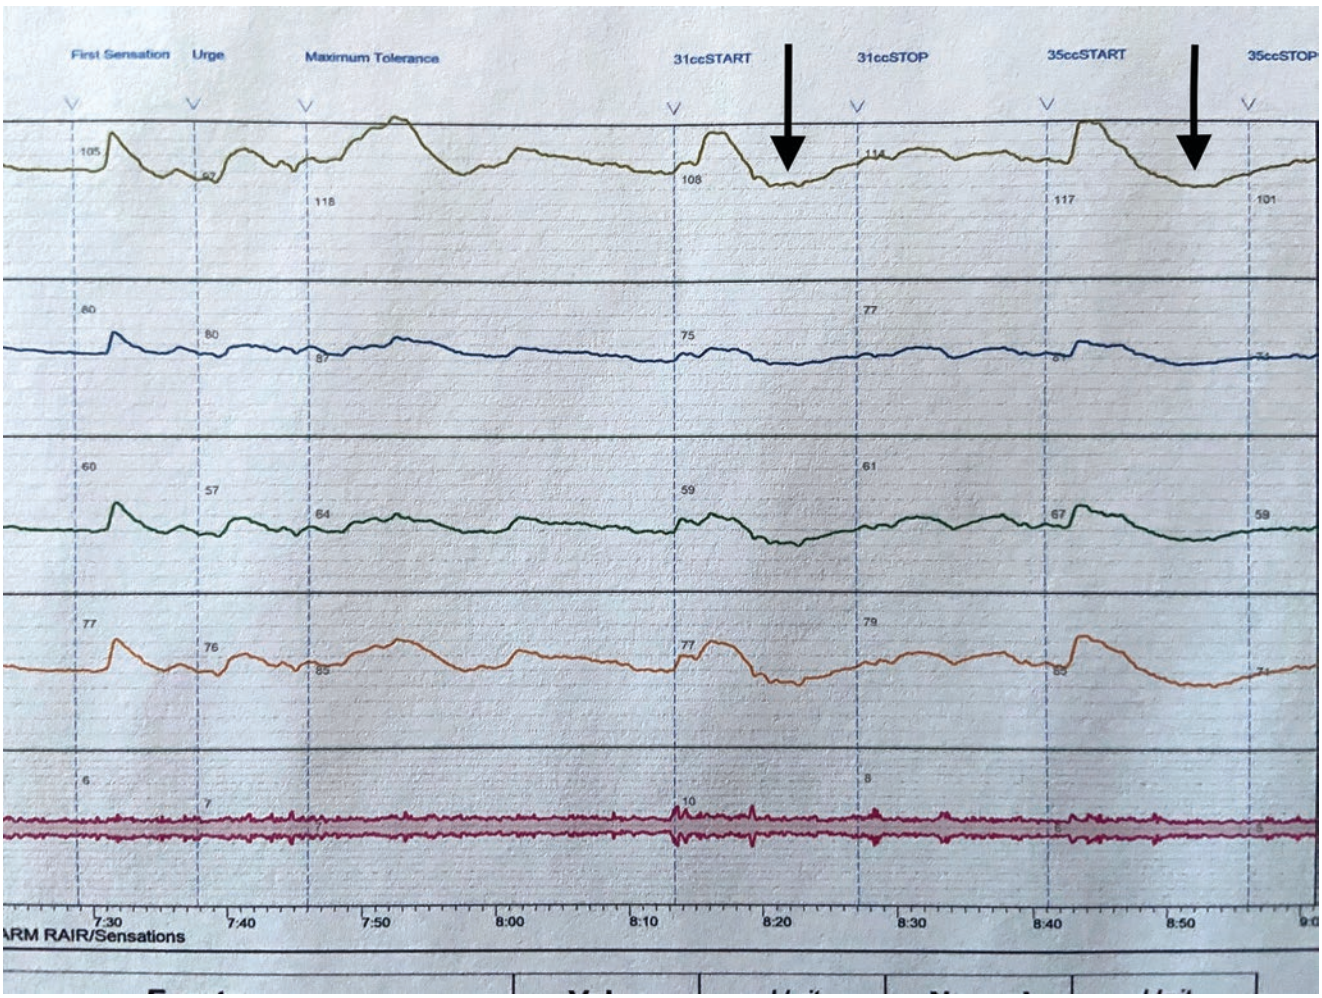

Fig. 57.4 Arrows show RAIR response: internal sphincter relaxation after rectal distension

Rectal hyposensitivity can be seen in 18–66% of patients with chronic constipation [66] and can identify a subset of patients who respond poorly to biofeedback [73] and colectomy [74]. Patients successfully treated for obstructed defecation with neuromodulation therapy have been shown to exhibit improved rectal sensation [75].

Balloon Expulsion Test (BET)

The balloon expulsion test is a screening test for obstructed defecation. A 4-cm balloon filled with 50 mL of warm water is placed into the rectum. The patient is then allowed to sit on a commode and pass the balloon privately. A functional defecation disorder is suggested if the patient cannot pass the balloon or if it takes more than 1 minute to pass [76]. A positive delayed BET is highly specific for obstructed defecation but with a low sensitivity of 50% [77, 78]. It does not define the mechanism of disordered evacuation.

London Protocol and Criteria

Between 2014 and 2018, the international anorectal physiology working group (IAPWG), consisting of 29 gastroenterologists, gastrointestinal physiologists, and colorectal surgeons, met to develop a consensus document on the performance of anorectal manometry and BET as well as a classification of anorectal disorders, similar to the Chicago classification of esophageal motility disorders [79]. The four-part London classification delineates (a) disorder of the rectoanal inhibitory reflex, (b) disorders of anal tone and contractility, (c) disorders of rectoanal coordination, and (d) disorders of rectal sensation. Major findings not found in healthy controls by this classification are rectoanal areflexia (absent RAIR), anal hypotension and hypocontractility, rectal hyposensitivity, and hypersensitivity. Minor and inconclusive findings, such as anal hypertension and dyssynergia, can be found in health as well as with symptoms. The development of the London protocol and classification aims to standardize a common language and testing protocol in the evaluation of patients with anorectal dysfunction [80].

Authors Note Conventional Versus High-Definition 3D Manometry

Presently both authors (AJT, LR) use conventional manometry with air-charged disposable catheters at our anorectal physiology labs. This is a more economical choice given the systems and disposable catheters are at lower costs compared to HRAM/HDAM and their fragile, reusable catheters. Present CPT codes do not differentiate reimbursement between conventional and HRAM/HDAM manometry exams. Although we are intrigued by the topography plots and analysis that higher resolution provides, we have not yet found this information to aid in our decision-making in treating patients with pelvic floor disorders.

A recent study by Benezech et al. [81] noted that an anterior additional high-pressure area on HDAM associated with an excessive perineal descent allowed the diagnosis of rectal intussusception with a positive predictive value and a specificity of 100% compared with fluoroscopic defecography. While this could be a possible clinical advantage of HDAM in diagnosing the etiology of obstructed defecation or fecal incontinence, it would not obviate the need to perform dynamic imaging in surgical candidates in our opinion.

Neurophysiologic Testing

EMG

Pelvic floor electromyography permits mapping of external anal sphincter defects, determination of striated muscle function, and assessment of denervation–reinnervation potentials [82]. Advances in anal sphincter imaging by endoanal ultrasound and MRI have diminished the clinical utility of needle EMG [83]. Needle electrodes are placed into the external sphincter or puborectalis to assess the muscle and innervation as a function of their electrical activity in the resting and squeeze phases. The test is painful and poorly tolerated by patients, leading to poor diagnostic yield.

Surface EMG allows a more global assessment of sphincter function and is easy to perform. Although surface pads may be better tolerated, the anal plug intraluminal electrode is believed to be more accurate given its close position to the external sphincter muscle which prevents artifact from gluteal and other accessory muscles [84]. EMG recruitment is seen simultaneously with an increase in anal pressures during squeeze and correlates well with sphincter pressures [85]. Surface EMG can be very useful in detecting paradoxical contraction or a lack of relaxation in patients with defecatory dysfunction [86]. A normal response would be a decrease in activity with push compared to rest; elevated activity is seen with push with paradoxical relaxation (Fig. 57.5). EMG is frequently used to retrain external anal function in patients with fecal incontinence and obstructed defecation [86, 87].

Pudendal Nerve Terminal Motor Latency (PNTML)

The pudendal nerve and its branches are vulnerable to stretch injury during the third trimester of pregnancy, sec-

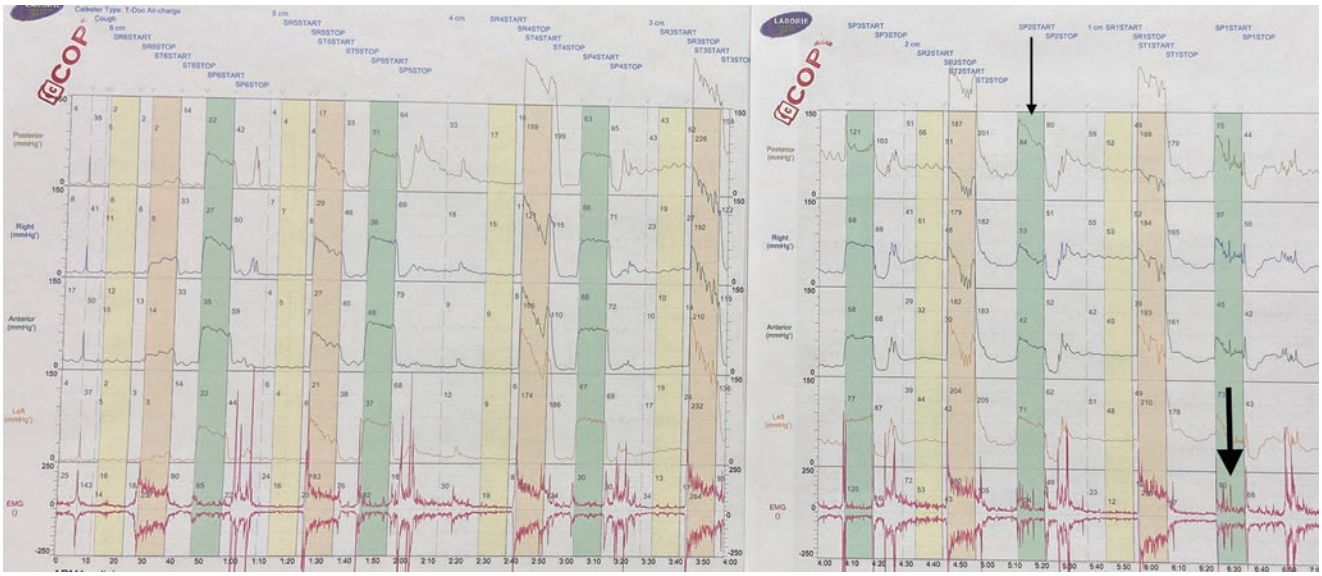

Fig. 57.5 Dyssynergic defecation with 2D manometry and simultaneous surface EMG. Yellow bars represent rest; orange bar is squeeze; green bars are push. Small arrow shows elevation of anal pressures with push. Large arrow reveals increased EMG activity with push, indicating paradoxical contraction

ond stage of labor, and forceps-assisted vaginal delivery. Injury can lead to denervation of the external sphincter muscle and fecal incontinence [88, 89]. PNTML measures the neuromuscular integrity between the pudendal nerve and external anal sphincter [82, 90]. The PNTML is performed by stimulating each pudendal nerve with a bipolar disposable electrode. This generates a compound muscle action response of the external anal sphincter (EAS); the time from stimulation to the beginning of the response is the PNTML [90]. A prolonged PNTML may suggest pudendal neuropathy or injury to some of its fast firing fibers [91]. There are many criticisms of the test and its utility: the test is very operator dependent [92]; it has poor sensitivity and specificity [90, 93]; it can have normal results if only some nerve fibers are damaged [94]; the latency has variable limits in health [12]; and its prediction on outcomes of clinical intervention, such as sphincteroplasty, is inconsistent [95, 96].

Spinal Motor Latency

Neurologic injury contributing to fecal incontinence can occur proximal to the origin of the pudendal nerves at the ischial spines. Transcutaneous stimulation of the cauda equina over the lumbar spine measures conduction along the cauda equina, the sacral plexus, and the branches from the plexus. Evoked responses can be recorded using standard EMG needles placed at the puborectalis, the external anal sphincter, and the urethral sphincter. Comparing latencies between multiple spinal levels allows the assessment of the level of neurologic injury [97]. Up to 23% of patients with idiopathic fecal incontinence will have cauda equina delay [98, 99].

Magnetic stimulation at multiple neurologic levels has been shown to induce motor-evoked potentials (MEPs) in the rectum and anus [100]. Using a probe with steel electrodes spaced to be in the rectum and low anal canal, rectal and anal MEPs can be measured after translumbar and transsacral magnetic stimulation. Rao et al. [101] found that TL and TS MEPs were significantly prolonged in patients with fecal incontinence compared to normal controls and that the MEP test was better tolerated than PNTML. MEPs were found to be prolonged in 87% of subjects with fecal incontinence, compared to prolonged PNTML in 63%. The clinical significance of prolonged spinal latencies in determining therapy for fecal incontinence remains to be seen.

Ultrasound and Dynamic Imaging

Anal ultrasound is the gold standard for evaluating anal sphincter pathology in the investigation of fecal incontinence [102]. Ultrasound works by measuring the reflection of sound waves off the structure being examined. Tissues that reflect ultrasound waves are hyperechoic and appear white on the image, whereas tissues that let more waves through are hypoechoic and appear black on the image. The external anal sphincter and puborectalis have higher reflection of sound waves, so they appear more hyperechoic, whereas the smooth muscle of the internal sphincter with its high water content appears more hypoechoic.

Indication

Anal ultrasound can help identify anatomic abnormalities of the anal sphincter complex. This has replaced electromyographic mapping as the modality of choice to assess sphincter defects for surgical repair [103]. Ultrasound is useful in patients with incontinence and fistulas (rectovaginal, cryptoglandular, or Crohn's). It can help determine defects in the sphincter complex that may be amenable to surgical repair and can measure the amount of muscle involvement in fistulas. It can also be useful in assessing the success of surgical repair of the sphincter complex and fistulas.

Equipment and Technique

The three-dimensional endoanal ultrasound has an endocavitary probe with a rotating transducer which acquires a 360-degree image. Most investigators use a BK Medical Anorectal 3D 20R3 high-resolution probe which has a frequency range of 3–20 MHz. This allows automatic collection of images over a 6-cm axis without moving the probe. In preparation, patients receive two enemas prior to the exam to clean the rectum of stool. The ultrasound is performed with the patient awake in the left lateral decubitus position. The probe is then inserted, and the tip of the probe is placed at the puborectalis, and the three-dimensional image is collected. Afterward, the images can be manipulated to visualize the sphincter complex in any plane making angles and distances measured more accurately [104].

Interpretation

The normal anal canal is divided into three sections: upper, mid-, and distal anal canal. The upper anal canal is identified by the hyperechoic horseshoe appearance of the puborectalis muscle (Fig. 57.6). In the mid-anal canal, you have the intact circles of the internal (hypoechoic) and external (hyperechoic) anal sphincters (Fig. 57.7a, b). In the distal anal canal, you have loss of the internal anal sphincter and visualize only the external anal sphincter. Ultrasound can visualize anterior sphincter defects from childbirth (Fig. 57.8).

To measure the perineal body length, digital pressure is placed to the posterior vaginal wall, which shows hyperechoic on image allowing distance measurement. Mean perineal body length in nulliparous healthy volunteers was 17.4+/−2.7 [105, 106]. A perineal body measurement <10 mm has been associated with an anterior sphincter defect [107]. The average anal canal length in females is 3 cm.

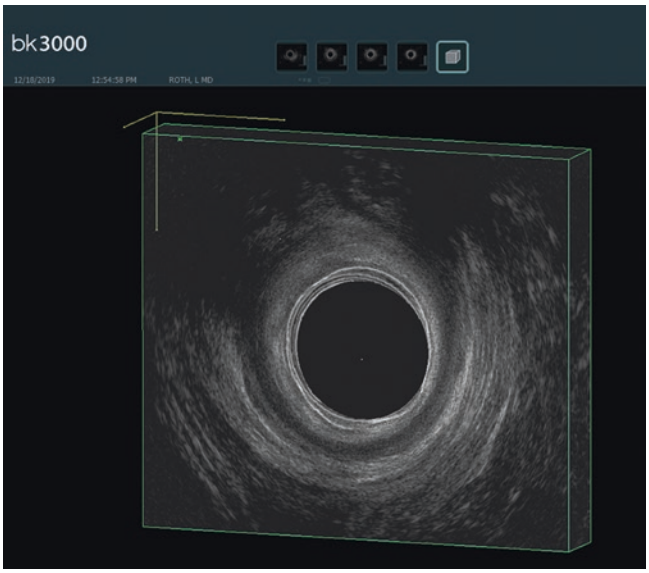

Fig. 57.6 Ultrasound image of upper anal canal

Looking at the sphincter complex, the average thickness of the internal anal sphincter in nulliparous women less than 30 years was 4.5 +/−0.7 mm vs. women over 50 5.9+/−1 mm. Older women have a 33% thicker internal anal sphincter [108]. The external anal sphincter in Nulliparous women is thicker posteriorly 24.7+/− 4.6 mm than anteriorly 6.6+/−1.7 mm [109].

MRI

Static MRI of the anal sphincter complex with or without an endoanal coil has fallen out of favor. It is expensive when compared to anal ultrasound and anal ultrasound. In a prospective study looking at patients with fecal incontinence for selection of surgical intervention, both endoanal MRI and anal ultrasound are sensitive tools and can be used to depict surgically repairable anterior external anal sphincter defects [110]. With the advancement of MR defecography, there is a limited role for static MRI.

Dynamic Imaging of the Pelvic Floor

Functional imaging of the pelvic floor has been an important step in the management of many pelvic floor disorders as multiple abnormalities can exist. For a long time, defecography was the only option. With the advancement of technology, MR defecography and dynamic ultrasound have come into play. We will look at the value of each of these as it pertains to colorectal surgery.

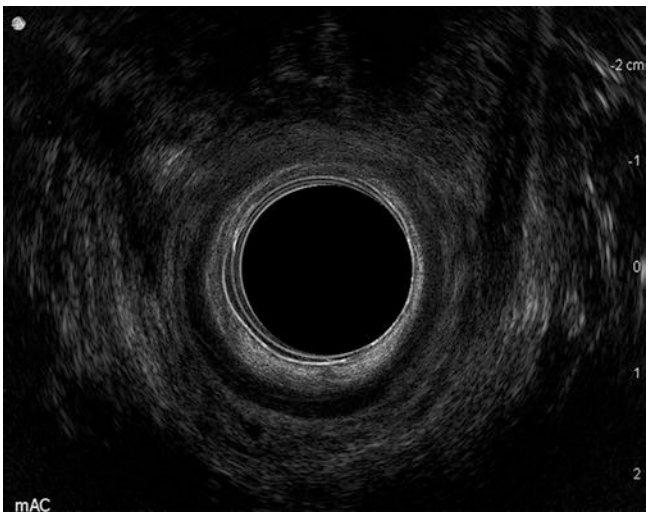

Fig. 57.8 Large anterior sphincter defect in the internal and external anal sphincters

Defecography

Evacuation proctography is the fluoroscopic imaging of defecation. It is a cost-effective procedure with an easy protocol, using standard radiology equipment, and allows the evaluation of the defecation process in the physiological sitting position. Defecography is used mainly to evaluate patients with difficulty in defecation (obstructed defecation) and pelvic organ prolapse (rectal prolapse, enterocele, cystocele). Thickened barium paste to simulate stool is placed in the rectum. Contrast can also be ingested orally to look for an enterocele and placed into the vagina and bladder to evaluate additional pelvic organs [111]. Images are captured on still and cine loop images. Defecography exposes patients to a mean radiation dose of 0.5–5.0 mSv [112, 113].

Normal Evaluation

The initial study in 1984 found five criteria for normal evacuation exist which include (1) increase in anorectal angulation, (2) obliteration of the impression of the puborectalis muscle, (3) wide opening of the anal canal, (4) total evacuation of rectal contents, and (5) normal pelvic floor resistance.

The anorectal angle is measured between the anal canal axis and the posterior rectal wall. There is variability in measuring this angle, as the structures are not fixed, making it somewhat unreliable. The mean value of the anorectal angle at rest was 91.96 degrees and during straining 136.76 degrees, for an increase of 44.8 degrees [114]. Subsequent studies of normal patients have shown a wide range of normal values, and the accepted range of normal for rest is 90–110 degrees and evacuation 110–180 degrees [115, 116]. The pubococcygeal line (line between the pubis and the tip of the coccyx) is the standard definition of the pelvic floor. Definitions of pelvic organ prolapse are based on how far below this line organs descend. Patients are asked during the exam to strain without evacuating contrast to assess pelvic floor descent (Fig. 57.9).

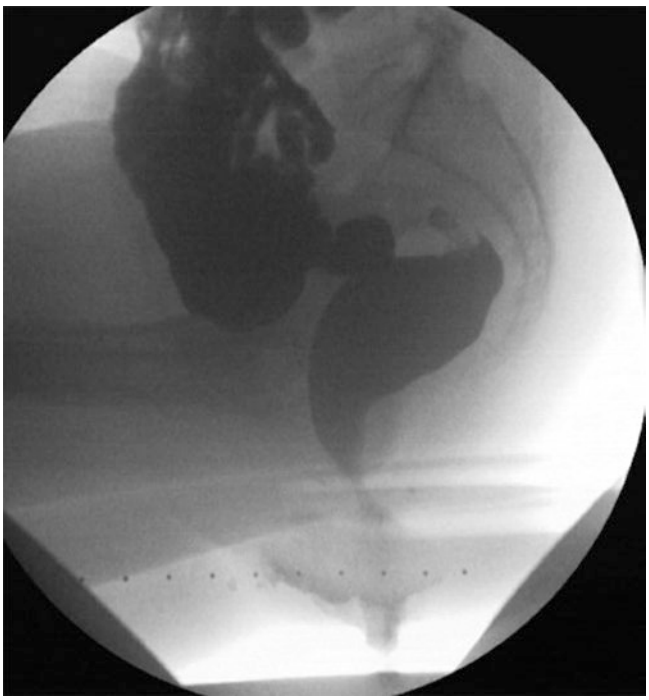

Fig. 57.9 Defecogram image at rest

Fig. 57.10 Defecogram with rectocele during evacuation. Arrow points to rectocele

Rectocele

A rectocele is the weakening of the tissues of the rectovaginal septum causing the anterior rectal wall to bulge into the vagina. Rectoceles less than 2–3 cm are normal in female patients and considered insignificant. Rectoceles can be seen in up to 93% of asymptomatic females [115]. The depth of the rectocele can be measured from the anterior border of the anal canal to the most anterior part of the rectocele (Fig. 57.10).

A rectocele is much better defined by defecography than by physical exam. A rectocele does not always interfere with evacuation and should be assessed post-evacuation to determine barium trapping. Large rectoceles must be associated with outlet dysfunction symptoms to be considered pathologic. Digitalization with pressure applied to the posterior vaginal wall or perineum is a common maneuver to help with evacuation of the rectocele [117, 118].

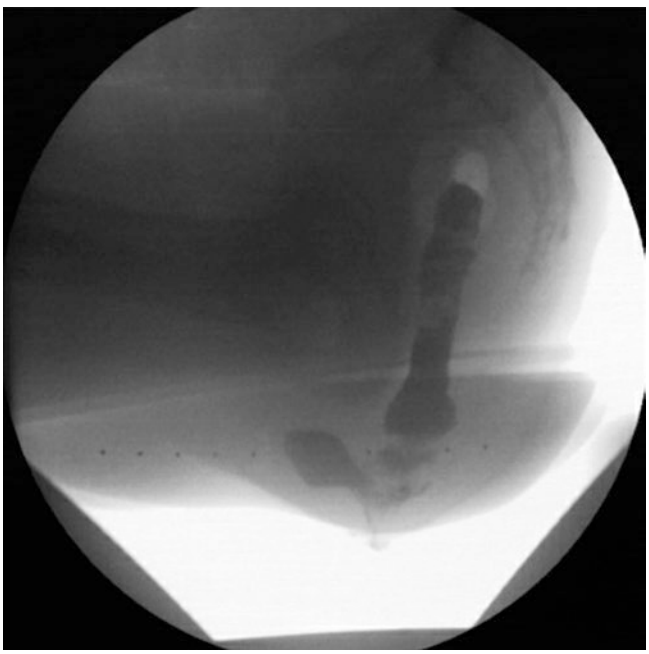

Fig. 57.11 Defecogram with internal prolapse

Intussusception/Prolapse

Occasionally on defecography the rectum can be seen to invaginate on straining. Intussusception is the unilateral or circumferential infolding of the rectum during straining (Fig. 57.11) [119]. Intussusception can be intrarectal, intra-anal, or external (complete rectal prolapse). The Oxford grading for rectal prolapse has five grades: Grades I and II do not descend into the anal canal, Grades III and IV descend into the anal canal but not protruding from the anus, and Grade V protrudes from the anus [113, 119, 120]. In a recent study, it was found that increasing grades of rectal intussusception are associated with increasing fecal incontinence but not constipation [120].

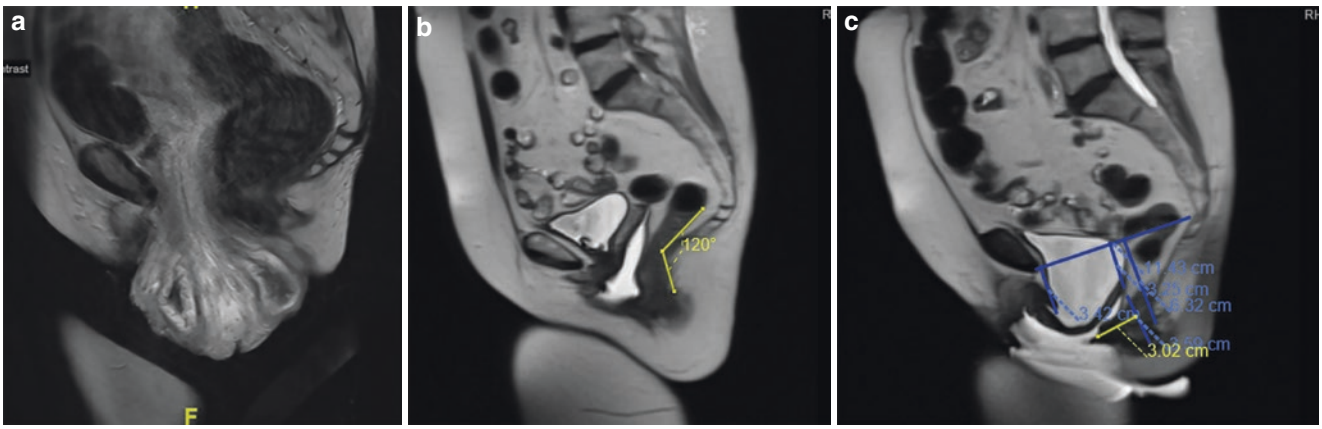

Fig. 57.12 (**a**) Sigmoidocele through vagina on MRI. (**b**) MR defecography at rest (and measurements). (**c**) MR defecography with rectocele (and measurements)

Enterocele/Sigmoidocele

An enterocele is a hernia of the small bowel between the rectum and vagina (pouch of Douglas). It is most common after a hysterectomy [121]. A sigmoidocele is a hernia of the sigmoid colon into the pouch of Douglas. These both are best seen during straining phase of defecography with oral contrast and cause symptoms of obstructed defecation. On normal defecography, bowel should not descend below the upper rectum.

Anismus

Anismus is the failure of normal relaxation of pelvic floor muscles during normal defecation. In a study evaluating the predictive value of impaired evacuation during defecography, it was found that 90% of patients who were unable to evacuate two thirds of a 120-cc contrast enema in 30 seconds had animus confirmed on further physiologic testing [122].

Pelvic Floor Descent

The pelvic floor descends normally during evacuation. This descent is usually less than 3 cm. This is measured by the descent of the anorectal junction during evacuation. Chronic straining and constipation can lead to abnormal descent of more than 3.5 cm. This can lead to hypermobility and stretching of muscles and nerves resulting in functional loss [123].

MR Defecography

MR defecography is similar to traditional defecography in that it takes images during the act of defecation. Before the exam, the vagina and rectum are filled with ultrasound gel. The patient is placed supine with knees slightly bent, and images are obtained during different maneuvers including defecation.

MR defecography allows for comprehensive structural and functional evaluation of the pelvic floor without radiation. The issue arises with the supine position of the patient, as patients do not normally defecate supine (they may find it very difficult) and some symptoms may not occur without the sitting position and gravity. This may limit validity of the findings of MR defecography (Fig. 57.12a–c) [124, 125].

A study from 2016, comparing MR defecography a traditional defecography, looked at 50 females who underwent both tests and compared the results of posterior compartment dysfunction (peritoneocele, rectocele, rectal prolapse, and anismus). In the study, they found no statistical significance in the tests and recommend that both tests can be used based on local availability and expertise. In difficult cases, both imaging modalities can be used to increase accuracy [125].

Dynamic Ultrasound

Defecography and MR defecography both have issues with radiation, cost, and accessibility in rural areas. They also require defecation of contrast material which can be embarrassing for the patient. Dynamic ultrasound removes these issues and has been shown to be a cheap, safe, well-tolerated dynamic assessment of the pelvic floor and allows visualization of anatomical and functional abnormalities and can visualize placement of tape and mesh [126, 127].

Dynamic ultrasound uses three separate probes (transperineal, transvaginal, and endoanal). The patient is given an enema prior to the exam for the endoanal ultrasound. They are positioned on the stretcher in dorsal lithotomy with hips flexed and abducted.

The transperineal portion is completed with a convex transducer positioned on the perineum from the mons pubis

to the anal margin with minimal pressure but maintaining good contact. Imaging is performed with the patient at rest, during maximal Valsalva maneuver and during pelvic floor muscle contraction, and the data is recorded as a cine loop which can be reviewed. This allows visualization of the entire puborectalis muscle and its attachment to the pubic rami. The transvaginal portion is performed in the same position with a biplane probe with a 360-degree rotational mechanical probe with minimal pressure as to not distort anatomy. This allows for imaging of the anterior and posterior compartments at rest, during maximal Valsalva and during pelvic floor muscle contraction. These images are recorded and saved for later review. The endoanal ultrasound uses the same probe as previously discussed in this chapter. The patient's position can be the same as the other tests or can be performed in left lateral decubitus. The images are recorded from the upper aspect of the puborectalis to the anal verge as previously described [127].

Dynamic transperineal ultrasound has been compared to standard defecography and MR defecography for evaluation of obstructed defecation. It has been shown that in experienced hands, dynamic transperineal ultrasound can more effectively diagnose peritoneocele, enterocele, and perineal muscle alterations and provides more information about the anterior and central compartments [128]. Some studies do show a lower detection rate of prolapse in transperineal ultrasound than defecography [129]. The three-dimensional transperineal ultrasound was also compared to two-dimensional endoanal ultrasound to look at anal sphincter defects and was found to have good agreement between the two modalities in detecting injuries [130].

A study looked at the accuracy of dynamic ultrasound (with three probes) compared to MR defecography in detecting rectocele, enterocele, intussusception, and cystocele. They blindly reviewed 68 females who underwent both tests. They found that dynamic ultrasound had a high negative predictive value and may serve as a screening tool for defecatory dysfunction, when normal, MR defecography can be avoided as abnormalities are unlikely [131].

Echodefecography

Echodefecography is a 3D dynamic ultrasound using ultrasound gel in the rectum to assess obstructive defecation. Patients receive an enema and then are examined in the left lateral decubitus position. Scan 1 is at rest without gel and visualized the anatomic integrity of the anal sphincters. Scan 2 is at rest/straining/rest without gel and evaluates muscle relaxation during defecation effort to demonstrate anismus. Scan 3 is at rest/straining/rest with rectal gel. This is repeated up to three times [132].

A prospective multicenter trial compared echodefecography to defecography in patients with obstructive defecation. They evaluated 86 women and found that it clearly demonstrates all the anatomic structures involved in defecation. Echodefecography is able to detect the same anorectal dysfunctions that defecography can detect, is minimally invasive and well tolerated, and avoids radiation [133].

Conclusion

Testing may be indicated for planning treatment in many patients with pelvic floor problems. Understanding how each study is done aids in determining which test(s) to order.

Evaluation of Constipation and Treatment of Abdominal Component

58

Kelly A. Garrett and James W. Ogilvie Jr

Key Concepts

- There are different subtypes of constipation requiring a careful history and selective diagnostic testing to elucidate.
- Most treatment algorithms of constipation begin with medical management.
- Abdominal constipation severely affecting quality of life may require surgical intervention.

Introduction

Constipation is a complex disorder. It is difficult to estimate its actual prevalence due to the different ways it has been defined or reported and the fact that many symptomatic people may not seek diagnostic testing or treatment. Chronic constipation has been estimated to affect approximately 15–20% of people in North America [1–3]. It is one of the most frequent gastrointestinal diagnoses made in outpatient clinics and is a common cause for referrals to gastroenterologists and colorectal surgeons. It accounted for approximately eight million annual visits to physicians in the United States between 2001 and 2004 [4]. A recent community healthy survey estimated the total direct health-care costs for patients with constipation were about $19 million per year [5].

Definition

In general, constipation has been defined as infrequent bowel movements; however, other symptoms such as excessive straining, hard or lumpy stools, a sense of incomplete evacuation or anorectal blockage, and the use of manual maneuvers to facilitate evacuation may be equally significant and maybe even more common [1, 6]. Symptoms that last less than a week are considered acute, whereas chronic constipation is defined by symptoms that persist for at least 3 months [7]. It is important to differentiate chronic constipation from other forms of functional bowel disorders. The Rome IV criteria categorizes disorders of chronic constipation into four subtypes: (a) functional constipation, (b) irritable bowel syndrome with constipation (IBS-c), (c) opioid-induced constipation, and (d) functional defecation disorders including inadequate defecatory propulsion and dyssynergic defecation (Table 58.1). If individuals have symptoms of chronic constipation for the last 3 months (with onset at least 6 months prior) and no organic gastrointestinal pathology, they can be categorized according to the Rome IV criteria [7, 8].

Etiology and Pathophysiology

Defecation relies on the formation of stool, motor function of the colon, and the muscles of the pelvic floor. Chronic constipation can be a primary disorder resulting from interruption at any portion of this pathway and can be categorized as normal transit constipation, slow transit constipation, and defecatory disorders. Slow transit constipation reflects colonic motor dysfunction, although it can also result from inadequate caloric intake [9]. Constipation can also be a secondary disorder due to diet, medications, endocrine disorders, or anatomic, neurologic, or psychosocial disease (Table 58.2). Patients can have a combination of both slow transit and defecatory dysfunction that may both need to be addressed.

Table 58.1 Rome IV criteria: constipation

Rome IV constipation subtype	Characteristics
Irritable bowel syndrome with constipation (IBS-C)	Predominant stool abnormality on days when they have abnormal stools is constipation (at least 25% of all stools Bristol types 1 and 2 and less than 25% types 6 and 7) Abdominal pain at least 1 day per week, where the pain is associated with at least two of the following: 1. Change in stool frequency – toward infrequent bowel movements 2. Change in stool form – toward harder stools 3. Related to defecation
Functional constipation (FC)	These patients do not fulfill the criteria for IBS Abdominal pain is absent or not predominant or occurs less than 1 day per week Must include two or more of the following: 1. Straining more than 25% of defecations 2. Lumpy or hard stools (Bristol stool type 1 or 2) more than 25% of defecation 3. Sensation of incomplete evacuation more than 25% of defecations 4. Sensation of anorectal obstruction/ blockage more than 25% of defecations 5. Manual maneuvers (digital assistance, support of pelvic floor) to facilitate more than 25% of defecations 6. Fewer than three spontaneous bowel movements per week
Opioid-induced constipation (OIC)	Diagnostic criteria similar to FC, but with the requirement that new or worsening symptoms of constipation occurred when initiating, changing, or increasing opioid therapy
Function defecation disorders (inadequate propulsion and dyssynergic defecation)	These patients must satisfy the criteria for IBS-C or FC but also demonstrate features of impaired rectal evacuation as demonstrated by two of the following three tests: 1. Abnormal balloon expulsion test 2. Abnormal anorectal evacuation pattern with anorectal manometry (or surface electromyography (EMG)) 3. Impaired rectal evacuation on defecography, but without structural lesions

Adapted from Lacy et al. [7]

Table 58.2 Factors associated with constipation

Medications (examples)	Opioids Anticholinergic agents Tricyclic antidepressants Calcium channel blockers Diuretics Bile acid sequestrants Calcium Iron
Mechanical	Colon cancer External compression Ischemic or diverticular strictures Endometriosis Inflammatory bowel disease Hirschsprung's disease Pseudo-obstruction
Metabolic	Diabetes mellitus Hypothyroidism Hypercalcemia Hypokalemia Hypomagnesemia Uremia Heavy metal poisoning
Myopathies	Amyloidosis Scleroderma
Neuropathies	Parkinson's disease Spinal cord injury or tumor Multiple sclerosis
Psychiatric	Depression Psychiatric illness Sexual abuse Eating disorder
Pelvic floor	Anal fissure Non-relaxing puborectalis Anal stenosis Pelvic organ prolapse
Other conditions	Degenerative joint disease Scleroderma Autonomic neuropathy Cognitive impairment Immobility Cardiac disease

Adapted from Bharucha et al. [10]

History and Physical

As with any patient, evaluation should begin with a thorough history and physical examination. When taking a history, it is important to understand what the patient means when reporting constipation. The history should include the duration of symptoms, frequency, and consistency of stools which can be aided by using the Bristol Stool Chart (refer to Fig. 56.2), the presence of excessive straining, feelings of incomplete evacuation, or need to use manual maneuvers in order to defecate. It is important also to obtain information on prior bowel habits, when bowel habits change, if a trigger can be identified, and what patients consider as normal. One should also be wary of identifying "alarm symptoms" such as sudden changes in bowel habits, unexpected weight loss, a family history of colon cancer, and rectal bleeding in the absence of bleeding hemorrhoids or fissure [10]. It should be noted if the patient has had a previous colonoscopy. A detailed medical and surgical history should be taken to exclude other organic causes as well as a complete medication list including over-the-counter medications, herbal supplements, and vitamins.

Physical examination should focus on the abdomen and the pelvic floor. Abdominal exam may be unremarkable but may also be significant for bloating and distention and should exclude any palpable masses. Anorectal and pelvic floor exam can be conducted in the prone position, left lateral position, and/or over the commode to exclude pelvic organ prolapse. On external anal exam, one can look for fissures, prolapsing internal hemorrhoids or engorged or inflamed external hemorrhoids, or evidence of full-thickness rectal prolapse. Digital rectal exam should focus on the presence of tenderness or palpable abnormalities such as a mass, stricture, impaction or rectocele, length of the anal canal, anal resting and squeeze tone, and ability to relax the pelvic floor muscles with straining. Anoscopy or rigid or flexible proctosigmoidoscopy can be performed in the office to look for any inflammation or other mucosal abnormalities such as solitary rectal ulcer.

Diagnostic Testing

A complete blood count (CBC) to look for anemia should be obtained if not recently performed. Thyroid-stimulating hormone and serum calcium should be performed when clinically indicated. Colonoscopy should be performed in patients with alarm symptoms or as required for age-appropriate screening [7, 11].

Testing for slow transit constipation or dyssynergic defecation is not justified in all patients presenting with constipation. Testing should be performed on a case-by-case basis and in general on patients who have not responded to trials of empiric therapy. In addition, providers may consider tailoring their workup based on patient's symptoms. If there is a suspicion for motility issues due to predominance of abdominal symptoms such as bloating and need to use large volumes of laxatives to have a bowel movement, one may choose to start with transit studies. In contrast, for patients with symptoms of outlet obstruction—the need to strain or use digital maneuvers—one may consider starting with manometry and defecography studies.

There are three techniques for assessing colonic transit: radiopaque markers, scintigraphy, and a colonic pH-pressure capsule. The simplest and most inexpensive method is using radiopaque markers. Patients ingest a gelatin capsule that contains radiopaque markers. Abdominal X-rays are then used to count the number of ingested markers in the abdomen. There is no standard way to perform this test, and there are different methods involving ingesting more than one capsule or getting one or more X-rays. In general, if a patient swallows one capsule and more than five (20%) of the markers are retained by day 5, slow transit constipation is diagnosed (Fig. 58.1) [12]. This is a reliable method; however, the number of retained markers has not been shown to correlate with symptom severity or quality of life (QOL) [13]. In addition, it is suggested that if markers are clustered at the rectosigmoid, this is suspicious for dyssynergic defecation. However, this has been challenged by several studies [14, 15]. Less widely used approaches are radionuclide gamma scintigraphy and wireless pH-pressure capsule. Scintigraphy tracks radioisotope movement from cecal instillation to defecation [12]. The wireless pH-pressure capsule determines when the capsule empties into the small intestine and thereafter into the colon by measuring pH. The SmartPill™ capsule also measures colonic motor activity which may be useful for discriminating among subtypes of chronic constipation. Motor activity may be greater in IBS or "painful" constipation than slow transit or "painless" constipation [16]. The benefit of these studies is that they can both also measure gastric emptying and small intestinal transit. Colonic scintigraphy is measured over 24–48 hours as opposed to 5–7 days for the radiopaque marker test which is beneficial for patients who cannot be off laxatives for a long time [17]. A large study comparing scintigraphy with the pH-pressure capsule and a smaller study comparing scintigraphy with radiopaque markers observed greater than 80% agreement between these techniques for discriminating between normal and slow colonic transit [18, 19]. Colonic manometry is another method that has been considered a standard diagnostic examination in pediatric patients. This study evaluates the intraluminal pressure activity of the colon and rectum by inserting a manometry catheter into the ileocecal junction through the anus. This test is invasive and not widely avail-

Fig. 58.1 Sitz marker study showing markers scattered throughout colon, consistent with abdominal constipation (slow transit constipation)

able, but it has been shown to help choose patients that would benefit from surgery by helping to distinguish between colonic neuropathy and myopathy [20]. This test may serve as an adjunct to current methods of assessing colonic function.

Pelvic floor function can be assessed by a variety of methods including anorectal manometry, balloon expulsion test, and barium and magnetic resonance imaging (MRI) defecography. Anorectal manometry provides a comprehensive assessment of the pressure activity in the rectum and anal sphincter region together with an assessment of rectal sensation, rectoanal reflexes, and rectal compliance. This can be used in combination with the balloon expulsion test to detect abnormalities during attempted defecation. Defecography provides information about anatomical and functional changes of the anus and rectum during defecation. This can be done seated on a commode with barium paste instilled in the rectum (also may be instilled in the vagina or orally) or in the supine position with MRI. Barium defecography or cine defecography has the advantage of simulating defecation in the normal posture; however, the techniques are incompletely standardized. There is limited reproducibility of the anorectal angle measurement; however, the significance of the anorectal angle is not always straightforward [21, 22]. In contrast, MRI defecography is performed in the supine position which is not the traditional position for evacuation; however, it is better for visualizing pelvic organ prolapse and bony landmarks which are necessary to measure pelvic floor motion [23]. These tests can be used alone or in conjunction to facilitate diagnosis of defecatory disorders.

Medical Management

Treatment should start by educating the patient and eliminating secondary causes of constipation. Once this is done, behavioral modification is one of the first steps in treatment. This includes increasing dietary fiber or considering the addition of a fiber supplement, increasing fluid intake, advising regular exercise, and allowing adequate time for bowel movements. A high-fiber diet increases stool weight and accelerates colonic transit time. Fiber supplements are divided into insoluble and soluble. Insoluble, non-fermentable fiber accelerates transit by increasing stool mass leading to direct stimulation of secretion and motility. Soluble, more fermentable fiber accelerates transit by hydrophilic properties and the osmotic effects of fermentation byproducts. A total of 20–30 grams per day of fiber is recommended, although bloating, distention, and flatulence can affect compliance. Patients with slow transit constipation and pelvic floor dysfunction are less likely to improve with fiber; therefore, fiber may not be a solution for all patients [10, 24, 25]. Although common sense supports increasing fluid intake, in a small study of healthy volunteers, consumption of extra fluid produced no difference in stool output [26]. Similarly, there is little evidence to support the role of exercise in improving constipation, but epidemiologic studies suggest that sedentary people are three times more likely to report constipation [27]. In addition, a recent meta-analysis of nine randomized controlled trials concluded that the real effect of exercise on constipation could not be definitely determined [28].

Laxatives are still commonly used as first-line therapy for constipation as they are cheap and readily available over the counter. Docusate sodium decreases the surface tension at the stool oil-water interface, allowing water to penetrate the stool. Although it is often recommended, there is limited data to support its use. In a double-blind, randomized, controlled trial of 170 patients with constipation, 100 mg of docusate sodium twice a day was less effective than psyllium [29]. Osmotic laxatives include polyethylene glycol (PEG)-based solutions, magnesium citrate-based products, sodium phosphate-based products, and non-absorbable carbohydrates (lactulose). These products work based on their hypertonicity by extracting fluid into the intestinal lumen to soften stools and accelerate colon transit. Side effects include dose-dependent abdominal cramping and bloating. A Cochrane review of ten randomized controlled trials concluded that PEG was superior to lactulose for improving stool frequency, stool consistency, and abdominal pain [30]. Among non-absorbable carbohydrates, lactulose and sorbitol have similar laxative effects, but lactulose was associated with more nausea in a randomized crossover study [31].

Stimulant laxatives include diphenylmethane derivatives such as bisacodyl and sodium picosulfate and conjugated anthraquinone derivatives such as cascara sagrada, aloe, and senna. This group of medications works by decreasing water absorption and stimulating intestinal motility and prostaglandin release [32–34]. The use of these laxatives is often limited by abdominal pain and diarrhea. In addition, these laxatives may be underused by physicians because of concerns that they can damage the colon when used long term. There has been concern about the possibility that stimulant laxatives, specifically anthraquinone laxatives, can induce permanent enteric nerve or muscle damage in the colon. This may be due in part to the development of melanosis coli, a brown pigment of the colonic mucosa that can occur within several months of regular use. This pigmentation is related to a substance called lipofuscin which is released during cellular apoptosis and contained in mucosal macrophages. Its functional significance is unknown, and it is completely reversible when laxative use is stopped [35]. There is no evidence to support the belief that stimulant laxatives are permanently harmful to the colon.

Secretagogues or prosecretory agents stimulate the net efflux of ions and water into the intestinal lumen, likely

accelerating transit and facilitating ease of defecation. Prosecretory agents available include lubiprostone which is a chloride-channel activator and linaclotide and plecanatide which are minimally absorbed guanylate cyclase-C agonists. In a 4-week randomized trial, lubiprostone was more effective than placebo in improving bowel symptoms in patients with chronic constipation. Nausea was the most commonly reported side effect [36]. Linaclotide and plecanatide are of similar efficacy and tolerability for treatment of chronic constipation [37]. Diarrhea is the most common adverse side effect which can require discontinuation of treatment in <5% of patients [38, 39]. Tenapanor, which was approved by the Food and Drug Administration in 2019, is a first-in-class, small-molecule inhibitor of the gastrointestinal sodium-hydrogen exchanger-3. This increases intestinal fluid volume and transit. This was shown to be superior to placebo in improving constipation symptoms in phase 2 and 3 studies [40, 41].

Serotonin (5-hydroxytryptamine, 5-HT4) agonists stimulate peristalsis and accelerate gastrointestinal transit. Tegaserod is a highly selective, partial 5-HT4 receptor agonist which was found to be superior to placebo in improving stool frequency and other constipation-associated symptoms in two randomized, double-blind, controlled trials [42, 43]. This medication was then taken off the market in 2007 due to concerns about a high rate of ischemic cardiovascular events inpatients on this medication. In April 2019, after re-examining the data that led to its withdrawal, the FDA approved the use of tegaserod in women younger than 65 years of age who do not have a history of ischemic cardiovascular disease and who have no more than one risk factor for cardiovascular disease [11, 44]. Prucalopride is a dihydrobenzofurancarboxamide derivative with greater selectivity for the 5-HT4 receptor compared with other 5-HT4 agonists [7]. In an integrated analysis of 6 randomized controlled trials, comprising 2484 patients with functional constipation, prucalopride was superior to placebo toward achieving at least 3 spontaneous bowel movements per week [45]. Prucalopride has also been shown to be superior to placebo in patients with opioid-induced constipation [46]. Common side effects include diarrhea and headache which normally disappear within the first week of treatment [6].

Opioid-induced constipation (OIC) is a consequence of the action of opioids on their receptors in the gastrointestinal tract. OIC occurs in 51–87% of patients receiving opioids for cancer and between 41% and 57% of patients receiving opioids for chronic non-cancer pain [47]. The key aspect of managing this subset of patients is early recognition. Initial management can begin with standard laxatives as well as addressing exacerbating factors. For patients who do not respond to a standard laxative regimen, second-line medications which consist of peripherally acting mu-opioid receptor antagonists (PAMORAs) should be considered. PAMORAs (i.e., nalexago, naldemedine, alvimopan, and subcutaneous methylnaltrexone) alleviate the symptoms of OIC by blocking the mu-opioid receptors within the gastrointestinal tract. These medications do not cross the blood-brain barrier, so they maintain central analgesia and minimize withdrawal symptoms. A systematic review and meta-analysis of 27 randomized controlled trials found PAMORAs more effective than placebo for the treatment of OIC. Naloxone and naldemedine were found to be the most efficacious treatments for OIC with naloxone being the safest [48].

Elobixibat is an inhibitor of the ileal bile acid transporter. This medication induces a state of bile acid malabsorption, increasing bile acid in the colon, thereby leading to increased stool frequency and looser stool consistency. In a randomized, double-blind, placebo-controlled, phase 3 trial conducted in Japan, researchers found that elobixibat resolved constipation in the short term and was well tolerated with both short-term and long-term treatments [49]. This drug is currently only approved in Japan for the treatment of chronic constipation.

Surgical Options for Slow Transit Constipation

When a patient presents for surgical consideration of abdominal or slow transit constipation, the ultimate question to consider is whether or not constipation is truly refractory to medical management. Unfortunately, as opposed to other chronic medical conditions, there are no existing standard definitions or algorithms to assist in decision-making whether a patient has reached a medically refractory state. Likewise, there is currently no consensus on which drugs, their dosages, or duration of use that would assist clinicians trying to decide if surgical management should be recommended [50]. It is therefore not surprising that as a result of the functionality of the disease process and the nature of surgical retrospective studies, some have advocated for a very cautious surgical approach or even none at all [51, 52]. Nevertheless, the number of colectomies for constipation has marginally increased in the United States during the early 2000s according to a Nationwide Inpatient Sample study [53]. Therefore, it is important for the gastroenterologist and surgeon to work together planning an individualized treatment approach, particularly if surgery is contemplated.

Abdominal Colectomy

The simple rationale behind abdominal colectomy with ileorectal anastomosis is to decrease the colonic transit time of stool resulting in more liquid contents delivered to the rec-

tum. This leads to easier evacuation and a noticeable increase in stool frequency. Since the first reports of colectomy for constipation over 100 years ago, retrospective surgical series have attempted to identify which subset of patients may benefit from surgery. The first step in proper selection is identification of constipation. As previously mentioned earlier in this chapter, typically this is done via a colonic transit study. As mentioned above, it cannot be surmised that a more abnormal transit study equates to worsening constipation or in turn improved outcomes following colectomy. Indeed, a study of 159 patients after colonic transit study found no correlation between location or number of retained markers and symptom severity [54]. Symptomatology does not show direct correlation with transit times, nor does success after surgery [55, 56]. Transit studies may also be limited by their reproducibility. In a study of 51 patients with chronic constipation in which two separate transit studies were performed, 31% had disparate findings on their second study [15]. When translated into surgical results, those with two abnormal tests that confirmed slow transit constipation were significantly more likely to have a successful outcome following surgery. Colonic transit studies should therefore be utilized mostly to identify those with normal transit and not as a marker of those who would most likely succeed after surgery.

Selecting patients for abdominal colectomy should also include an evaluation for any concomitant pelvic floor dysfunction. Some authors have suggested that of those with chronic constipation, the majority will have some degree of outlet obstruction [57]. While an adequate pelvic floor physical examination will often identify most patients with pelvic floor dysfunction, additional testing such as anorectal manometry or defecography may be used to identify other contributors to constipation [58]. This becomes critical because smaller subsets of patients with co-existing outlet obstruction demonstrated by either surface electromyography or defecography prior to surgery were much less likely to have satisfactory results after surgery [59, 60]. Abnormal manometric findings of rectal hyposensitivity have also been associated with decreased satisfaction after surgery [56, 61]. It should also be noted however that the mere presence of an abnormal defecography or manometry finding does not preclude surgery, as many findings are either asymptomatic in nature or a byproduct of the constipation itself. As Reshef et al. demonstrated in a study of 41 patients with abnormal test finding that suggested obstructed defecation, some patients may still have satisfactory results after colectomy and ileorectal anastomosis, and therefore all findings must be taken in context as part of careful patient selection [62].

An additional consideration in patient selection is the presence of simultaneous gastric or small bowel dysmotility. In smaller retrospective series, those with delayed gastric emptying consistently had less successful outcomes following total colectomy [63–65]. When evaluating outcomes based on the results of small bowel studies, Zmora et al. identified a cohort of 17 patients and found no difference in success rates of total colectomy based on small bowel transit findings [66]. Nevertheless, it is generally recommended that prior to considering surgery, a full enteric motility workup be considered.

Another area that may enter into patient selection for surgical consideration but difficult to tease out is the role of the underlying mental health issues, psychiatric disease, and/or history of sexual trauma that may accompany abdominal constipation. Psychologic disturbances and psychiatric disease have been associated with chronic constipation for decades. Psychiatric assessment has revealed higher levels of anxiety and depression compared to matched controls [67]. While these factors, including a history of sexual abuse, do not guarantee an unsuccessful outcome, they may help predict the likelihood of additional abdominal complaints after surgery [68]. A formal psychiatric evaluation may not be indicated in every situation; however, cognitive behavioral therapy with trained psychologists can play an important role in helping patients improve their behavior and coping mechanisms associated with functional disorders or chronic conditions such as constipation, especially prior to surgery.

Appropriate patient selection for abdominal colectomy, as for any surgery, but especially for constipation, centers on appropriate preoperative counseling and managing expectations. It should be emphasized that all functional bowel disorders represent a spectrum of disease. For example, while both slow transit constipation and irritable bowel syndrome with predominant constipation (IBS-C) have a decrease in the frequency of bowel motions, the symptoms of pain and bloating have often been attributed mainly to IBS-C (Fig. 58.2). Nevertheless, the latest Rome criteria highlight that even pain and bloating will be present to a degree in cases of functional constipation, albeit not the predominant symptoms [7]. If they are, surgery should be cautiously entertained but not abandoned [13]. Recent retrospective surgical series have consistently identified preoperative abdominal pain and bloating, via SF-36 questionnaires, Wexner Constipation Scores, or Gastrointestinal Quality of Life scores to be present in preoperative patients [69–71]. In each of these series, symptoms were significantly improved post-surgery. The degree of improvement in abdominal pain that can be expected after surgery is not clear. In one study utilizing postoperative telephone interviews, 41% had ongoing abdominal pain, yet 81% were "at least somewhat pleased" with the frequency of bowel motions [72].

With these caveats in mind, a reasonable multidisciplinary approach to patient selection was published by Dr. Staller and colleagues (Fig. 58.3) [13]. If surgery is to be considered, the 2016 ASCRS Clinical Practice Guidelines gave strong recommendations (based on low-quality evidence) that a total abdominal colectomy with ileorectal anastomosis

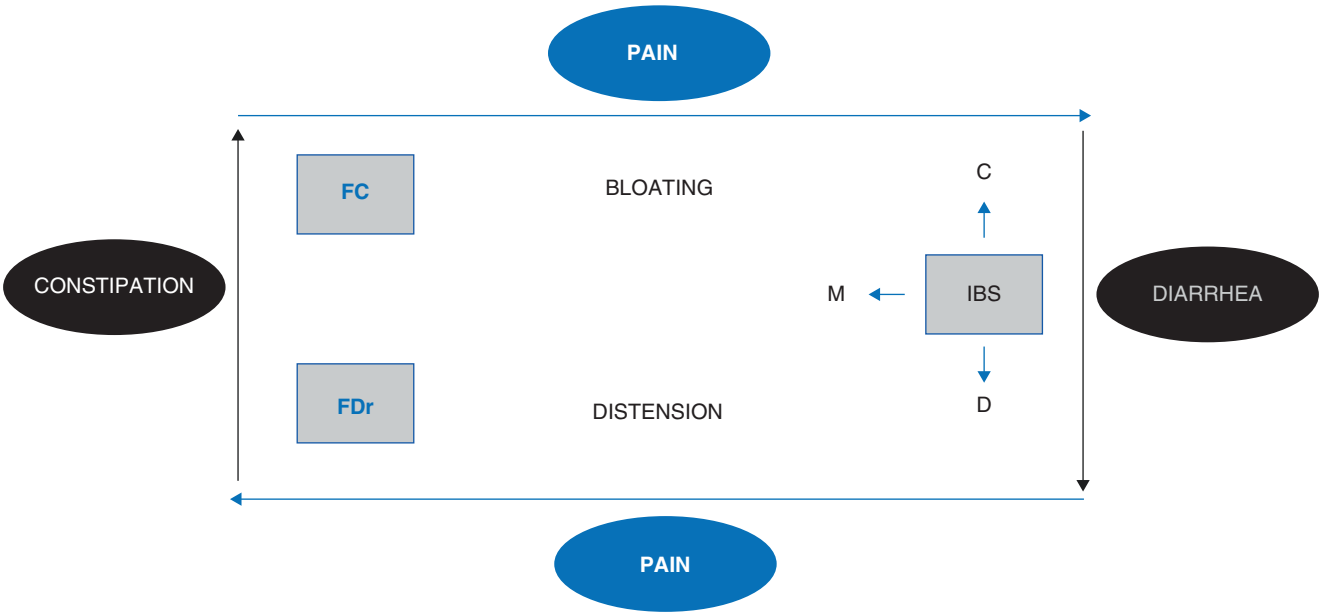

Fig. 58.2 Spectrum of functional bowel disorders. FC functional constipation, FDr functional diarrhea, IBS-C irritable bowel syndrome with predominant constipation, IBS-D irritable bowel syndrome with predominant diarrhea, IBS-M irritable bowel syndrome with predominant irregular bowel habits (mixed D/C). (Modified from Lacy et al. [7])

is the procedure of choice [73]. Likewise, a 2017 dedicated review by the Association of Coloproctology of Great Britain and Ireland concluded that colectomy may benefit some but again cautioned that insufficient evidence exists to guide adequate patient selection [74]. Although the abdominal colectomy has been best studied and recommended by these associations, it should be noted that multiple centers have reported small series involving segmental colon resections based on preoperative transit studies that have identified certain locations to be more abnormal than others [56, 75]. Although the tailored approach of a lesser degree of colectomy may sound appealing, it is hampered by the accurate isolation of the certain "diseased" segment, the lack of larger data sets, and the number of reported treatment failures post-segmental colectomy [51].

In appropriated selected patients, long-term results following total abdominal colectomy are satisfactory. After a median of almost 11 years, Zutshi et al. found that 77% of respondents remained pleased with the results after surgery [76]. The most frequent morbidity was small bowel obstruction (20%, 8 of 14 who required repeat surgery), although 90% of cases were done in an open fashion. After a median of 16 years, Patton et al. also reported high satisfaction, although again noting a 21% rate of small bowel obstruction requiring admission. Detailed investigations into bowel frequency have revealed the majority (41%) of patients had between 1 and 3 bowel motions a day, albeit 8 of 17 remained on laxatives. Small numbers (18%) had 7–10 bowel motions/day and fewer (7%) with >10 per day [77]. Therefore, it is not surprising that 29% reported moderate incontinence and 21% had severe incontinence as graded by the St. Mark's incontinence score.

Worries over incontinence and diarrhea after total colectomy have prompted some investigators to modify the classic ileorectal anastomosis by sparing the ileocecal valve via an anti-peristaltic cecorectal anastomosis (double-stapled anastomosis from rectal stump to cecum). Others have endorsed a cecorectal anastomosis with colonic bypass (without colectomy) or a side-to-side anastomosis between the ascending colon and rectum (Jinling procedure) [78–81]. Despite reporting satisfactory results, there are few comparative studies looking at these technical variations. Xie et al. compared 20 patients who had abdominal colectomy with anti-peristaltic cecorectal anastomosis to 35 who had standard ileorectal anastomosis and found no difference in postoperative outcomes including Wexner Constipation scores, Cleveland Clinic Incontinence and Constipation scores, as well as Gastrointestinal Quality of Life scores [71].

Less Standard Approaches

While the diagnosis of slow transit constipation implies some degree of a functioning rectum, a small number of patients may present with dysfunctional bowel that continues down through the rectum. In these rare situations where constipation is combined with some degree of megarectum or rectal inertia, colectomy with ileorectal anastomosis may prove inferior. If a formal diagnosis of megarectum (dilation of >6.5 cm at level of pelvic brim as seen on contrast enema) is made, then an abdominal colectomy has been associated with poorer outcomes, especially in terms of recurrent constipation [82]. In such cases, there are small series suggesting restorative proctocolectomy with ileal pouch anal anastomosis (IPAA) may improve quality of life, but even in one small series of 15 patients, 13% underwent eventual pouch excision [83, 84]. It is imperative to ensure that the anus and/or pelvic floor relax appropriately before considering a pelvic pouch. The ASCRS Clinical Practice Guidelines Committee warns that even in cases of refractory constipation, available studies do not justify IPAA, and this should only be offered after all other options have been exhausted [73].

Less Invasive Surgical Alternatives

In lieu of bowel resection for refractory constipation, the principle of regular colonic irrigation has been employed either retrograde via a transanal delivery system or antegrade via an appendicostomy or other conduit (antegrade colonic enemas, ACE). Transanal irrigation (TAI) has been successful for patients with neurogenic constipation or obstructed defecation and has been expanded to chronic refractory constipation [85, 86]. In one study of 102 patients with idiopathic constipation, using 500–1000 mL of water delivered ~3×/week, 63% were moderately or much improved after 12 months, and 53% continued to perform irrigations [87]. Other studies have found lower success rates (34–45%) within the subgroup of chronic constipation [85, 88]. Regardless, successful acceptance of this form of treatment requires appropriate training and follow-up as discontinuation rates can be high [89].

Given the relative success of ACE in the pediatric population, it has been used at various centers in the adult population as well. A 2016 systematic review identified 209 patients who had an ACE for constipation. After a median of 39 months, 68% were deemed to have a successful outcome, despite the lack of validated outcome measures in the majority of studies [90]. Few studies define success—other than ongoing usage of the ACE. A Dutch cohort found only 37% were successful using the ACE and measuring long-term quality of life, the results were no different than controls [91]. Moreover the need for surgical revision for stenosis and leakage remains high, even at specialized centers where reoperation rates approach 90% [92]. As a result, the ASCRS practice guidelines warn that this is not a common alternative and should be reserved for only highly selected, motivated patients [73].

A more recent, intriguing minimally invasive option for slow transit constipation is the expanding use of sacral neu-

romodulation (SNM). Physiologic data have shown that stimulation of the S3 or S4 nerve root will increase the transit and contractility of the distal colon [93]. Despite the current lack of approval by the US Food and Drug Administration, multiple centers outside the United States have reported their retrospective experience with this modality. Unfortunately, recent clinical data with longer follow-up have not been as promising as initial results with success ranging from 5% to 30% [94–96]. One drawback looking at studies of SNM for constipation is that all constipated patients are grouped together. A more rigorous prospective study grouping patients with similar constipation (i.e. abdominal in one group and pelvic in another) may provide a better idea of who would benefit. The indiscriminate grouping of constipated patients may help explain why SNM studies have failed to find predictors that may identify the small percentage of potential responders [93].

Ileostomy creation for slow transit constipation may be reasonable in the setting of significant fecal incontinence, increased operative risk, or those adverse to a colectomy. All retrospective series suggest ileostomy is a reasonable alternative either as a salvage maneuver after complications (diarrhea, incontinence) related to abdominal colectomy or as a final resort when other non-surgical modalities have failed [97]. A 2018 retrospective review from St. Mark's in the United Kingdom reported on 24 patients who underwent an ostomy for refractory constipation [98]. Only 59% responded to post-surgical questionnaires to measure quality of life, but they found 64% were satisfied with the ostomy despite a lower than average health-related quality of life and 20% reoperation rate. Similar reoperations rates (29%) for stomal retraction and hernia have also been reported from other institutions [99]. While surgeon familiarity with ostomy creation may allow better navigation of the associated complications, there still remains a paucity of studies to guide clinicians on appropriately patient selection.

Conclusion

Constipation can present with a myriad of symptoms. A thorough history and physical examination is important. Diagnostic treatment is not always necessary but can help differentiate between subtypes of constipation. Initial treatment should begin with fiber supplementation, dietary manipulation, behavioral modification, and over-the-counter or prescription laxatives. If patients with constipation fail medical management, surgical treatment may be considered.

Treatment of Difficult/Obstructive Defecation

59

Massarat Zutshi and Lucia Camara Castro Oliveira

Key Concepts

- Obstructed defecation syndrome is a subtype of constipation wherein patients usually complain of straining; incomplete, unsuccessful, or painful evacuation; bowel infrequency; abdominal pain and bloating; and the possible need for digitation.
- Initial management is lifestyle advice, laxatives, and bowel retraining programs, including biofeedback and psychological support.
- Diagnostic testing may point to a diagnosis, but clinical correlation should always be used.
- Dyssynergic defecation is a clinical diagnosis and requires knowledge of anatomy and physiology for management.
- Patients with overt rectal or anterior compartment prolapse and symptoms of obstructed defecation should be managed surgically.
- Rectoceles, when symptomatic, require a surgical option.
- Enteroceles and sigmoidoceles need a multimodal approach for effective symptom relief.

Introduction

As the general population is aging in most of the occidental world, pelvic floor disorders are increasingly seen, especially within the elderly female population [1]. The effects of a lifetime of damage to the pelvic floor such as from parity, obesity, and surgical trauma to the pelvic ligaments may directly lead to evacuation and voiding disorders. In the USA, 16% and 9% of women, respectively, will experience bladder or bowel incontinence. Pelvic organ prolapse affects 3% of women [1]. Constipation is a general term that involves a complex variety of clinical scenarios, commonly divided into three major groups: colonic inertia (abdominal), pelvic (obstructed defecation), and constipation with normal transit time associated with irritable bowel syndrome. In this chapter, we will discuss patients with pelvic constipation and obstructed defecation symptoms.

Physiology of Defecation

The process of defecation is determined by complex and multifactorial mechanisms, involving the integration of somatic and visceral functions, under the control of the central nervous system [2]. Therefore, there is an interaction between the brain, spinal cord, enteric neurons, and the muscle of the colon, rectum, anus, and pelvic floor. The structures that require coordination are dependent on conscious control. The defecation process is very complex and not very well understood.

Defecation is triggered by the entry of feces into the rectum as a result of the peristaltic movements of the colon. As the peristaltic movements increase, the rectum receives a larger quantity of feces, thus triggering the defecation reflex. Involuntary passage of feces and gas are controlled through the voluntary contraction of the external sphincter muscle and the puborectalis muscle and the change in the anorectal angle. At the appropriate time, the defecation reflex initiates the process of elimination of the rectal contents, causing the abdominal muscles to contract, the pelvic floor to relax, and the anal canal angle changes, opening it and allowing the passage of feces.

Definition and Etiology

Individuals who present with a clinical condition of difficult evacuation are frequently labeled as being constipated although they may have a normal transit. As constipation is a poorly defined symptom, an international working group standardized its meaning creating a consensus document frequently referred to as the Rome Criteria. Using common symptoms described by the patients, this consensus usually requires two or more complaints for at least 12 months without the use of laxatives to qualify. According to the Rome IV criteria [3], functional constipation must include ≥2 of the following symptoms (refer also to Table 59.1):

1. Straining during >25% of defecations
2. Lumpy or hard stools in >25% of defecations
3. Sensation of incomplete evacuation >25% of the time
4. Sensation of anorectal obstruction/blockage >25% of the time
5. Manual maneuvers to facilitate defecation >25% of the time
6. Less than three bowel movements per week

Dyssynergic Defecation

Obstructed defecation as a result of a paradoxical contraction or inadequate relaxation of the pelvic floor muscles during attempted defecation and/or inadequate propulsive forces during attempted defecation can occur in up to 40% of all constipated patients [4]. This condition has been variously named dyssynergic defecation, anismus, or paradoxical contraction of the puborectalis. Patient complaints are dominated by a feeling of incomplete evacuation and excessive straining. Physiological testing in these patients shows pathological patterns in inappropriate contraction of the pelvic floor muscles or incomplete relaxation of the anal sphincter or a combination of both [5].

This functional obstructed defecation syndrome is clinically defined by either clinically observing nonrelaxation of the puborectalis or paradoxical contraction of the puborectalis at the anorectal junction during Valsalva or evacuation. This is best done clinically with a digital rectal examination [6]. Testing includes anorectal manometry and/or cinedefecography.

Dyssynergic defecation can be categorized into four types based on anorectal manometry (see Chap. 57). This utilizes the patient's ability to generate an adequate pushing force and the type of sphincter contraction.

Obstructed defecation symptoms may also be a consequence of a structural abnormality within the pelvis such as a rectocele, enterocele, and sigmoidocele. In addition, internal and overt prolapse can lead to obstructive defecation symptoms.

Table 59.1 Physiological and imaging testing for obstructed defecation syndrome

Test	Purpose	Message
Anorectal manometry/ high-resolution anal manometry (HRAM)	Measurement of pressures in the anal canal Assessment of the rectoanal inhibitory reflex (RAIR), rectal sensitivity and compliance Assessment of anismus	Resting pressure = function of the internal anal sphincter Squeeze pressure = function of the external anal sphincter Loss of the reflex typically in Hirschsprung patients HRAM: Color differentiated waveform
Cinedefecography	Evaluation of the dynamic of evacuation after filling the rectum with a barium paste and the bowel with barium and/or the vagina with jelly	Evaluation of rectocele, enterocele, internal prolapse, perineal descent, anorectal angle
Echodefecography	Dynamic ultrasonography evaluation of the anal canal. Evaluation of rectocele, enterocele, internal prolapse, perineal descent after filling the rectum with ultrasound gel	Judgment of the integrity of sphincter muscles (defect?) Hypertrophy of the internal anal sphincter? Structural abnormalities
Colonic transit time study with radiopaque markers	Evaluation of the pattern of evacuation and demonstration of retention of the radiopaque markers	Diffuse spread of radiopaque markers typically for STC Collection of markers in the pelvis as sign for ODS
MR defecography	Functional judgment of the pelvic floor and the internal organs and their mobility	Structural substrate (e.g., rectocele) or only functional disorder (e.g., anismus)
EMG of the pelvic floor	Judgment of the motor unit potentials (MUP) Interference pattern	Loss or alteration or signs of denervation or reinnervation; Malfunction of muscle groups (e.g., anismus)
Pudendal nerve terminal motor latency (PNTML)	Function of the nerve supplying the pelvic floor	Useful for prognosis, if surgery is planned

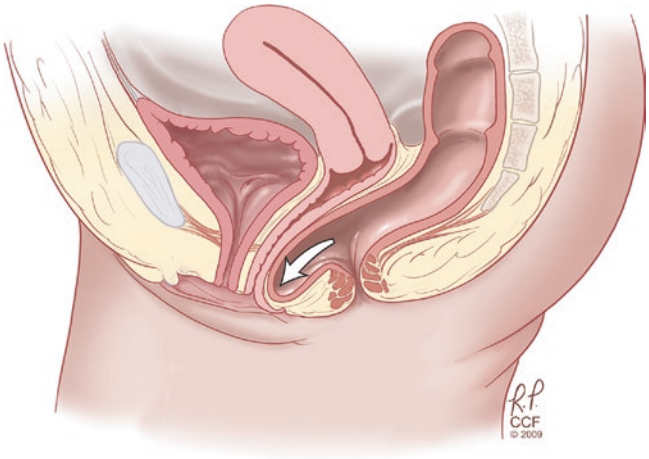

Fig. 59.1 Rectocele: Invagination of the anterior wall of the rectum into the vagina. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 1999–2020. All Rights Reserved)

Rectocele

A rectocele is a herniation of the rectal wall typically into the vagina (Fig. 59.1). Risk factors for developing a rectocele are age, obesity, obstetric injury, and/or multiple vaginal deliveries. On cinedefecography, a rectocele is a bulging of the rectal wall into the vagina. An observation regarding its size and whether the rectocele empties with defecation with or without digitation can help to guide treatment. Radiologically, rectoceles are graded as small (<2 cm), moderate (2–4 cm), and large (>4 cm) based on size [7]. Non-emptying or emptying with digitation are those that are considered for a surgical option based on symptoms.

Enterocele

On defecography, an enterocele is classified as presence of the small bowel between the rectum and vagina, reaching lower than the upper third of the vagina during the evacuation effort (Fig. 59.2). A first-degree enterocele lies above the pubococcygeal line. A second-degree enterocele is that which lies below the pubococcygeal line but above the ischiococcygeal line, and a third-degree enterocele lies below the ischiococcygeal line. Herniations of the peritoneal sac with other organs/structures contained can result in peritoneoceles, omentoceles, sigmoidoceles, and enteroceles. These can be graded as small (<3 cm), moderate (3–6 cm), and large (>6 cm) by measuring the largest distance between the pubococcygeal line and the most inferior point of the sac on cinedefecography [7] or dynamic MRI.

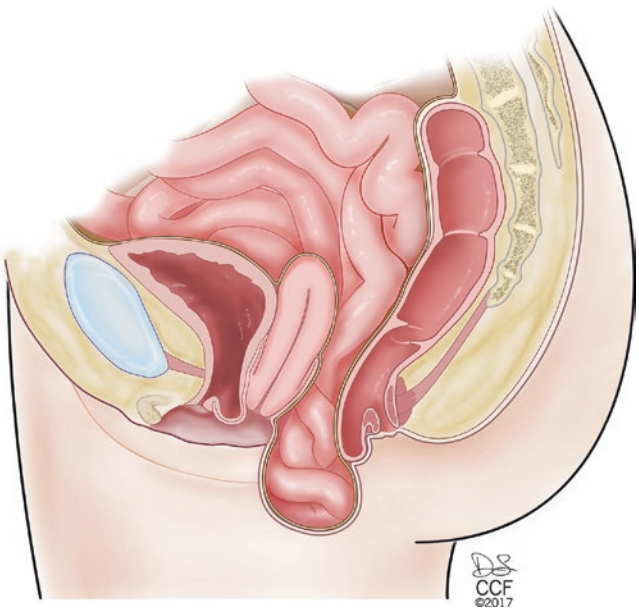

Fig. 59.2 Anatomical depiction of an enterocele. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 1999–2020. All Rights Reserved)

Internal Prolapse

Internal or occult rectal prolapse or rectal intussusception is a funnel-shaped infolding of the rectal wall that occurs during defecation. This infolding does not protrude out the anus.

Rectal Prolapse

Rectal prolapse is a circumferential full-thickness intussusception of the rectal wall with protrusion beyond the anal canal.

Scoring Systems

The Constipation Severity Instrument (CSI) [8] is a tool consisting of 78 items which aims at identifying and quantifying different subtypes of constipation. Another scoring system worth mentioning is the obstructed defecation syndrome score (ODS) [9] which has been prospectively validated. To assess the quality of life of constipated patients, the Constipation-Related Quality of Life (CRQOL) is a statistically validated questionnaire [10]. For patients with symptoms of both the anterior and posterior pelvic compartments, the Pelvic Floor Distress Inventory (PFDI) utilizes a pelvic

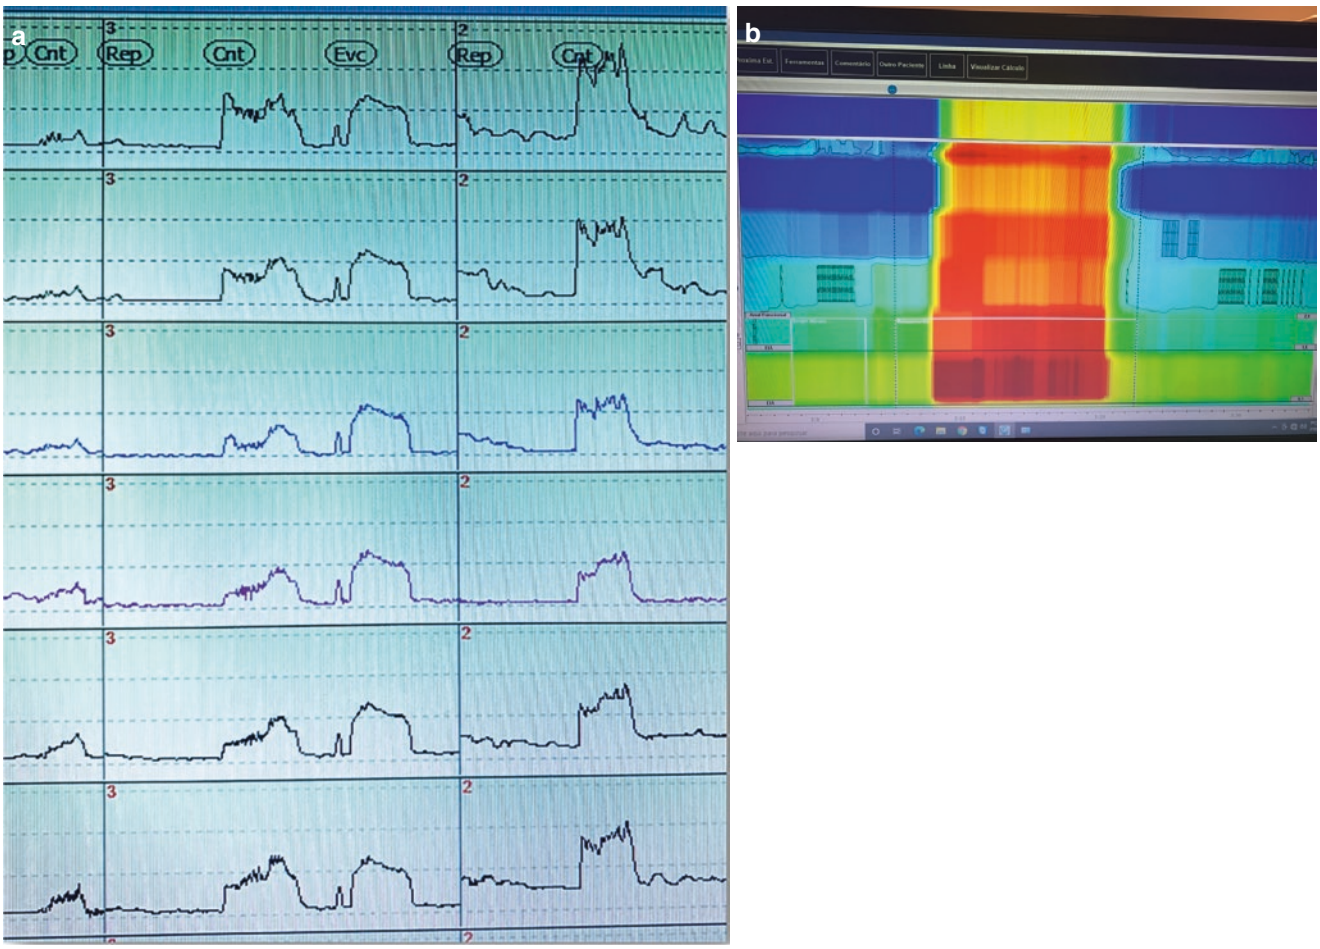

Fig. 59.3 (**a**) Water perfused anal manometry with patient simulating evacuation (bearing down) with non-relaxation of the puborectalis. (**b**) High-resolution manometry when patients bear down with non-relaxation of the puborectalis

organ prolapse score and a Colorectal-Anal Distress Inventory (CRADI) score [11].

It is essential to evaluate the number of evacuations, stool consistency, presence of mucus or blood in the stool, evacuation pain, sensation of incomplete evacuation, and the necessity of digital maneuvers to aid in defecation. It should be noted that most patients with dyssynergic defecation have greater difficulty evacuating soft stool. Detailed information about laxative and diet habits must also be obtained. Other bowel problems (e.g., irritable bowel syndrome, cancer, celiac, and diverticular disease) should be considered in patients that have symptoms such as abdominal pain particularly if located in the left lower quadrant. Abdominal bloating and recent altered bowel habits may also be related to other bowel disorders. Painful evacuation can be present in patients with anorectal inflammatory pathologies.

Physical exam should include the inspection of the anorectal area in order to exclude rectal tumors, anal stenosis, internal prolapse, thrombosed hemorrhoids, or anal fissures. A complete proctologic exam may reveal the presence of melanosis coli (which indicates chronic abuse of laxatives), solitary rectal ulcer, rectal prolapse, descending perineal syndrome, and rectoceles. The presence of fecal impaction requires further investigation in the elderly and children.

Testing for Obstructed Defecation Syndrome

Although a medical history and physical examination may provide an adequate evaluation of patients with symptoms of obstructed defecation, anorectal physiology testing and imaging modalities may aid in defining functional situations from a structural abnormality. Testing may also be helpful in planning a surgical option [4, 8, 12–15]. Anorectal manometry (Fig. 59.3), static and dynamic endoanal ultrasound (Fig. 59.4), colonic transit study (Fig. 59.5), cinedefecography [7] (Fig. 59.6), and electromyography and pelvic MRI (Fig. 59.7) are commonly utilized tests (Table 59.1).

Treatment of Obstructed Defecation

Treatment is individualized and based on a detailed history and physical with additional testing as needed. An algorithm is presented in Fig. 59.8 as a guide to possible therapy.

Treatment of Obstructed Defecation Syndrome Due to Puborectalis Pathology

A tight or dysfunctional puborectalis or levator ani muscle can give rise to dyssynergia leading to paradoxical contractions as described by the Rome IV criteria. The incidence is about 4.6% in patients without IBS [9]. These patients are diagnosed clinically and tested as described above. Many of these patients may have concurrent constipation and may need bowel management as part of their treatment. This is especially problematic as one may lead to the other; however both problems need to be addressed simultaneously for effective results.

An honest discussion with the patient, highlighting the etiology and allaying fears that patients may have, is the initial step. It is important to emphasize that this abnormal muscle contraction can be "unlearned." The next step is physical therapy with a trained pelvic floor physical therapist. Often the patient returns to the referring physician, and when questioned it becomes apparent that the physical therapy was actually focused on Kegel exercises, which is the exact opposite of the intended treatment; therefore, it is important to question the patient on what they actually did during physical therapy. In order to teach relaxation of the pelvic muscles, physical therapy may use sensory biofeedback, electrical stimulation, visual manometry, and simulated defecation techniques to aid the patient in understanding when their muscles are paradoxically contracting [10]. This should involve diaphragmatic breathing and relaxation for efficient relaxation. Patients should continue with physical therapy for multiple visits before considering this therapy a failure. In patients with no access to a trained physical therapist, home-based physical therapy may be offered [16]. If physical therapy is unsuccessful, the next available options are either injections of botulinum toxin A (BOTOX™) or electrogalvanic stimulation (EGS).

EGS is an office procedure where a rectal probe attached to an electrical stimulating device is inserted into the anal canal. The muscle is stimulated transanally at different current amplitudes using galvanic current as tolerated by the patient with an aim to fatigue the muscle. Multiple treatments are required to achieve the desired result [17]. Recommended treatment is three times a week for the first week, two times for the next week, and once a week for several weeks. Maintenance treatments as indicated are provided based on response to treatment and patient tolerance. Most studies have not shown a greater result of EGS over biofeedback, and this may be in part due to nonstandardization of the method of administration. At the Cleveland Clinic,

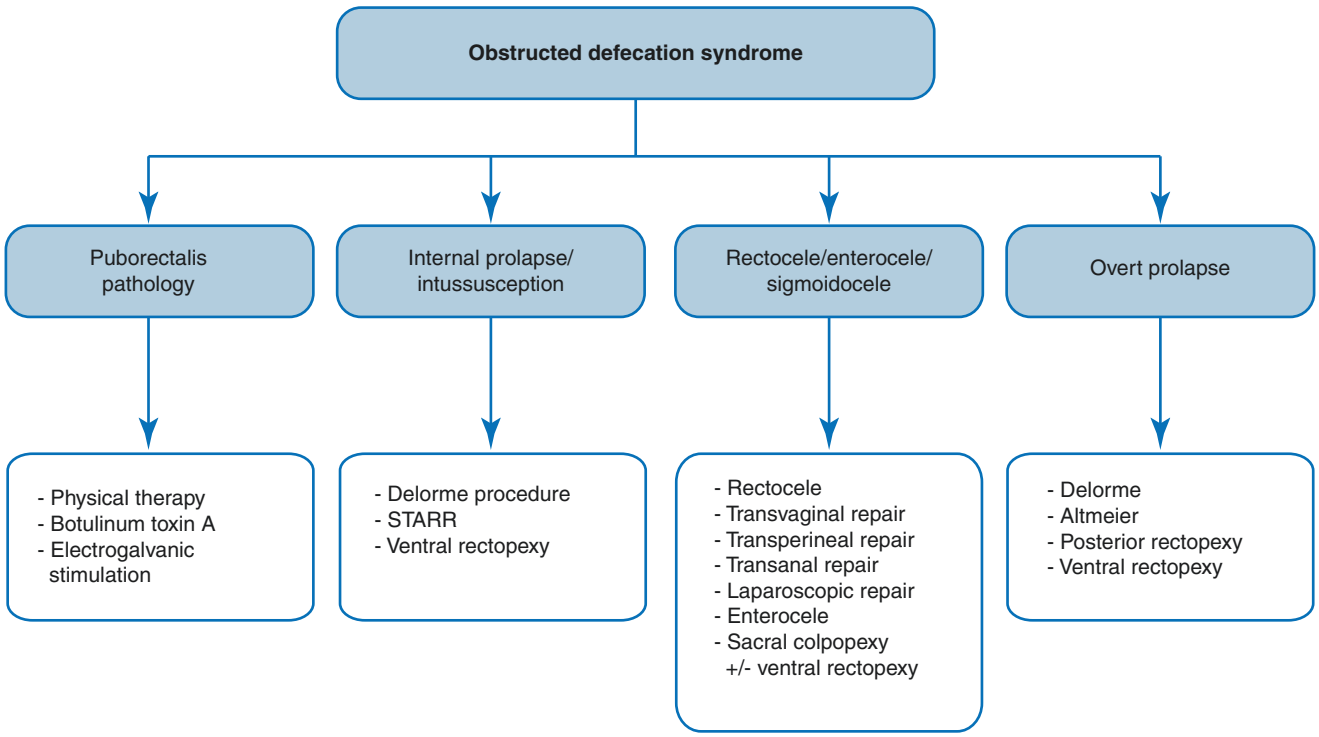

Fig. 59.8 Treatment algorithm for patients with obstructed defecation

EGS is administered over 1 hour and at the frequency described above with anecdotal good results in a selected population. The adverse effects of the treatment are increased pain, rectal irritation, and bleeding. EGS treatment results are varied and few centers offer this treatment.

Botulinum toxin A injections may be given to patients with refractory symptoms. Botulinum toxin A acts by binding to nerves which use acetylcholine. This blocks its release, so the nerve is not signaled to contract and leads to paralysis. The process is reversible and results in temporary paralysis of the muscle fibers. The injections are given under anesthesia followed by an aggressive anal massage [18]. Briefly, 200 units of botulinum toxin A is diluted in 6–7 cc of saline and loaded in six tuberculin syringes. The injections are carried out from the perineum with a finger in the rectum guiding the needle into the levator muscle. The mixture is injected posteriorly, posterior-laterally, laterally, and anterolaterally in the direction of the fibers of the levator muscle (Fig. 59.9). If digital examination reveals a tight internal anal sphincter, this may be included. However, if the internal sphincter is injected, the patient should be warned about temporary fecal incontinence.

Results of botulinum toxin A injections are varied. No consistent dose nor technique is used across various centers. We recommended to continue physical therapy while the effects of botulinum toxin A are in effect. The injections may be repeated at 3-month intervals if good results are obtained. It is unclear if repeated injections dilute the effects over time.

Another treatment with uncertain results is a myomectomy of the puborectalis muscle. This technique has been described but not popularized [19].

Patients who fail all treatments may be offered fecal diversion as a last resort. Patients with both slow transit constipation and dyssynergia and have failed medical treatments are a challenging group to treat. They may be offered colectomy for slow transit constipation (possibly with an ileostomy) followed by treatment of dyssynergia after surgery.

Treatment of ODS Due to Internal Prolapse/ Rectal Intussusception

Internal intussusception may be clinically suspected and demonstrated on cinedefecography. The radiological results should be correlated with the clinical findings. Symptomatic patients may be offered surgery and many treatment options have been described. A decade ago stapled transanal rectal resection or the STARR procedure was popularized. Initially after acceptable results, the procedure has lost favor in the

USA. Currently few centers offer it. Although results were good, it has been postulated that the positive effect is overestimated due to the variety of patient-reported outcome measures used to calculate ODS [20]. The procedure is still popular in some countries, and variations have been described and include using different stapling techniques like the Transtar™ [21, 22].

Ventral rectopexy has emerged as the newest technique to address symptomatic internal intussusception. Complications related to nonabsorbable mesh have been published [23]. Similar outcomes have been reported using absorbable/biodegradable mesh. The procedure will be discussed in detail in Chap. 60 which focuses on rectal prolapse.

Treatment of ODS Due to Overt Rectal Prolapse

The approach for surgical treatment of rectal prolapse is based on surgeon preference and patient characteristics. Based on this data, it is either a perineal or abdominal approach. Patients who have constipation associated with rectal prolapse may need further testing and further consideration of a sigmoid resection based on findings. The decision-making details and surgical procedures will be discussed in Chap. 60 (rectal prolapse).

Treatment of ODS Due to Rectocele/Enterocele/Sigmoidocele

Optimal therapy for ODS due to a rectocele, enterocele, or sigmoidocele may involve a team approach which includes urogynecologists and colorectal surgeons. Diagnosis is based on a thorough history and physical examination. Further investigations with a cinedefecography and anal physiology interpreted in a multidisciplinary manner guide therapy.

Rectoceles may be treated surgically when symptomatic, usually manifested by requiring vaginal support to aid defecation. Defecography may demonstrate that the rectocele does not empty. Rectoceles may be treated surgically via a laparoscopic, vaginal, transperineal, or transanal approach. Most of these patients may have associated urological/gynecologic issues which should be addressed at the same time.

Transanal repairs require an incision in the anterior wall of the rectum with excision of the mucosa over the rectocele and plication of the rectovaginal septum. The mucosal defect is then closed (Fig. 59.10). Results show a 30–90 percent decrease in the symptoms; however there may be a recurrence of symptoms in about 48 months [24, 25]. Complications include dyspareunia, fecal incontinence, and rectovaginal fistulas.

The STARR procedure has been extensively studied as a treatment for rectoceles. The procedure is done under general anesthesia in the lithotomy position. It consists of full-thickness excision of the rectal wall using two staplers (PPH01) one used anteriorly and one posteriorly. Care should be taken to prevent drawing the vaginal wall in the purse string suture or including it in the staple line. Complications include bleeding, anastomotic leak, rectovaginal fistula, and rectal pain. In the short term good results were reported, but long-term data shows that recurrence of symptoms occurs in about 40% of patients [26]. Currently the STARR procedure is on the decline in Europe [27].

Repairs through the transperineal route have an advantage of not breaching the vaginal mucosa. This involves a transperineal incision with dissection up to the vaginal apex. The surgical procedure is a simple fascial repair from the apex to the perineum. The repair may be augmented using mesh although the use of synthetic mesh has been controversial.

The transvaginal route starts with a vaginal incision followed by separation of the vaginal mucosa from the fascia. Several fascial stitches close the rectocele. The repair may be augmented as in the transperineal repair with mesh. Excess mucosa is trimmed (Fig. 59.11). Recurrence rates are about 7.1% [28]. Complications include dyspareunia, bleeding, and wound infection. In a meta-analysis native tissue transvaginal repairs are preferentially recommended over other repairs [29].

Treatment of an Enterocele/Sigmoidocele

Enteroceles and sigmoidoceles are described as a pelvic floor herniation of the bowel into the pouch of Douglas. Treatment is not recommended on the basis of radiological diagnosis alone. Demonstration of an outlet obstruction along with a substantial hernia warrants surgical consideration. The treatment plan is usually made in conjunction with a urogynecologist. All pelvic surgical problems may be addressed at the same procedure. The preferred repair is a sacrocolpopexy using a monofilament nylon mesh (Fig. 59.12).

Conclusions

Patients who suffer from obstructed defecation are a special category of patients. Knowledge of normal pelvic anatomy and physiology are essential to make a clinical diagnosis. A detailed history and physical examination are essential. Testing should be complementary to aid in diagnosis or to plan a surgical option. Radiological evidence of mild structural abnormalities may not necessarily be associated with a successful surgical outcome. Recurrent symptoms after a surgical repair or complications may lead to patient dissatisfaction. Patient education and obtaining the patient's trust is an important aspect of treatment.

Rectal Prolapse

60

Margarita Murphy and Sarah A. Vogler

Key Concepts

- Full-thickness rectal prolapse can present with many symptoms including rectal/pelvic pressure, bowel habit irregularity, incomplete evacuation of stool with defecation, seepage of mucous, occasional blood on stool or toilet paper, fecal urgency, and outlet dysfunction constipation. Additionally questions directed at symptoms from the middle and anterior compartments should be asked to plan treatment. A multidisciplinary approach can enhance the outcomes.
- Testing is done to gain insight into the strength, coordination, and anatomic pelvic deficits associated with the prolapse.
- Treatment is nearly always surgical with over 100 procedures reported to treat rectal prolapse. The approach is either perineal or abdominal.
- Ventral mesh rectopexy facilitated by a laparoscopic or robotic approach has rapidly gained acceptance as a favored surgical therapy for rectal prolapse.

Introduction

Rectal prolapse is full-thickness protrusion of the concentric rings of the rectum through the anal canal. It can occur in men and women of all ages but most commonly presents in parous women in the seventh to eighth decade of life. The anatomic changes that occur with rectal prolapse lead to symptoms that are not life threatening but can be lifestyle limiting for patients. These symptoms can span from fecal incontinence and urgency to constipation and outlet dysfunction. Rectal prolapse is a surgically correctable problem. There are over 100 surgical techniques that have been described to repair rectal prolapse. All of these techniques have a risk of developing recurrent rectal prolapse, and none have been declared as a gold standard. Choosing the optimal surgical repair for a patient can involve many factors, including general health, bowel function, bothersome symptoms, and concomitant pelvic organ prolapse.

Multidisciplinary Approach

The female pelvis can be divided into three anatomic compartments: anterior, middle, and posterior. The rectovaginal space and rectum are considered the posterior compartment. Historically, rectal prolapse has been considered a problem that is isolated to the posterior compartment, and colorectal surgeons have focused their repair on this compartment in isolation. A multidisciplinary approach that evaluates all the pelvic compartments is increasingly recommended. Literature has shown that an anatomic defect in a single pelvic compartment is frequently present with symptoms or defects in other pelvic compartments [1, 2]. For example, a patient with rectal prolapse may also present with urinary incontinence or vaginal bulging. This concomitant pelvic organ prolapse (POP) may include enterocele, genital, and bladder prolapses. This correlation increases with age, higher BMI, and in those who have undergone a hysterectomy [3–6]. Overlooking this association during treatment planning may result in exacerbation of symptoms in another pelvic compartment after an isolated repair. This is of particular importance because patients with POP have earlier and higher recurrence rate after rectopexy alone and a higher number of reoperations both for the rectal prolapse and for

repair of the other compartments [3, 4]. A multidisciplinary approach may offer a more robust surgical plan and avoidance of sequential surgeries [7–9].

Pathophysiology

The mechanism by which full-thickness rectal prolapse occurs remains poorly understood. There have been multiple theories. Broden and Snellman and others have suggested that full-thickness rectal prolapse is initiated by mid-rectal intussusception that progresses down through the anal canal [10, 11]. Connective tissue disorders have also been proposed as a contributing factor in developing rectal prolapse, especially in younger patients. Associated symptoms that may contribute to the development of prolapse include constipation with repeated straining during defecation and solitary rectal ulcer. Intestinal motility abnormalities which include slow transit constipation and malabsorptive diarrhea have also been associated with an incidence of rectal prolapse. Finally, multicompartment pelvic organ prolapse, suggesting weakness in the tissues throughout the pelvis, may also contribute to progressive deterioration in posterior compartment support and eventual development of rectal prolapse.

It is important to differentiate full thickness rectal prolapse from internal rectal intussusception and rectal mucosal prolapse. The underlying mechanism of developing each of these anatomic abnormalities might be the same, but the treatment options may vary. Rectal mucosal prolapse refers to only the rectal or anal mucosal protruding from the anal opening. Internal rectal intussusception involves telescoping of the full rectal wall down toward the anal canal but without full protrusion through the anal opening. The Oxford group has developed a grading system for rectal prolapse (Table 60.1) [12, 13]. This grading system is useful in discerning the severity of rectal intussusception on defecography or exam. The degree of rectal intussusception or rectal prolapse can be correlated to a patient's clinical symptoms and subsequently helpful in developing a surgical plan.

Table 60.1 Oxford rectal prolapse grading system

Oxford rectal prolapse grade	Radiological characteristics of rectal prolapse
Internal rectal prolapse/intussusception	
I (low grade)	Descends no lower than proximal limit of the rectocele
II (low grade)	Descends into the level of the rectocele, but not into anal canal
III (high grade)	Descends into proximal anal canal
IV (high grade)	Descends into distal anal canal
External rectal prolapse	
V (overt rectal prolapse)	Protrudes from anus

Patients with symptomatic deep rectal intussusception may benefit from surgical repair, similar to full-thickness rectal prolapse [13, 14]. However, rectal intussusception may be present in patients who are relatively asymptomatic, and a repair should not be considered in these patients.

Solitary Rectal Ulcer Syndrome

Solitary rectal ulcer syndrome (SRUS) is a disorder of defecation which is often associated with rectal prolapse or internal intussusception. Patients may present with rectal bleeding, difficult defecation, tenesmus, mucus discharge, and anal or pelvic pain. On occasion, the rectal bleeding can be severe enough to require transfusion. The mucosal ulcerations and thickening are due to intussusception of the rectum, which traumatizes the mucosa as it invaginates downward. This repeated trauma my lead to transient ischemia which has been speculated to be part of the etiology.

On examination, there is typically thickened mucosa located on the anterior rectal wall with ulcers seen in about 23% of cases and polyps or masses in 74% [15]. If present, rectal ulcers can be single or multiple shallow ulcers with hyperemic margins and a pale base. This uncommon condition may be misdiagnosed as a polyp or even a cancer because of the alarming appearance seen in some with SRUS. Colitis cystica profunda (CCP) is considered a related disorder that produces similar symptoms to SRUS and may have a similar gross appearance.

Characteristically on biopsy, SRUS has fibrotic obliteration of the lamina propria. There can be a thickened muscularis mucosa. Biopsies of CCP demonstrate mucous cysts lined by columnar epithelium deep in the muscularis mucosa. It is conceivable that with trauma from a cephalad prolapsing area of the rectum, mucosa may be forced beneath the surface to produce these mucous cysts. A correct diagnosis of both these conditions is made with accurate pathologic evaluation.

The workup for both SRUS and CCP includes an in-depth history assessing for straining to defecate, rectal bleeding, and other anal symptoms. Endoscopy with biopsy is essential to make an accurate diagnosis. Treatment of these conditions is challenging, and defecography and anal manometry may be useful to guide choices. Interestingly in SRUS, a thickened internal anal sphincter has been reported as a typical finding on endoanal ultrasonography [16]. Treatment is primarily directed toward normalizing the defecatory disorder with diet modifications and bowel retraining utilizing pelvic floor physical therapy [17, 18]. Argon plasma coagulation has also been described as a potential treatment modality, particularly to control bleeding [19].

In those patients who have a deep rectal intussusception, Oxford grades 3–4, secondary to pelvic floor weakness, and

multicompartment pelvic organ prolapse, surgical correction of the prolapse with a rectopexy can be offered [20–25]. A careful history, physical exam, and testing with manometry and defecography should be performed to differentiate individuals with SRUS secondary to weakness versus those with defecatory dysfunction and SRUS secondary to straining. Surgical correction in those with internal prolapse secondary to weakness and multicompartment prolapse could involve a form of rectopexy, either suture, mesh, or ventral rectopexy, and consideration of combined surgery with urogynecology [26, 27]. Surgical correction is not recommended in those patients who have defecatory dysfunction secondary to straining and pelvic floor dyssynergia. These patients benefit from pelvic floor physical therapy.

Evaluation of the Patient

History and Physical Exam

The evaluation of a patient with rectal prolapse should start with a careful history that includes an overview of general health and specific attention to pelvic floor symptoms and gastrointestinal complaints. Symptoms that occur commonly with rectal prolapse include rectal/pelvic pressure, bowel habit irregularity, incomplete evacuation of stool with defecation, seepage of mucous, occasional blood on stool or toilet paper, fecal urgency, and outlet dysfunction constipation. Reviewing if there is a prior history of rectal prolapse repair or other pelvic organ prolapse repair is important and can impact your surgical planning. Asking the patient about symptoms related to other pelvic compartments, such as urinary incontinence, urinary hesitancy, vaginal pressure, dyspareunia, or vaginal bulging, will help in determining if a multidisciplinary treatment team is necessary [28]. Jackson, et al. found that 20–35% of patients with rectal prolapse reported urinary incontinence. Additionally, 15–30% of patients with rectal prolapse also have significant vaginal vault prolapse [2].

A full physical exam should be performed with special attention to the abdomen and pelvis. A digital rectal exam will help in understanding anal sphincter tone and strength. Asking the patient to squeeze and bare down during digital rectal exam will help in assessing their pelvic floor coordination. Also, asking the patient to bare down while sitting upright on a commode and using a mirror to visualize their perineum will allow for visualization of rectal prolapse and vaginal protrusion or widening.

Since patients will commonly present with a change in their usual bowel habits, either constipation or incontinence, a review of their colonoscopy history should be performed. A colonoscopy should be considered to rule out any other cause for their change in bowel habits.

Patient Questionnaires

It is important to understand patients' bowel habits prior to surgical repair of rectal prolapse. This can be done as part of the history and also by using more objective measurement tools such as validated questionnaires. Capturing this information helps in setting patient expectations for their bowel habits after surgery and allows for counseling as to medical bowel regimens that can be started preoperatively and may help to alleviate some of these bothersome symptoms. While surgical correction of the rectal prolapse may improve or relieve these symptoms, it is also possible that these symptoms may be persistent or exacerbated by surgery. Changes in functional symptoms, such as incontinence or constipation, can evolve for several months after surgery. Standardized questionnaires can help in objectively following this evolution. Since rectal prolapse, and even more so multicompartment pelvic organ prolapse, can span a very broad range of patient reported symptoms, it is difficult to choose the single best questionnaire to recommend for routine clinical use. In 2019, the Pelvic Floor Disorders Consortium identified the validated surveys most highly recommended for several symptoms and combined these into a single validated instrumented labeled IMPACT (Initial Measurement of Patient-Reported Pelvic Floor Complaints Tool) [29]. IMPACT allows for capturing multiple patient-reported symptoms related to prolapse and how these symptoms improve, worsen, or develop over time.

Anorectal Physiology Testing

The size of the rectal prolapse or depth of rectal intussusception can result in changes that are seen on anal physiology studies such as manometry. Repeated stretching of the anal sphincter complex by protrusion of tissue through this canal results in low anal rectal pressures and diminished recruitment of anal squeeze pressures. Understanding the baseline strength of the anal sphincter complex prior to surgical repair of rectal prolapse may help in counseling patients as to expected postoperative continence or the potential need for postoperative physical therapy to regain strength.

EMG recruitment studies may have variable results in the setting of POP due to the pressure applied to the pelvic floor from prolapsing tissue with Valsalva or evacuation. The EMG tracing may show appropriate relaxation of the pelvic floor muscles. Interestingly, a paradoxical increase in EMG activity with Valsalva may occur due to the mounting pressure from prolapsing tissue. This can mimic the EMG recruitment results seen with dyssynergia of the pelvic floor, so clinical correlation to the test results is imperative.

Imaging

Fluoroscopic defecography imaging is the most helpful test to better understand the anatomic pelvic dynamics that are occurring during defecation. Full-thickness rectal prolapse can be easily seen on physical exam with the patient straining on a commode. However, physical exam is unable to determine the extent of internal pelvic organ collapse with evacuation, so defecography is used to capture this. Additional findings on defecography that may be contributing to the extent of rectal prolapse or the cause for rectal prolapse include anterior rectal wall weakness with rectocele, internal rectal intussusception, enterocele, sigmoidocele, uterovaginal prolapse, or cystocele (Fig. 60.1a–c).

An alternative is dynamic magnetic resonance imaging defecography (dMRD) [30]. This imaging technique is almost always performed with the patient in a supine position as opposed to the more physiologic sitting position used during fluoroscopic defecography. Ramage et al. [31] reported that the dMRD is less sensitive than fluoroscopic defecography. Miss rates for anorectal intussusception and rectal prolapse were significantly higher with dMRD than with the use of fluoroscopic defecography. Small rectoceles and vaginal vault descent were also less likely to be detected.

Treatment

In the vast majority of circumstances, treatment of rectal prolapse is surgical. Bowel habits can be improved by starting a bowel regimen prior to surgery to achieve optimal stool consistency and regularity. Pelvic floor physical therapy may also help to optimize pelvic floor coordination. However, only in rare cases of extreme constipation and straining causing rectal prolapse will these measures allow for full resolution of rectal prolapse.

There are two main categories of surgical repairs for rectal prolapse: abdominal and perineal. The surgical approach is chosen based on a patient's general health, prolapse-associated symptoms, concomitant pelvic organ prolapse, prior surgical history, and surgical urgency. Incarcerated rectal prolapse requires a perineal approach. Otherwise, a perineal repair generally has a higher risk of prolapse recurrence and is thus reserved for patients who are very poor surgical candidates [32, 33]. The newest surgical options include minimally invasive techniques and multidisciplinary surgical teams. Overall, the optimal operation for rectal prolapse is unclear [34, 35].

Perineal Repairs

Perineal repairs can be performed with the use of light anesthetic without paralysis and at times with spinal or local anesthetic. Avoidance of abdominal incisions also minimizes postoperative discomfort and can help to facilitate early ambulation, deep breathing, and coughing. The three main perineal procedures are anal encirclement, Delorme procedure, and Altemeier procedure.

Anal encirclement (Thiersch procedure) has generally fallen out of practice because of high failure and complication rates. Thus, it is reserved for patients with the most extreme comorbidities or those with prolapse and a permanent colostomy who cannot tolerate other options. The procedure involves reduction of the prolapse and placement of a permanent material that encircles the anus in the subcutaneous space. A thick suture, biologic mesh, permanent mesh, or wire has been used for the encirclement with the goal of nar-

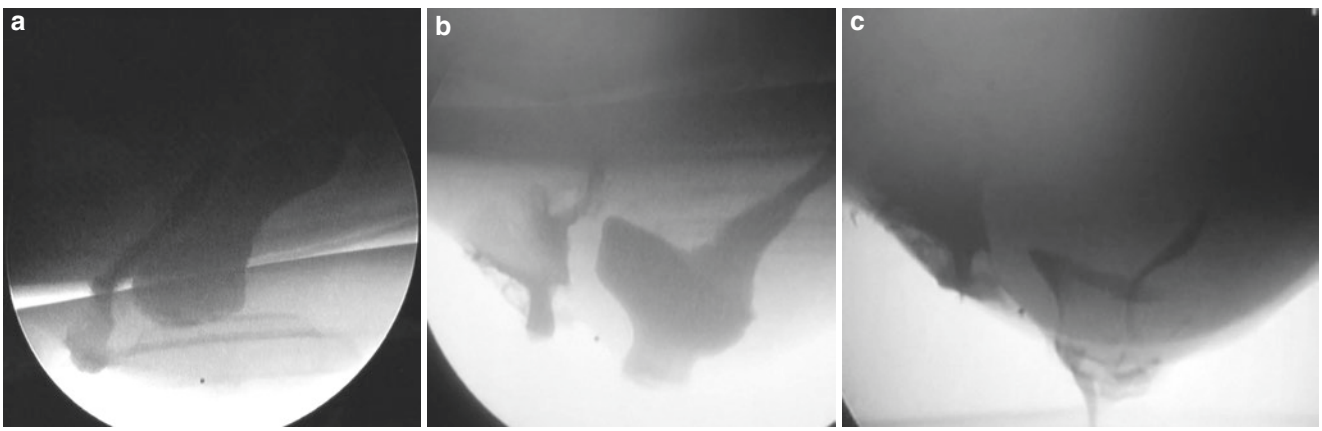

Fig. 60.1 Defecography images: (**a**) Pre-evacuation – vaginal silhouette and rectum prior to evacuation. (**b**) Mid-evacuation – development of rectocele and loss of vaginal apical support. (**c**) End of evacuation – rectal intussusception has progressed into short segment of full-thickness prolapse

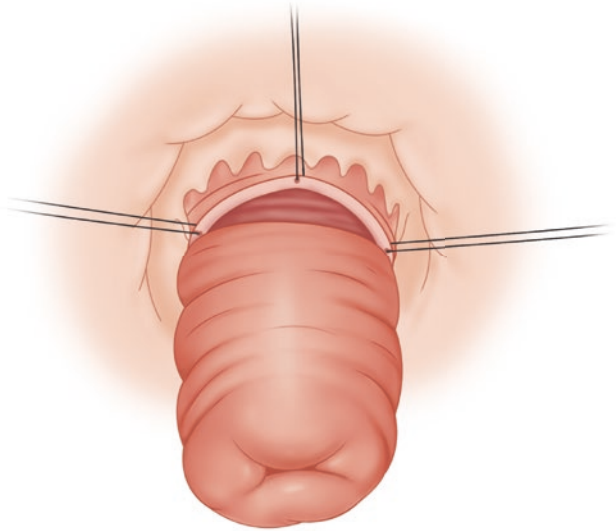

Fig. 60.2 Delorme procedure. Two centimeters proximal to the dentate line, a circular line is marked out in the mucosa with the bovie. The area is injected with a vasoconstricting agent. An incision is then made through the mucosa but not full thickness through the entire rectal wall. The bovie is an excellent means to make the mucosal incision

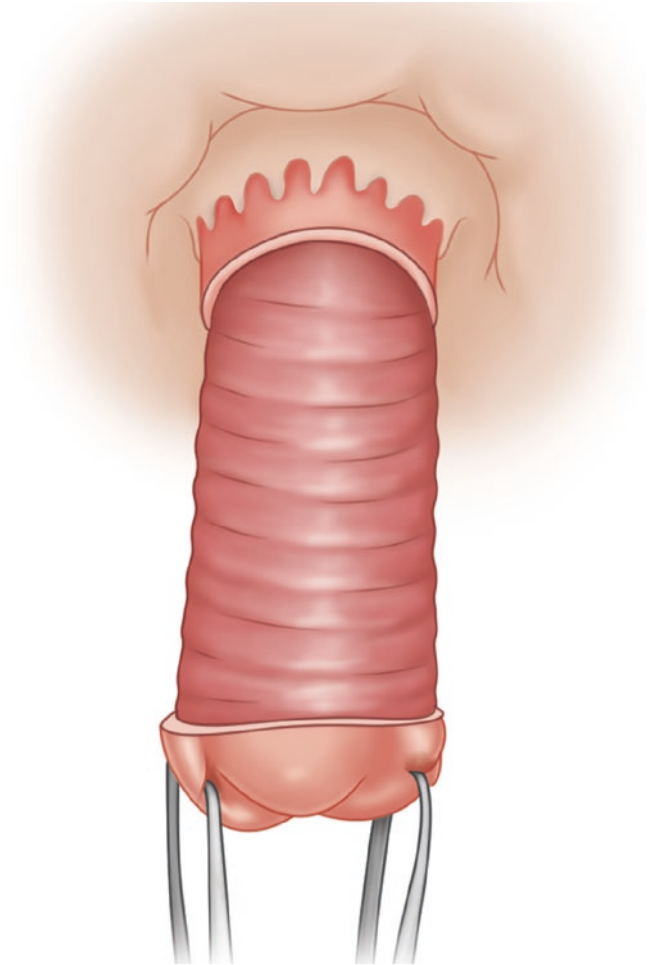

Fig. 60.3 Delorme procedure. Working cephalad, a sleeve of mucosa is dissected off the muscular layer of the rectal wall. Liberal injection of saline with or without a vasoconstricting agent assists in developing the correct plane. Care is taken to achieve meticulous hemostasis as there are penetrating vessels in this plane of dissection which will need to be tied or coagulated

rowing the anal canal to prevent recurrent prolapse. Complications include erosion of the encircling device, severe outlet dysfunction, and recurrent prolapse. The risk of recurrent prolapse ranges from 33 to 44% [36].

The Delorme procedure was first described by Delorme in 1900 and involves a mucosal sleeve resection. The mucosa of the prolapsed segment is stripped and resected (Figs. 60.2 and 60.3). Then the underlying muscle layers are plicated, and the proximal and distal mucosa is re-approximated (Figs. 60.4 and 60.5). This procedure is most commonly performed on patients who are poor abdominal surgical candidates and have a short segment of rectal prolapse. The morbidity and mortality associated with this procedure are very low; however, the prolapse recurrence rates are high and range from 16% to 30% [37–39]. For a description of the procedure, please see Fig. 60.6.

The Altemeier procedure is a perineal rectosigmoidectomy and was first described in the 1960s. To start this procedure, the rectum is prolapsed out of the anus, and a circumferential full-thickness incision is made, starting approximately 2 cm above the dentate line. Once the mesorectum is visible, it is systematically divided by identifying the point of maximal tension and working circumferentially to continue pulling the redundant rectum and sigmoid colon out through the anal canal. The peritoneal reflection in the rectovaginal septum is encountered anteriorly, and the peritoneal cavity is commonly entered as the dissection proceeds proximally. Once the rectal redundancy or redundant sigmoid colon loop is maximally pulled through the anal canal, the colon is divided at this proximal resection point, taking care to ensure adequate blood supply and lack of tension. A sutured coloanal anastomosis or low end-to-end stapled colorectal anastomosis is created. This procedure can be combined with a levatorplasty to help in supporting the weak pelvic floor muscles and possibly improve postoperative continence [40]. Since this procedure involves a full resection, it carries the risk of anastomotic bleeding, pelvic abscess, or anastomotic leak. Recurrence rates can range up to 20% (Figs. 60.7, 60.8, 60.9, 60.10, 60.11, 60.12, and 60.13) [41].

Concomitant pelvic organ prolapse and a history of prior prolapse repairs are important parts of surgical decision-making and planning. In patients with vaginal prolapse, a colpocleisis can be performed in combination with a Delorme or Altemeier procedure. A prior history of an abdominal surgery for prolapse repair does not preclude doing a perineal procedure for recurrent prolapse. However, an Altemeier

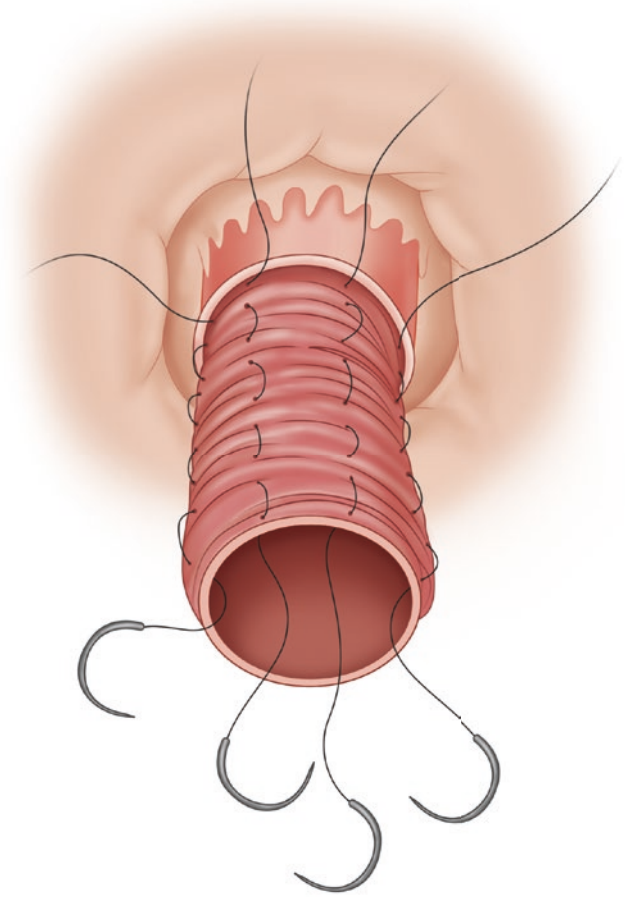

Fig. 60.4 Delorme procedure. When there is tension at the plane of the mucosal dissection, this is completed. After ensuring that complete hemostasis exists, the muscular layer (the rectal wall) is approximated using sutures starting at the proximal cut mucosal end and including bites of the rectal wall every few centimeters until the other cut edge is reached at the anal region. Placement of these sutures is along the longitudinal axis of the rectal wall and is not full thickness but deep enough to ensure when tied they do not tear through the tissue. As these sutures are placed, they compress the wall in an accordion (or concertina) like fashion. Four to six futures are typically required to stabilize the compressed rectal wall

procedure cannot be performed if there is a prior history of sigmoid resection due to the risk of vascular disruption to the coloanal anastomosis [42].

Incarcerated Rectal Prolapse

An attempt should be made to manually reduce rectal prolapse if the prolapsed rectum appears pink and well perfused. Coating the prolapse with granulated sugar may help to decrease the swelling which will facilitate manual reduction. If the prolapse cannot be reduced or appears gangrenous, then an Altemeier procedure should be performed to excise the incarcerated rectum (see Figs. 60.14 and 60.15). A

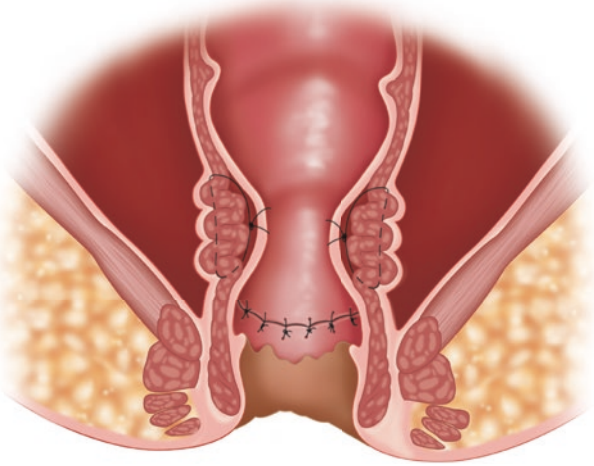

Fig. 60.5 Delorme procedure. After the sutures that have been placed in the rectal wall are tied down, the two cut ends of the mucosa will be in close proximity. The mucosa is then reapproximated with sutures to create a neo-anastomosis in the anal canal proximal to the dentate line

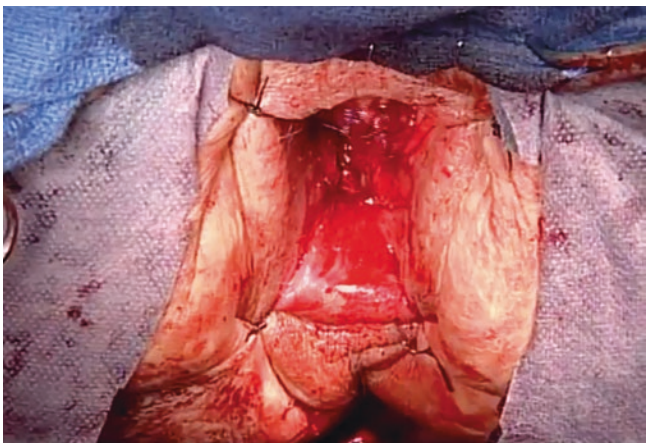

Fig. 60.6 Delorme procedure

tension-free coloanal anastomosis can be performed in this scenario if the proximal bowel appears healthy with a good blood supply.

Abdominal Repairs

Minimally invasive (laparoscopic and robotic) or open approaches can be used to perform a rectopexy during which the rectum is anchored to the anterior longitudinal ligament near the level of the sacral promontory, thereby correcting the telescoping of the prolapsing bowel. This approach has shown lower recurrence rate, better functional results, and low morbidity compared to perineal operations. Advanced age has been considered a factor to exclude abdominal surgeries as a possible treatment option. The

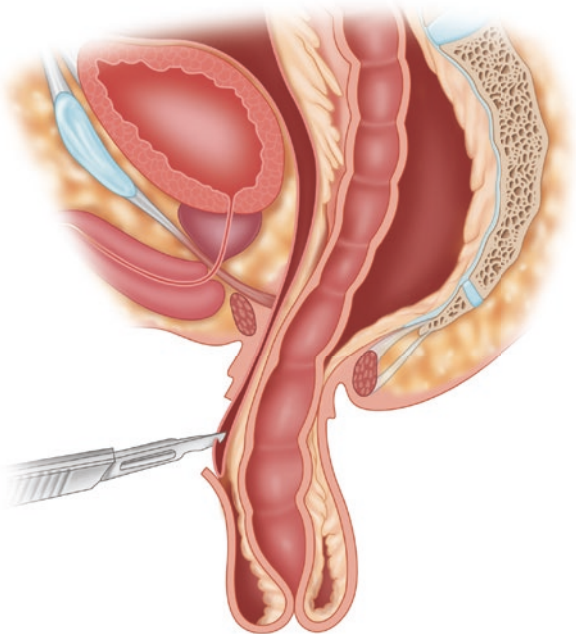

Fig. 60.7 Altemeier procedure. A circular incision is mapped out approximately 2–5 cm cephalad to the dentate line in the rectal mucosa

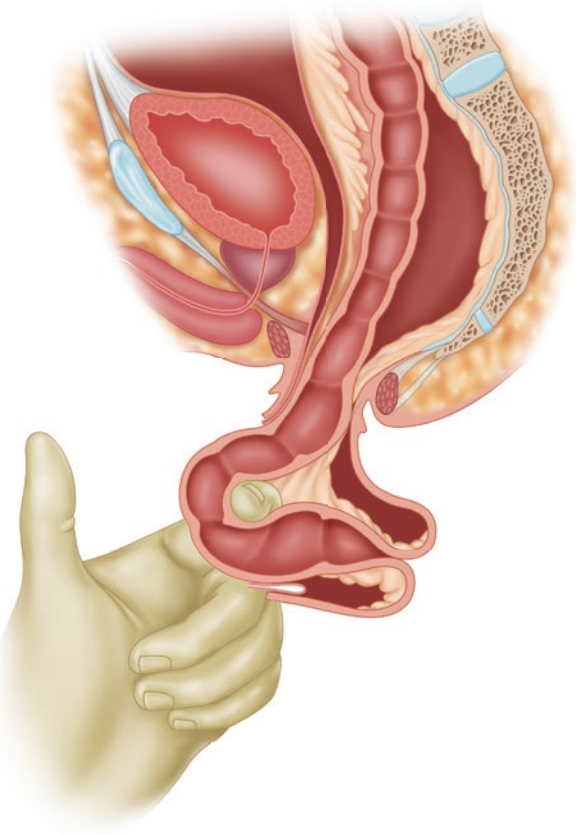

Fig. 60.8 Altemeier procedure. The rectum is pulled out of the anus and the mesentery divided stopping at a point just distal to where the rectum (or sigmoid) no longer easily can be pulled out of the anus

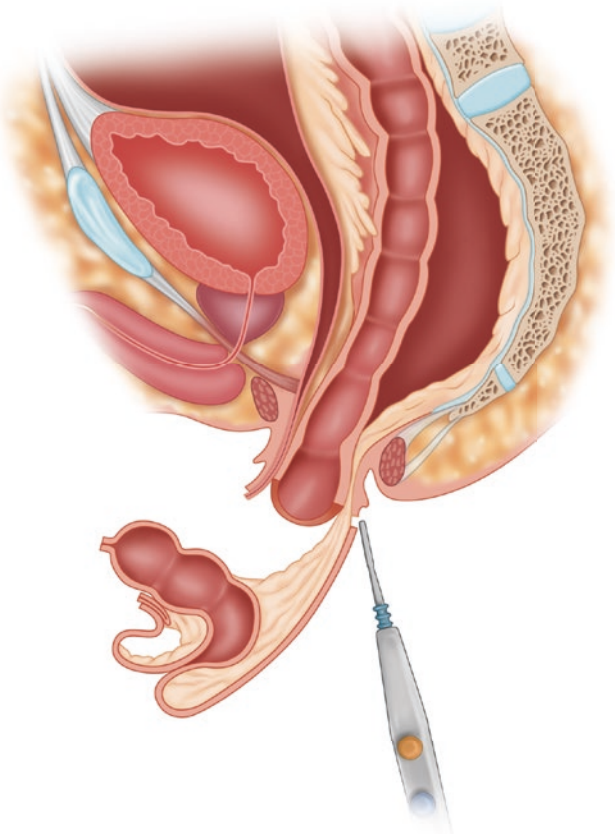

Fig. 60.9 Altemeier procedure. The redundant rectum and sigmoid colon are excised. It is important to ensure that the proximal bowel has sufficient mesentery to avoid ischemia to this segment

rationale is that perineal procedures can be performed on these elderly and frail patients without a general anesthetic and with lower morbidity and mortality. Fang et al. queried the American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP) database in 2008 [43]. Results showed that in patients who were considered high risk, defined as ASA of 3 and 4, the relative risk for mortality was four times greater in the group that underwent perineal procedures than in the abdominal procedure group. Furthermore, the mortality in the laparoscopic approach was 0%. Bjenker and Mynster [44] reviewed the National Danish Registry data to include 2004 through 2014. The overall 30-day mortality rate was only 2.1% despite 41% of their patients being octogenarians. In this study, perineal procedures had a higher mortality rate when compared to abdominal procedures ($p < 0.0001$). Specifically, mortality was 3.3% after open rectopexy, 1.4% after laparoscopic rectopexy, 4.4% after Altemeier, and 2.3% after Delorme. Also, the recurrence rate was much higher for the perineal procedures with the highest being for that of the Altemeier operation (50%). Although these retrospective reviews have some inherent bias as to which patients underwent perineal versus abdominal sur-

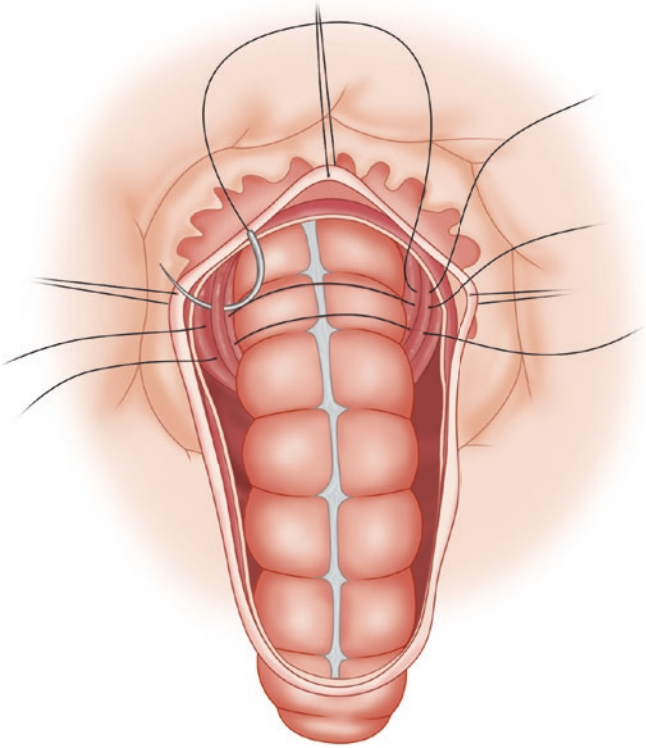

Fig. 60.10 Altemeier procedure. Anteriorly the levator ani muscles may be approximated with sutures (levatorplasty) which may improve fecal continence

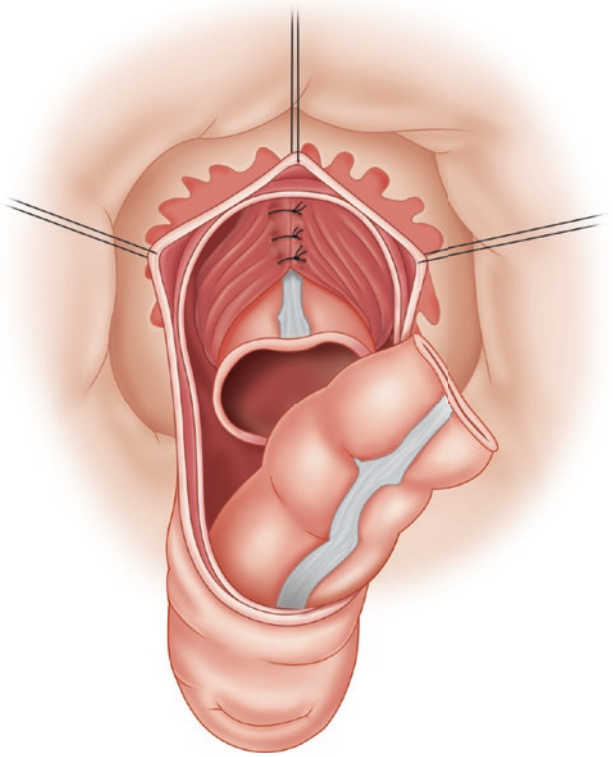

Fig. 60.11 Altemeier procedure. The redundant rectum and sigmoid colon are excised. It is important to ensure that the proximal bowel has sufficient mesentery to avoid ischemia to this segment. This figure also demonstrates the completed levatorplasty

geries, there is growing evidence that minimally invasive abdominal procedures can safely be performed on elderly patients with rectal prolapse.

Suture Rectopexy

This was first described by Dr. Daher Cutait in 1959 and was presented as a video at the Royal Academy of Medicine. For this approach, the rectum is mobilized anteriorly and posteriorly to the level of the levators with identification and preservation of the hypogastric nerves. The rectum is then pulled cephalad, and the mesorectum is sutured to the anterior longitudinal ligament at the sacral promontory with nonabsorbable suture. Some surgeons may use other fixation devices such as tacks. Long-term results have shown recurrence rates of up to 20% [45, 46]. Improvement in continence can be seen in up to 34–42% of patients; De Brujin et al. also reported new onset incontinence in 7% [46]. New onset constipation is seen in up to 50% percent of cases [35, 37]. Denervation of the rectum from the neural efferent nerves residing in the lateral ligaments is thought to contribute to worsening function and constipation. Unilateral pres-

Fig. 60.14 Incarcerated rectal prolapse

ervation of a lateral stalk and unilateral fastening of the rectal mesentery to the sacrum can be considered to mitigate worsening function [47]. Hidaka et al. reported a 6-year follow up of a double-blind, randomized study comparing laparoscopic suture rectopexy versus laparoscopic ventral mesh rectopexy [48]. The recurrence rate was reported as 23.3% in the suture rectopexy group compared to 8.2% in the ventral rectopexy group. The functional outcomes, including obstructive defecation symptoms, incontinence, constipation, and quality of life, also favored laparoscopic ventral mesh rectopexy.

Fig. 60.15 Strangulated rectal prolapse with compromised blood supply

Suture Rectopexy with Sigmoid Resection

As described by Frykman and Goldberg in 1969, [49] adding a sigmoid resection to the rectopexy decreases postoperative constipation, especially in those patients who present with this complaint preoperatively [50]. The possibility of anastomotic leak was thought to add unnecessary morbidity to the treatment of what is otherwise a quality of life, benign pathology. This, however, has not proven to be the case. The number of anastomotic complications reported in the literature is low, varying from 0% to 2.3% [51–53]. Laubert et al. [51] noticed an overall improvement in incontinence symptoms in 64% of the patients and improvement in constipation in 77% of their patients. Formijne et al. [24] had similar findings and found that when compared with laparoscopic ventral rectopexy, both techniques achieved the same improvement in constipation and obstructive defecation symptoms. Rectal prolapse recurrence rate is lower than that of rectopexy alone, between 10% and 13% (Fig. 60.16) [52].

Posterior Rectopexy with Mesh

Professor Charles Wells first described this procedure in 1959 when he reported using a polyvinyl alcohol sponge (Ivalon) in 15 patients [54]. Pelvic sepsis in up to 16% of patients forced the evolution of the technique to the use of mesh and avoidance of the sponge [55].

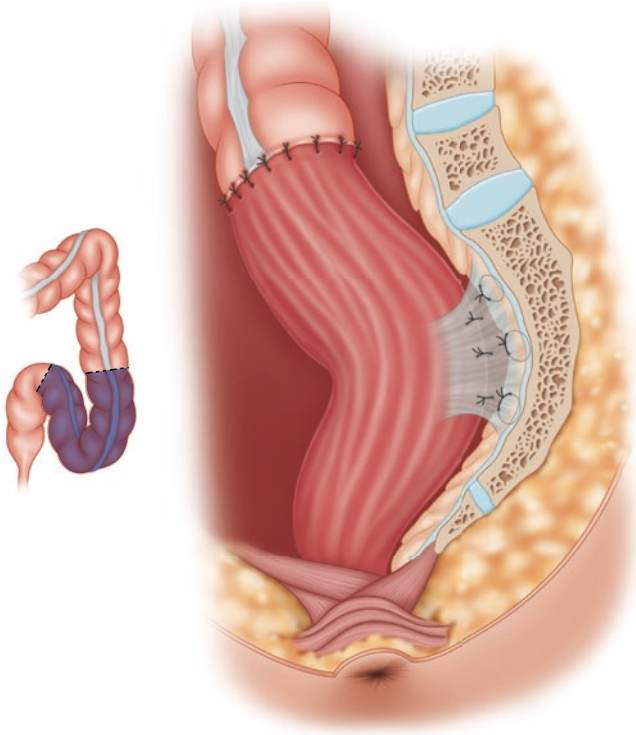

Fig. 60.16 Resection/rectopexy. The sigmoid colon is excised and an end-to-end anastomosis performed. The rectum is mobilized, and non-absorbable sutures are placed in the lateral rectal ligament. The suture is then placed in the anterior sacral ligament (tacks can also be used) to anchor the rectum securely to the sacrum at about the S1 level. It is important to position the needle to enter the sacrum at a right angle. The needle is pushed into the bone and minutely pulled back. Then the curve of the needle is followed when continuing the suture placement at the sacrum. This ensures the suture will be in the anterior sacral ligament. Two sutures on the right are typically placed. Sutures can be placed also on the left side of the rectum, but when tying them down, it is crucial to ensure the rectum is not kinked/occluded

The rectum is mobilized anteriorly and posteriorly to the level of the levator muscles. The sacral promontory is exposed, and a piece of mesh is sutured to the anterior longitudinal ligament. The rectum is then pulled cephalad, and the mesh is wrapped around the rectum leaving the anterior wall of the rectum open. The mesh is attached to the lateral stalks. Constipation is significantly worse postoperatively, and the recurrence rate has been reported to be 6% for a complete rectal prolapse and 12% for mucosal prolapse, but with longer follow-up, the recurrence rate increases [56–59]. Even with mesh, as opposed to the sponge, the morbidity secondary to pelvic sepsis is still high [58].

Ripstein Procedure

The Ripstein procedure, also known as anterior sling rectopexy, was first described by Ripstein in 1952 [60]. Multiple variations of the technique have since been described. After complete mobilization of the rectum, an anterior sling made with fascia lata or mesh is fixated to the anterior rectum and then to the anterior longitudinal ligament on both sides. Recurrence rate has been described up to 13%. Roberts et al. reported recurrence was three times higher in males (24%) than in females [61]. Reports show some improvement in continence but not in constipation symptoms. De novo constipation is seen in 14% of patients and fecal impaction requiring hospital admission for management in 5%. To decrease the incidence of obstruction, Ripstein himself modified the procedure such that the sling would not go all the way around the anterior portion of the rectum, but rather a gap is left between the two edges [56, 58, 61]. Roberts et al. reported a 52% complication rate [62]. Due to the high morbidity of this procedure and the risk of rectal outlet dysfunction, this procedure is performed much less frequently.

Ventral Mesh Rectopexy

The ventral mesh rectopexy (VMR) technique was first described by D'Hoore and has rapidly become an important option in the armamentarium for the treatment of rectal and pelvic organ prolapse [63]. The dissection is purely an anterior dissection and thus avoids potential complications of a posterior rectal dissection. To begin, the sacral promontory is exposed,s and then the rectum is mobilized anteriorly, opening the rectovaginal septum all the way to the pelvic floor (Fig. 60.17). The visualization and extent of this dissection is facilitated by a laparoscopic or robotic approach. Mesh, either biologic or synthetic, is cut to the appropriate size and is sutured to the rectum and sometimes the pelvic floor itself (Fig. 60.18). Typically, 8–12 stitches are placed between the mesh and to the distal and mid-anterior rectum. The mesh is then sutured to the anterior longitudinal ligament at the level of the sacral promontory (Fig. 60.19 and 60.20). This allows for elevation of the pelvic floor and correction of rectocele, rectal prolapse, and intussusception. In those patients with

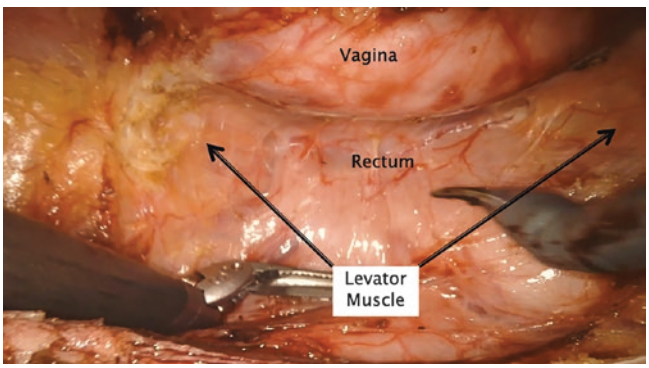

Fig. 60.17 VMR dissection down to the pelvic floor in preparation for mesh placement

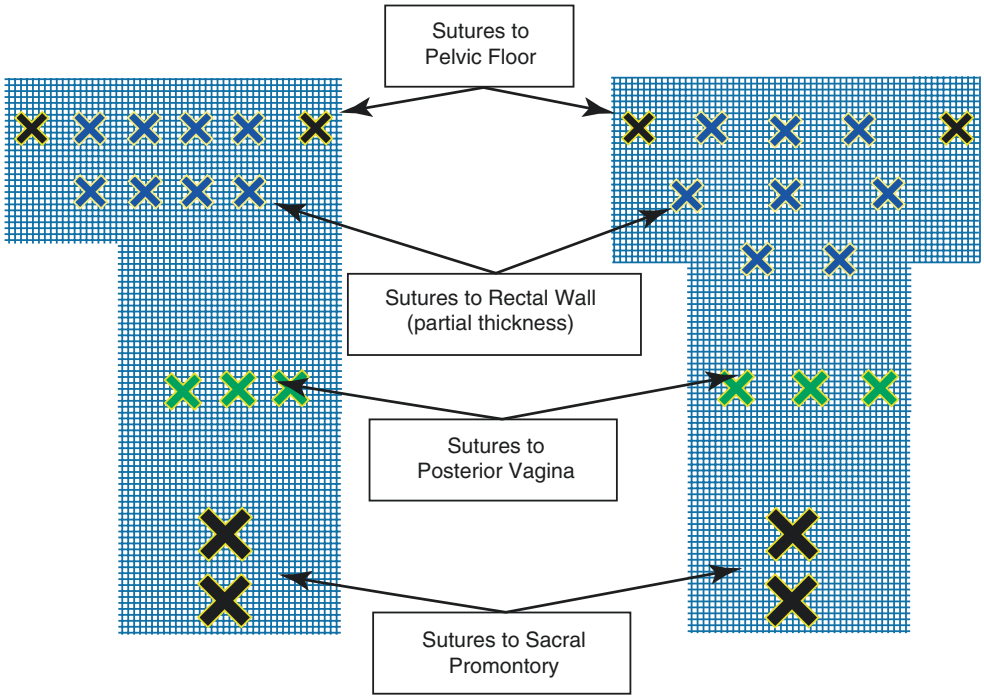

Fig. 60.18 Mesh used for VMR can be cut to various configurations and sizes depending on surgeon preference and pelvic anatomy. This diagram shows two possible mesh configurations and suture locations

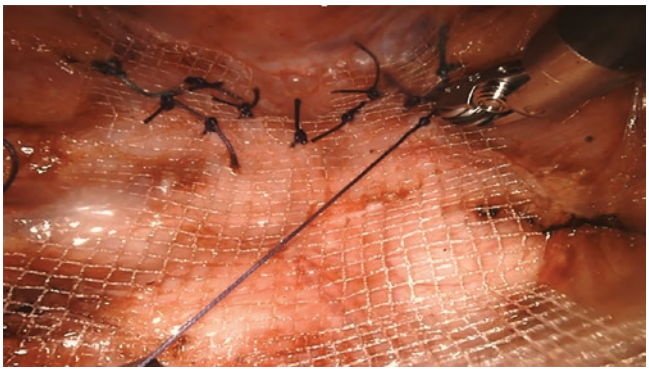

Fig. 60.19 Securing mesh to the anterior rectal wall during VMR

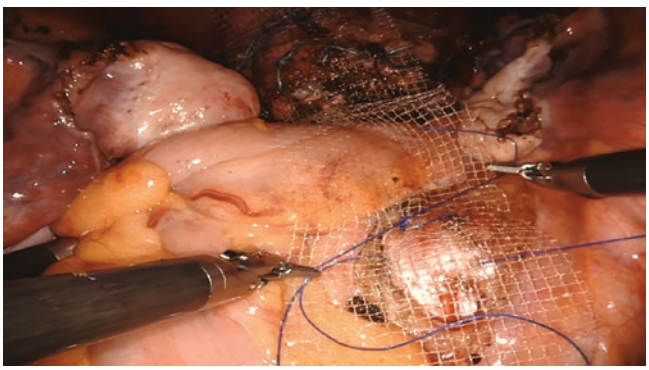

Fig. 60.20 Securing mesh to the sacral promontory during VMR

severe pelvic floor laxity, stitches may be placed between the mesh and the levator ani and the pubococcygeus muscles [64]. Once the mesh is completely secured in place, the peritoneum is reapproximated over the mesh (Fig. 60.21).

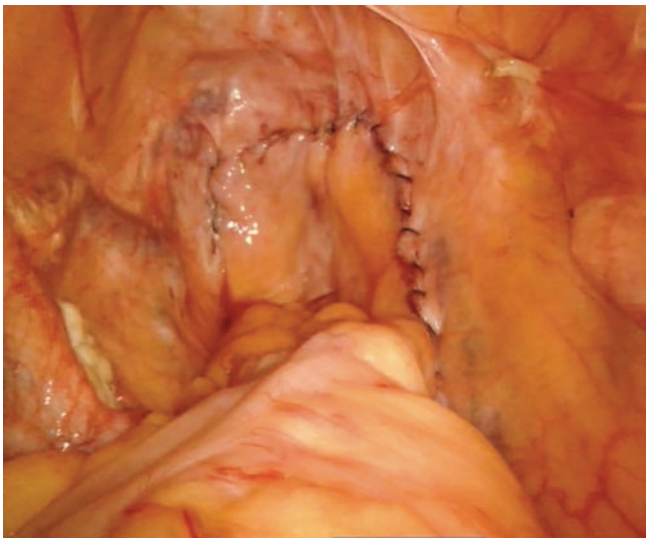

Fig. 60.21 Closure of peritoneum over mesh at completion of VMR

One advantage to VMR is that it avoids autonomic nerve damage that can occur with posterior rectal mobilization and division of the lateral stalks. But the greatest advantage is that VMR allows the opportunity to correct the anatomic defects or laxity of the middle and anterior pelvic compartments. This approach also makes operating with a multidisciplinary team easy since the entire dissection remains in the rectovaginal septum with a large portion of the dissection being identical for both VMR and sacrocolpopexy. Additionally, the same surgical port sites and similar instruments, i.e., mesh and sutures, are used by both surgical teams.

D'Hoore initially described placing stitches between the mesh and posterior vaginal wall (posterior colpopexy) to

obliterate the rectovaginal septum prior to anchoring the mesh to the sacral promontory [63]. The goal is to fix an enterocele or sigmoidocele and provide additional protection from pressure being applied to the anterior rectal wall. Several variations have been described for the colpopexy and/or hysteropexy. The vaginal fornix or vaginal vault is raised with a vaginal retractor, and the anterior side of the VMR mesh is sutured to the posterior vaginal wall, as described by D'Hoore. Alternatively, a separate piece of mesh may be attached to the posterior wall of the vagina and uterus and then attached to the sacrum. If the uterus is absent or a concomitant supracervical hysterectomy is performed at the same time as VMR, then a sacrocolpopexy may be performed which involves suturing mesh to the vagina anteriorly and posteriorly. The sacrocolpopexy will improve middle compartment support and also boost the bladder forward.

The use of mesh in VMR continues to be studied in regard to adverse events related to mesh fixation techniques and mesh material. Evans et al. reported mesh erosions after laparoscopic VMR in only 2% of 2203 patients [65]. Of these, 42 (2.4%) occurred in the synthetic mesh group and 3 (0.7%) in the biological mesh group. Of the three cases of biologic mesh erosion, two were actually non-absorbable suture (Ethibond®) sinuses as opposed to full mesh erosion. In the synthetic group, the use of polyester mesh was associated with much higher risk of erosion (6.5%), and the risk of erosion for polypropylene mesh was only 1.6%.

The type of suture used to secure mesh to the rectum and vagina may also impact the risk of mesh erosion. Tejedor et al. looked retrospectively at 495 cases of laparoscopic VMR with synthetic mesh (polypropylene) to compare the use of absorbable (PDS®) versus non-absorbable suture (Ethibond®) [66]. There was a 4% erosion in the non-absorbable suture group as opposed to 0% in the control group. Four erosions occurred into the rectum and two into the vagina.

Other than the concerns for mesh erosion, discitis has been described as a complication of any procedure that uses sacral fixation [52, 67–69]. Specifically for ventral rectopexy, it has been described in 0.1–2% of cases [25, 64, 65, 67]. It should be suspected in a patient with back pain radiating to the lower extremities and immediate evaluation and aggressive therapy initiated.

In general, VMR has been shown to improve functional symptoms of constipation and fecal incontinence. There is significant improvement in fecal incontinence in 60–80.2% of patients undergoing VMR [25, 70–72]; similarly the improvement in constipation is reported to occur in 58%–85% of patients [59]. In particular, symptoms of obstructive defecation syndrome (ODS) are reported to improve in 78.6% of patients. There are significant benefits in the function of the whole pelvic floor when combined with sacrocolpopexy as shown by improvement of the three axial perineal evaluation (TAPE) scores [73]. TAPE is an assessment that includes two questionnaires for each compartment. Improvement in stress urinary incontinence is seen in 53% of patients, gynecological prolapse symptoms in up to 93.75%, and statistically significant improvement in sexual dysfunction [67]. New onset or worsening of fecal incontinence after VMR has been reported in 1–3.9% [74], and new onset or worsening of constipation has been described in 1.4–12.9%.

The published recurrence rate of rectal prolapse after VMR varies from 0% to 15%, and the recurrence rate for pelvic organ prolapse is 8.5% [52, 64, 67, 70, 75]. Due to these low recurrence rates and symptomatic improvement in constipation and fecal incontinence, minimally invasive VMR is now considered the gold standard treatment for rectal prolapse in Europe. Laparoscopic VR is technically demanding and requires a complete ventral dissection of the rectovaginal septum (rectovesical in men) down to the pelvic floor and suturing skills within a confined space that further maximizes the difficulty. Mackenzie and Dixon reported that the proficiency gain learning curve for the relevant clinical and quality-of-life outcomes for laparoscopic VR was between 82 and 105 cases [74]. Proficiency with respect to reduced operating time was reached at 54 cases. Poor technique minimizes the functional benefit and increases the risk for complications.

Ventral rectopexy is ideally suited for robotic surgery. There is some evidence that the use of the robot may have better functional results possibly because of the better opportunity to overcome the difficulties of operating in the deep pelvis and of suturing on the distal rectum and the pelvic floor muscles. [70] Systematic review and meta-analysis comparing the outcomes of robotic VMR versus laparoscopic VMR reveal similar recurrence, conversion, and reoperation rates [76]. The meta-analysis shows that operative time is significantly longer for robotic VMR, but the robotic approach is associated with a significantly lower blood loss, fewer postoperative complications, and shorter hospital course.

Recurrent Rectal Prolapse

Deciding how to manage recurrent rectal prolapse is difficult, and the current quality of evidence is insufficient to create an algorithm. That being said, female patients with multicompartment POP at the time of their rectal prolapse recurrence should have a multidisciplinary evaluation and treatment plan that minimizes the risk of recurrent prolapse. Gurland et al. reported recurrence rates after ventral rectopexy to be much higher and occurring sooner on patients who had prior prolapse surgeries (25% at 5-year follow-up) compared to those who had VMR for their primary repair (9.7% at 5-year follow-up) [77]. This study also found the risk of full-thickness rectal prolapse recurrence to be even higher if the initial oper-

ation had been a Delorme procedure. Similarly, Hotouras et al. reported that patients who were treated for a rectal prolapse recurrence with a perineal approach had a much higher risk of a second recurrence [78]. This has been reported to be as high as 50%. Given the lower rates of re-recurrences with abdominal procedures, a recurrence should ideally be managed with an abdominal approach. An important consideration is that of vascular supply when performing a resection rectopexy on a patient with a prior Altemeier procedure. The possibility of leaving a devascularized segment of rectum in between the two anastomosis is more than theoretical as reported by Fengler et al. and Steele et al. [33, 79]. These reports included one patient who had sloughing of the rectal mucosa and two patients with postoperative strictures. The same warning would apply for those patients who had a resection rectopexy initially; an Altemeier procedure with a second anastomosis should be avoided unless the prior anastomosis can be included in the specimen. In VMR, if a recurrence occurs early, detachment of the mesh from the sacral promontory should be suspected and reattachment considered. In some situations, a more extensive dissection even to include a posterior dissection may be performed. Overall, based on the current literature, patients with recurrence should be warned of their much higher risk of re-recurrences no matter which operation is performed.

Conclusion

The ideal operation for rectal prolapse would be one with the lowest morbidity, best functional results, and lowest recurrence rate. The single, most ideal surgical repair has not yet been determined. A careful history and physical exam can help in understanding the patient's symptoms and their expectations from undergoing surgical repair. Additional evaluation with validated questionnaires, pelvic floor physiology testing, and defecography imaging can provide deeper insight into the strength, coordination, and anatomic pelvic deficits associated with the prolapse. Thus, several factors influence the exact surgery offered to a patient. In those patients who do not have prohibitive comorbidities, an abdominal repair seems to have the best anatomical and functional results with the lowest mortality. As with other surgeries, there is higher morbidity and mortality with open approaches as opposed to minimally invasive surgical approaches. Robotic surgery may provide some technical benefits in performing ventral mesh rectopexy.

There is growing evidence that a multidisciplinary evaluation is necessary in women presenting with rectal prolapse, and surgical planning should treat the pelvis as a single functional unit. As such, the choice of operation should be one that encompasses all three compartments if necessary. Women who have pelvic organ prolapse have a higher recurrence rate after isolated rectal prolapse repair; furthermore, there is evidence that correcting only one of the pelvic floor compartments often worsens symptoms in the other compartments [71, 80, 81].

In male patients, and females without multicompartment POP, the choice of operation maybe more difficult to determine. The current level of evidence does not provide a single, clear recommendation. Regardless, better functional outcomes and lower recurrence rates are seen with sigmoid resection with rectopexy and with ventral mesh rectopexy. Ultimately, surgical correction of rectal prolapse can allow for significant improvement in life-altering symptoms such as fecal incontinence, constipation, pelvic pressure, and outlet obstruction, but all surgical options carry a risk of developing recurrent rectal prolapse.

Fecal Incontinence: Evaluation and Treatment

61

Giovanna da Silva and Anders Mellgren

Key Concepts

- A thorough history and physical examination and conservative management measures should be the initial step in managing fecal incontinence.
- Preoperative physiology testing can assist the surgeon in selecting the optimal treatment modality.
- Sacral neuromodulation is successful for patients with and without sphincter defects; however, reinterventions are not uncommon.
- Biomaterial injection may provide limited benefits.
- Overlapping sphincteroplasty is an option for younger patients with an isolated sphincter injury, as after obstetric injury.

Introduction

Fecal incontinence (FI) is a distressing and embarrassing condition, which is usually defined as uncontrolled passage of feces or gas (anal incontinence) over at least 1 month's duration in an individual who had previously achieved control. The estimated prevalence varies in the literature, according to the definition, methods used, and population studied. An up-to-date systematic review of 4840 articles showed an estimate rate ranging from 1% to 19% [1]. The severity of FI varies widely but can have a significant negative impact on affected individuals with reduced quality of life, depression, and associated social stigma [2].

Continence is a complex mechanism which depends on the interaction between stool consistency, anal sphincter function, rectal compliance, neurologic function, and pelvic floor muscle coordination. FI is frequently multifactorial and caused by disruption of one or more of these components (Table 61.1).

Evaluation

History and Physical Exam

Evaluation starts with a detailed history and physical exam, which allows the physician to identify potential cause(s) of FI and direct counseling and management. Bowel habits should be assessed for frequency of bowel movements, presence of diarrhea or constipation, and any recent changes. Medications should be carefully reviewed. Comorbidities, such as diabetes, neurologic conditions, irritable bowel syndrome, inflammatory bowel disease, previous radiation inflammatory bowel disease, rectal prolapse and previous radiation can contribute to FI. Concomitant urinary symptoms or anterior prolapse should be inquired can contribute to FI. Past obstetric and surgical history, including episiotomy, colectomy, and/or anorectal procedures, should be documented. A proper history can determine the severity of FI and its impact on patient's

Table 61.1 Etiology of fecal incontinence

Anatomical abnormalities	Sphincter trauma: obstetric, accidental, anorectal surgery Rectal prolapse/intussusception Imperforate anus
Neurologic	Pudendal neuropathy (stretch injury, diabetes mellitus, radiation, chemotherapy) Central nervous system (stroke, dementia, spinal cord injury, trauma, tumor, multiple sclerosis, cauda equina)
Stool characteristics	Diarrhea (infectious, IBS, inflammatory bowel disease, malabsorption, laxative abuse, radiation enteritis) Constipation (overflow incontinence)
Rectum	Radiation proctitis, LAR/coloanal anastomosis, etc.

Table 61.2 Cleveland Clinic Florida-Fecal Incontinence Score (CCF-FIS) [44]

	Frequency				
Type of incontinence	Never	Rarely	Sometimes	Usually	Always
Solid	0	1	2	3	4
Liquid	0	1	2	3	4
Gas	0	1	2	3	4
Wears pad	0	1	2	3	4
Lifestyle alteration	0	1	2	3	4

Never, 0; rarely, <1/month; sometimes, <1/week, ≥1/month; usually, <1/day, ≥1/week; always, ≥1/day. Minimum score 0 (perfect continence), maximum score 20 (complete incontinence)

quality of life. Several scoring systems have been developed to help in the evaluation of these patients. The Cleveland Clinic Florida Fecal-Incontinence Scoring System (CCF-FIS) is a validated tool that is simple and helpful in the evaluation of these patients (Table 61.2).

Physical examination starts with inspection of the perianal skin for rash, scars, trauma, deformities, fistula, excoriation, patulous anus, prolapsing hemorrhoids, and rectal prolapse. The patient should be asked to bear down to further examine for rectal prolapse and descending perineum, which is a sign of pelvic floor weakness. Sensation is assessed by using a cotton ball and/or a sharp object to touch the perianal skin. The presence of the anocutaneous reflex ("anal wink") suggests an intact sacral reflex arc and pudendal nerve innervation of the external anal sphincter. On digital rectal exam, the resting tone and voluntary squeeze increase are noted. Attention to whether the gluteus is used to help in contraction, presence of rectocele, and thickness of the perineal body are noted.

Anorectal Manometry

Anorectal physiology testing can give insight and objectively document pelvic floor function. Although manometry may not always correlate with clinical examination or predict response of treatment, the assessment can be helpful to guide therapy [3]. Anorectal manometry measures the internal (resting) and external (squeeze increase) sphincter pressures, sphincter length, anorectal sensation, rectal compliance, and anorectal inhibitory reflex. Sphincter pressures are usually low in FI; however they might be normal or increased in the presence of anismus or incomplete evacuation, especially in men with FI [4]. Low internal sphincter pressures are seen in patients with leakage or passive incontinence, whereas the external sphincter pressures are associated with urgent, active incontinence. Rectal hyposensitivity can lead to constipation associated with incontinence [5], whereas rectal hypersensitivity is seen in patients with urgency, diarrhea, IBS, low anterior resection syndrome, or radiation. The lack of rectoanal inhibitory reflex is seen in Hirschsprung's disease, after anorectal surgery, or in patients with connective tissue disorders. The rectoanal inhibitory reflex can be difficult to see/ evaluate in patients with low anal resting pressures. Compliance can be decreased in inflammatory bowel disease, after radiation, or in patients with scleroderma.

Ultrasound

Anal ultrasound provides an objective assessment of the sphincter integrity and can readily diagnose injuries or anatomic deficiencies of the internal and external anal sphincters. Ultrasound is relatively cheap, is conveniently available for the surgeon, and offers the best imaging of the internal sphincter. MRI can be an alternative for imaging, especially for the anterior part of the external sphincter or imaging of concomitant pelvic prolapse. In experienced hands, complete pelvic floor ultrasound with transperineal and transvaginal techniques can offer excellent imaging of all pelvic compartments. Pelvic floor ultrasound can identify pelvic organ prolapse and other anatomical abnormalities that may contribute to FI.

Neurophysiology Testing

Anorectal neurophysiology testing of the pelvic floor can be achieved with pudendal nerve terminal motor latency (PNTML) testing and electromyography (EMG). PNTML evaluates the neuromuscular integrity between the pudendal nerve and the anal sphincter. A finger is introduced into the rectum, with an electrode mounted on a glove, and electrical impulses are delivered to the pudendal nerve. The latency between the electrical impulse and the muscle response is measured as PNTML, and a prolonged latency can be indicative of neuropathy. Recent data indicates that a prolonged PNTML does not independently predict the success of treatment and the technique [6–8] and the technique has slowly faded away as a diagnostic modality [9].

Sphincter mapping with EMG can identify sphincter defects and identify signs of nerve injury. The technique involves placing a needle into the sphincter muscle, which may cause significant discomfort and is nowadays infrequently used [10].

Defecography

Defecography evaluates the dynamic of defecation and can be performed with fluoroscopic or MRI technique. For FI, the exam can be valuable to confirm the inability to retain stool, which is a measurement of the severity of the FI, and to identify impaired evacuation and/or pelvic organ prolapse contributing to FI. The presence of a rectal intussusception is

a negative predictive factor for sacral nerve neuromodulation [11], and these patients may be possible candidates for ventral rectopexy. Incomplete evacuation and anismus have been associated with anal leakage, especially in men.

Colonoscopy

Colonoscopy is indicated according to the screening guidelines and in patients with bowel symptoms. Colonoscopy can exclude underlying pathology, such as malignancy and IBD, in patients with FI. In patients with diarrhea, especially older women, colonoscopy with biopsies should be performed to rule out microscopic colitis.

Treatment

Goals of treatment include decreasing the frequency and severity of FI accidents and improve quality of life. Most patients benefit from starting with conservative treatment modalities, especially since the below treatment alternatives rarely can offer complete resolution of incontinence symptoms. Conservative treatment and regulation of bowel habits can be combined with pelvic floor exercises or a rectal or vaginal insertion device.

Patients who don't respond to conservative treatment or biofeedback can benefit from minimally invasive treatment options or surgery. The most common minimally invasive treatment option is sacral neuromodulation (SNM). Alternative minimally invasive treatments include injection of a bulking agent injection, percutaneous tibial nerve stimulation, and radiofrequency remodeling (SECCA). There are also other minimally invasive therapies, including stem cell therapy and anal sling, but they are currently not available in the USA.

Patients with a defined sphincter disruption may be potential candidates for surgical sphincter repair (sphincteroplasty). Another surgical alternative, in patients with rectal intussusception or rectal prolapse, is ventral rectopexy. Gracilis muscle transposition can potentially help to strengthen the anal sphincters. Electrical stimulation of the gracilis muscle has been advocated to achieve improved results, but this treatment alternative is currently not available. Other treatment alternatives, which are currently not available in the USA, include the magnetic anal sphincter (MAS) and artificial bowel sphincter (ABS).

Conservative Treatment

First-line therapy should include dietary modifications avoiding sweeteners, dairy, caffeine, and medications known to aggravate FI. Antidiarrheal, cholestyramine, and/or fiber supplement to bulk the stool can lead to improvement in a significant portion of patients.

Bowel management may consist of enemas or suppositories to reduce the volume of stool in the rectum (and thereby decrease FI episodes). More recently, an anal irrigation system (Peristeen™) has been used in adults with low anterior resection syndrome with an improvement of symptoms quality of life [12]. The device consists in a balloon that is introduced into the rectum, a pump, pressure control unit, and a water container. Patients are trained to irrigate the colon with up to 1.5 L of water a few times per week.

Pelvic Floor Exercises

Pelvic floor exercise, or biofeedback, is a first-line therapy in FI patients. Although some studies have shown biofeedback results to be no different from advice and education [13], a Cochrane review found some evidence that biofeedback and electrical stimulation may enhance the outcomes of treatment compared to electrical stimulation alone or exercises alone [14]. Biofeedback therapy can improve rectal sensation and may enhance coordination between perception of rectal distention and external sphincter contraction in patients with reduced rectal sensation. In a study including 124 patients, Regadas et al. [15] found a 50% reduction in FI score in approximately 50% of the patients. Patients less likely to respond to biofeedback were those with CCF-FI score $\geq$10, previous vaginal delivery, and anorectal and/or colorectal surgery and those unable to maintain a squeezing effort.

Anal Insertion Device

Anal plug (Fig. 61.1) is an adjunct to conservative therapy. The plug is inserted into the distal rectum by the patient, with the goal of blocking the involuntary passage of stool. A Cochrane review noted that plugs can be difficult to tolerate [16]. A multicenter prospective study [17] evaluating a soft silicone anal insert found that 77% of the 73 patients who completed the study (62% of 91 intention-to-treat patients) achieved a $\geq$50% reduction in incontinence frequency over a 12-week period. The insert might be of greater benefit for patients with mild FI [18].

Vaginal Bowel Control System

The vaginal bowel control system (Fig. 61.2) is another supplementary tool that consists of a vaginally introduced insert with a balloon and a pressure-regulated pump designed to

temporarily occlude the rectum from the vagina. The device is deflated for defecation. Some patients find the device difficult to fit and uncomfortable. In a recent multicenter study [19], an open label trial with 137 patients, 62% could be fitted with the device. In this study, 73 patients with moderate FI (mean CCF-IS of 14.1) and who were able to keep the device had a success rate of 94% at 12 months. In these patients there was a significant improvement in the Fecal Incontinence Quality of Life score, and the satisfaction rate reached over 94% at 12 months.

Fig. 61.1 Renew anal insertion device

Sacral Neuromodulation

SNM has become a popular treatment for patients with moderate or severe FI. Initially, SNM was offered to patients with an intact external anal sphincter or patients with a limited sphincter defect. Over time, however, the treatment indications have widened. Today SNM treatment is offered to patients with or without a sphincter defect, and both groups achieve similar treatment results (Fig. 61.3).

The mechanism of action is not clearly understood. Postulated mechanisms include stimulation of the somatovisceral reflex, direct effect on anal sphincter complex, and afferent neuromodulation. The SNM procedure is performed in two stages. The first stage consists placing a lead to evaluate the treatment effect over a 1–2-week period. Patients who achieve a ≥50% improvement of the number of FI episodes qualify for the stage 2. The trial period can be performed by placing a unipolar stimulation lead percutaneously (PNE) in the office, which is later removed, or by inserting a quadripolar lead in the operating room. Whereas PNE might have a slightly higher failure rate [20], testing with a quadripolar lead may have a slightly higher risk of infection [21].

The US multicenter trial that led to FDA approval demonstrated the efficacy of SNM [22]. Of the 120 patients who underwent permanent implantation, 83% had ≥50% reduction of incontinent episodes at 1 year, and 41% achieved 100% continence. The success was maintained at 5-year follow-up, with 89% (64/72) of patients achieving ≥50%

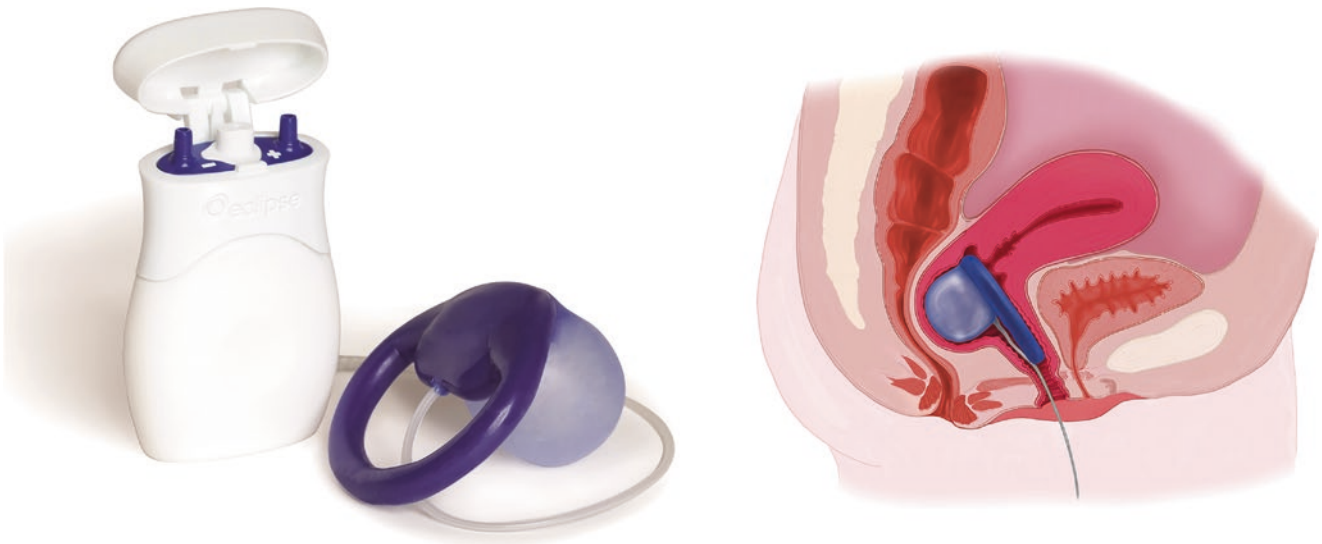

Fig. 61.2 Vaginal bowel control system (Eclipse). The vaginal bowel control insert is folded and deflated for insertion (right) and inflated as it would sit in the vagina; the insert is inflated with a handheld pressure-regulated pump. (Reused with permission from Pelvalon Inc.)

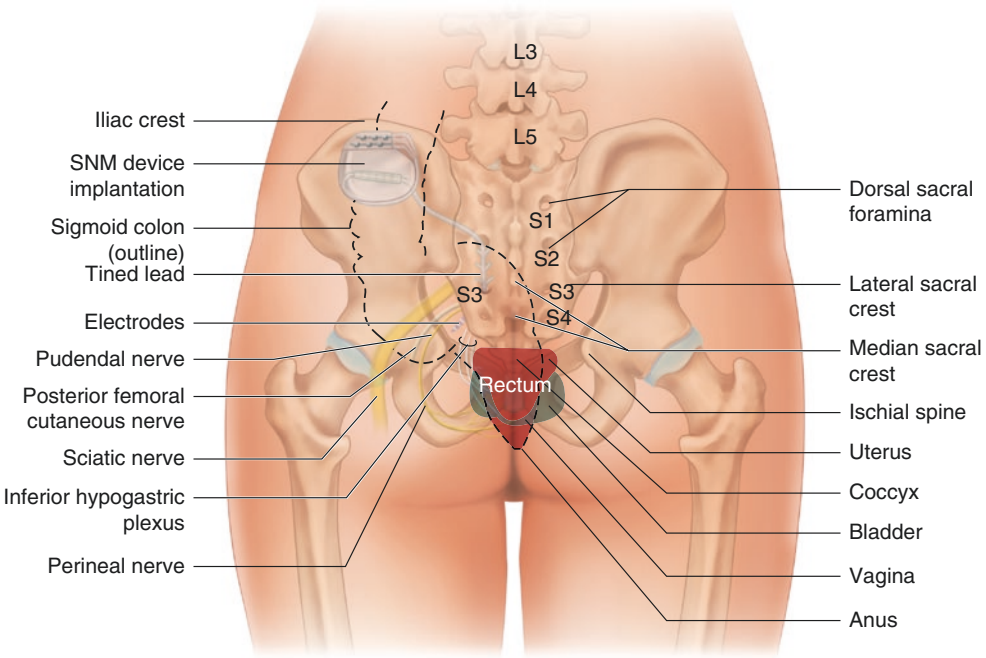

Fig. 61.3 Sacral nerve stimulation. Sacral nerve modulation: the lead is placed through the S3 foramen, and the implantable pulse generator is placed below the iliac crest and lateral to the sacrum

improvement ($p < 0.0001$) and 36% ($n = 26/72$) of patients reporting complete continence. Fecal Incontinence Quality of Life scores also significantly improved [23]. In a longer follow-up of 7 years, the European SNS group reported sustained success in 71.3% of patients who retained the device, and half of the patients sustained success on intention-to-treat analysis [24].

Complications related to sacral nerve stimulator placement include pocket complications, lead complications, infection, pain, and loss of efficacy. Infection frequently requires an explant of the lead and stimulator. Otherwise, most complications can be managed or improved by conservative means including medication or reprogramming. The reoperation rate can however be as high as 42% [25, 26], and the stimulator needs to be changed every 3–5 years. Recently, a rechargeable device has been introduced for SNM. This device can be used for up to 15 years and patients can undergo full-body MRI conditionally safe. The results of this device seem comparable with the original InterStim [27].

Bulking Agents

Multiple agents have been proposed to increase the bulk of the anal canal. In 2011, the US Food and Drug Administration (FDA) approved a nonanimal stabilized hyaluronic acid/dextranomer gel for submucosal injection (NASHA Dx) for the treatment of FI (Fig. 61.4). The largest randomized controlled trial to date [28] compared NASHA Dx versus sham injection. The treatment arm demonstrated treatment success (a 50% decrease in the number of FI episodes) in 52% vs. 31% of patients in the placebo group ($P = 0.0089$). There was no significant difference in the FI scores between the groups at 2 months. At long-term follow-up (36 months), there was a sustained reduction in incontinence episodes (52%) with significant improvement in quality of life measures [29]. A randomized trial comparing NASHA Dx with biofeedback failed to show any difference in outcomes [30]. The final role of NASHA Dx in the treatment of fecal incontinence remains unclear. Most studies were not designed to evaluate if NASHA Dx works better in patients with minor or major symptoms of incontinence. In clinical practice indications have evolved and NASHA Dx is a treatment option more commonly for patients with mild or moderate incontinence, male patients with incontinence (especially if they have soiling), patients with residual incontinence after treatment with sacral neurostimulation, and for patients with postoperative key hole defects.

Percutaneous Tibial Nerve Stimulation

Percutaneous tibial nerve stimulation (PTNS) is thought to cause similar changes in anorectal neuromuscular function as SNM because of the shared sacral segmental innervation. Earlier studies reported success rates between 63% and 82%,

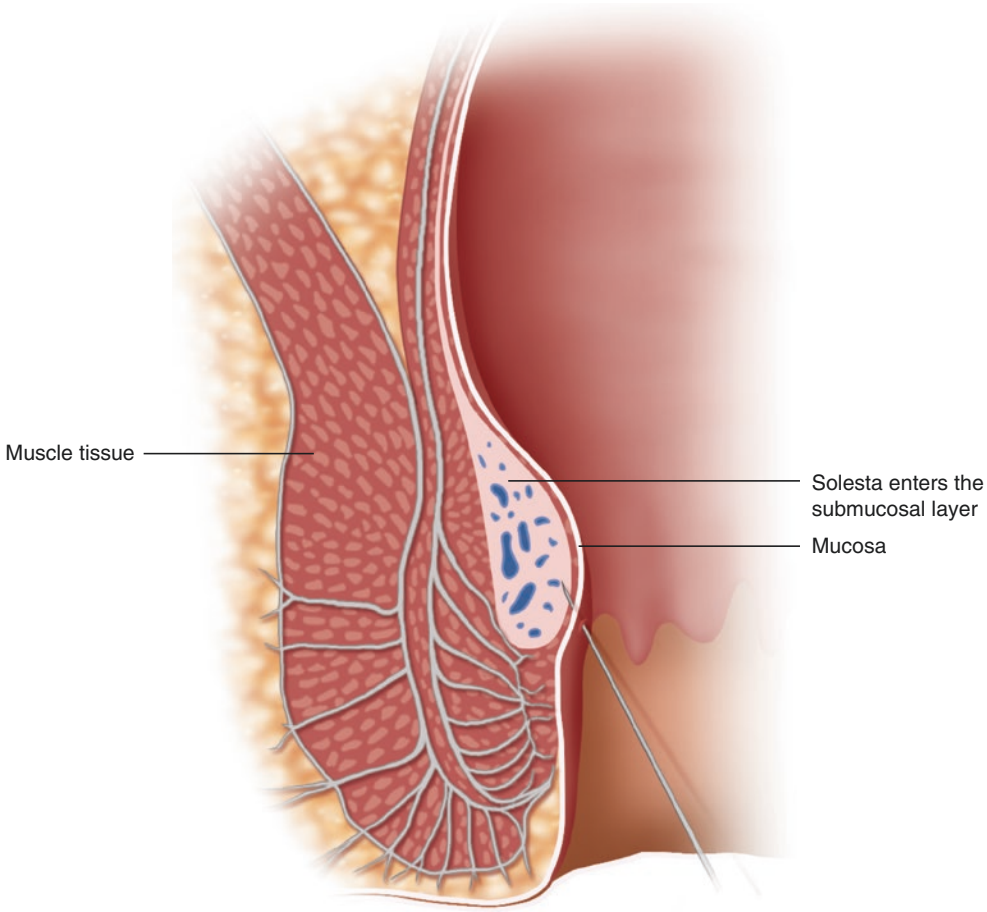

Fig. 61.4 Bulking agents. Biomaterial injection is performed by inserting the needle above the dentate line and into the submucosa

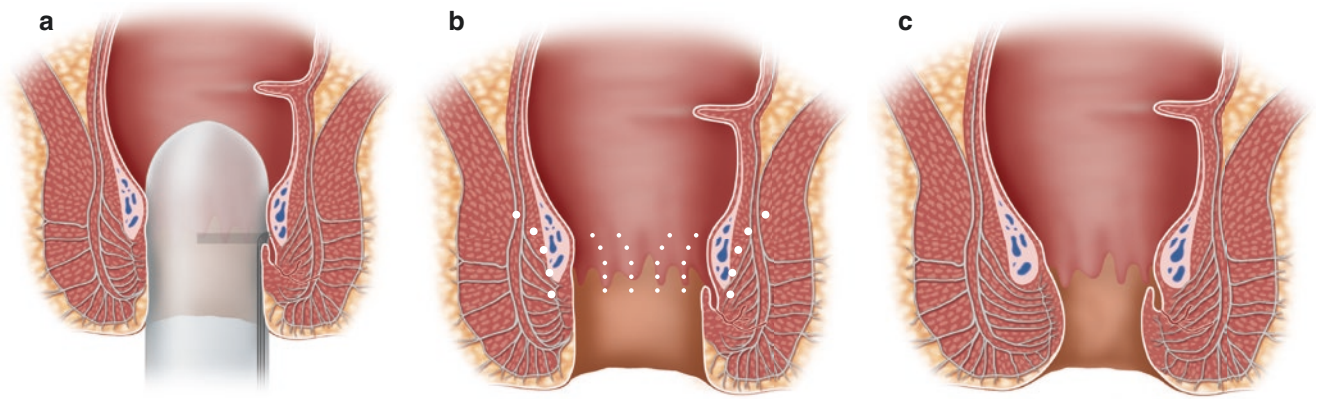

Fig. 61.5 Radiofrequency (SECCA) procedure. (**a**) Anoscope wires are deployed in three to four quadrants circumferentially and are meant to enter the internal anal sphincter. (**b**) Radiofrequency treatment is performed at four levels within anal canal, both above and below the dentate line. (**c**) Procedure leads to internal anal sphincter thickening

with different variability in the technique and frequency of stimulation [31]. A randomized double-blind controlled trial was performed in the UK [32]. The study included 227 patients, with 115 receiving PTNS and 112 sham stimulation. There was no significant difference between the groups at 12 weeks after treatment. A systematic review comparing PTNS with SNM demonstrated SNM to be associated with better functional outcomes and quality of life [33].

Radiofrequency Energy Delivery

Radiofrequency tissue remodeling (SECCA®) is a therapeutic option for patients with mild-to-moderate FI with intact or limited sphincter defects (Fig. 61.5). Radiofrequency energy is delivered into the internal anal sphincter to stimulate collagen deposition and thickening of the muscularis propria and thereby increase the outlet resistance.

Frascio et al. [34] reviewed the outcomes across several studies and found 55–80% of patients with mild-to-moderate FI were deemed responders at 12 months, showing limited improvement in CCF-FIS scores. Reported long-term results are variable [35–37]. One study reported a 3-year durability of improvement, without need for reintervention, in 22% of patients. Another study found that only 6% of patients maintained their results after the same time interval. A recent randomized controlled trial compared the clinical response of SECCA® to a sham procedure in 40 patients [38]. The authors demonstrated a statistically significant decrease in the Vaizey FI scores in patients undergoing the SECCA® procedure, although only two patients met the criteria for clinically relevant improvement (≥50% reduction in FI score or episodes). The ASCRS clinical practice guidelines state that SECCA® may be used to treat FI but recommend that alternative treatments be pursued before considering this therapy [9].

Stem Cell Therapy

The mechanism of action of stem cell injection is not fully understood, but is postulated as a means of providing recovery of sphincter function through regeneration of damaged striated sphincter muscle and/or expediting the healing process [39]. The most common studied stem cells in the treatment of FI are derived from muscle, bone marrow, and adipose tissue. In the first human study, ten women with FI from obstetric injury underwent injection of autologous myoblasts into the external sphincter [40]. At 12 months, the CCF-IS decreased by a mean of 13.7 points, anal squeeze pressures were unchanged, and overall quality of life scores improved. These results were sustained at 5-year follow-up [41]. Using myoblasts, Boyer et al. [42] reported the results of a phase II randomized, double-blind, placebo-controlled study. The authors enrolled 12 patients in the treatment arm and 12 in the control arm. At 6 months, CCF-IS score decreased in both groups, but at 12 months, the treatment group continued to show improvement in the CCF-IS score, while the control arm did not. No severe adverse events were reported. Stem cell is not FDA approved for FI at this time.

Anal Sling

Sling procedures involve correction of pelvic floor support with restoration of the appropriate anorectal angle, which is important for continence. Mellgren et al. [43] reported the results of a prospective, multicenter study involving 152 patients at 14 centers in the USA using the Transobturator Posterior Anal Sling (TOPAS, American Medical Systems). The TOPAS system involves looping a polypropylene mesh tape posterior to the anal canal using a minimally invasive needle-based delivery system. At 1-year follow-up, nearly 70 percent of women reported had ≥50% reduction in incontinent episodes as well as improvement in quality of life scores, with 19% reporting complete continence. Sixty-six patients reported one or more adverse events, the most common of which was pelvic pain. The TOPAS system is not available in the USA.

Surgical Sphincter Repair (Sphincteroplasty)

Anal sphincter damage sustained during childbirth is a common cause of fecal incontinence in women of childbearing age [44]. Occult sphincter defects during vaginal deliveries have been diagnosed by anal ultrasound in more than 30% of primiparous women and more than 40% of multiparous women and are especially common after forceps deliveries [45]. Sphincteroplasty may be an alternative for the younger patient with a defined sphincter defect as after an obstetric injury. Anal sphincteroplasty has the ability to also correct anatomical defects, such as a thinned perineal body or a rectovaginal fistula.

The operation is performed under general anesthesia and usually with the patient in the prone jackknife position. The operation starts with a curvilinear incision on the perineum, and the dissection is carried laterally to encounter the anal sphincter laterally on each side (Fig. 61.6a–d). A levatorplasty can be added to the procedure (Fig. 61.6e). Separate attention to the internal anal sphincter imbrication has not been demonstrated to add to the overall durability of sphincteroplasty [46, 47]. The ends of anal sphincter muscles are usually overlapped and repaired with mattress sutures, providing new bulk to the sphincter complex.

Short-term results (<5 years) are usually quite good, with improvement rates of about 70–90%. Few patients are completely relieved of their symptoms and results often deteriorate with time [48]. However, satisfaction remains relatively high despite deterioration of symptoms over time [48, 49].

Ventral Rectopexy

Patients with external rectal prolapse or significant rectal intussusception frequently have FI symptoms. Ventral mesh rectopexy (VMR) was first described by Andre D'Hoore et al. [50] in 2004. The initial idea for the procedure was derived from the cinegraphic data of Broden and Snellman [51], who demonstrated that the intussusception of the rectum starts usually in the anterior aspect. VMR aims to correct the descent of the posterior and middle compartment by mobilizing the rectovaginal septum down to the pelvic floor between the rectum and the vagina. Once the rectovaginal septum is dissected, it is reinforced with a mesh, and the mesh is fixed to the promontory.

The procedure carries a low rate of recurrence and offers good functional results in several studies. In a systematic review by Samaranayake et al. [52], the overall decrease in

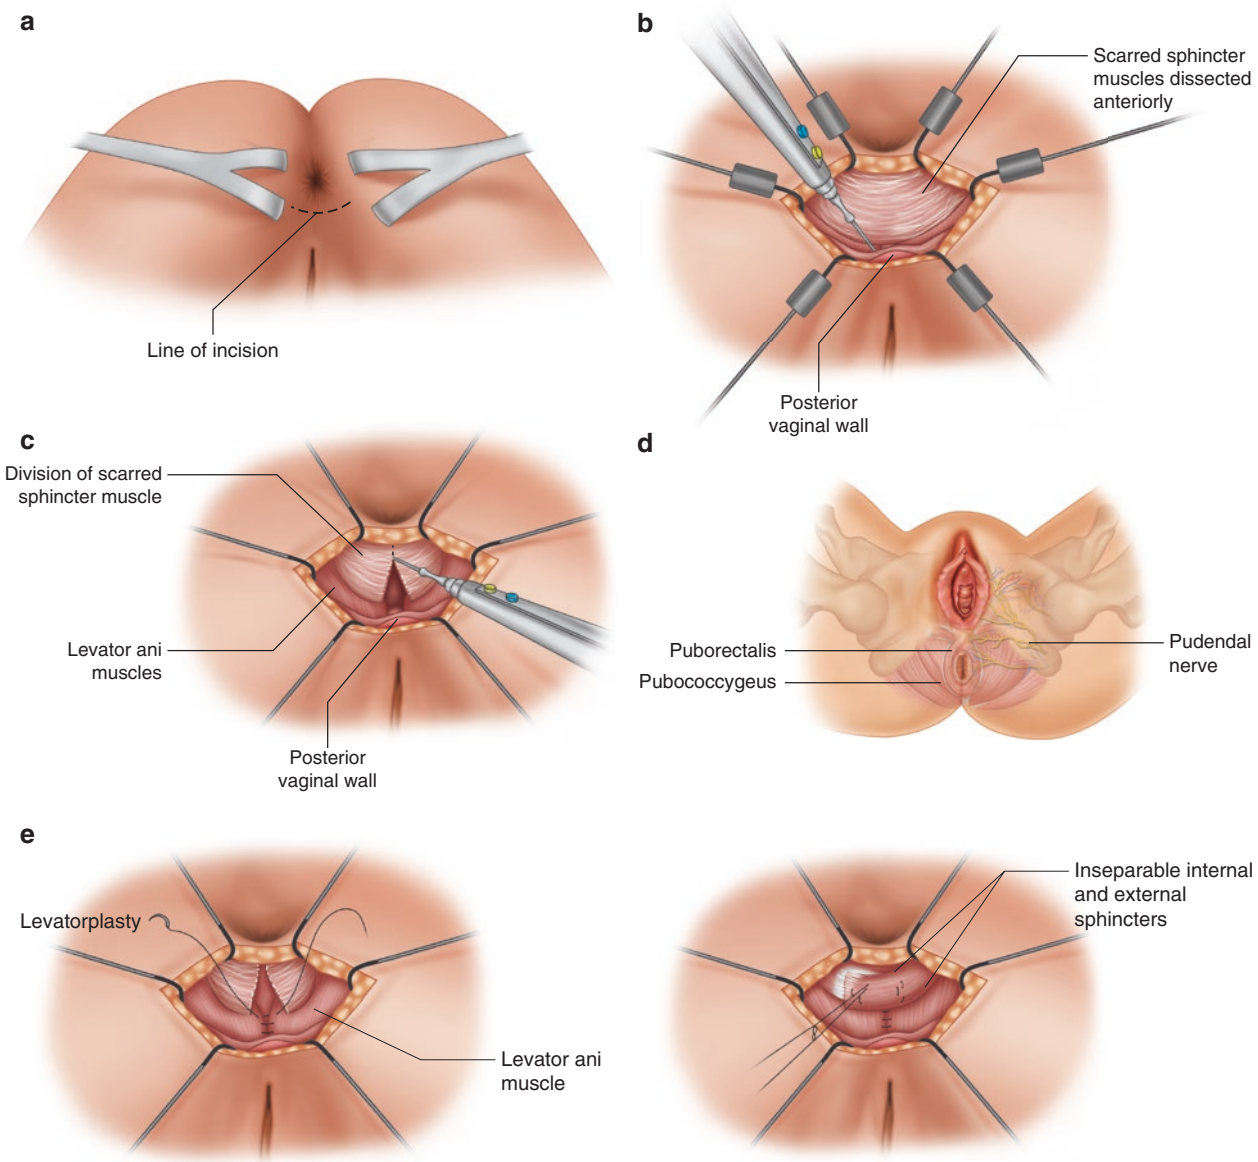

Fig. 61.6 Overlapping sphincteroplasty. (**a**) A curvilinear incision is made on the perineal body. (**b**) Scars with attached retracted sphincter muscles are dissected anteriorly. (**c**) Overlapping sphincteroplasty: anterior scan/sphincter complex is divided. (**d**) Surgeons must be aware of the course of the pudendal nerve and aim to minimize pudendal nerve injuries at the sphincter of sphincter repair by avoiding dissection beyond more than 180 degrees anteriorly. (**e**) Levatorplasty: (**a**) is performed when appropriate, (**b**) scar-sphincter complex is overlapped to allow the ends of the retracted muscles to be realigned as close as possible to each other

fecal incontinence score was 45% along with a significant decrease in constipation symptoms. VMR has therefore gained widespread acceptance in Europe as the treatment of choice for rectal prolapse. Some centers have expanded the indications to include patients with advanced internal prolapse (Oxford grades 3 and 4) with a combination of symptoms of FI and outlet obstruction symptoms [53, 54]. More studies comparing the functional outcome after VMR with other types of prolapse repair are still warranted.

Complication concerns include mesh complication, including mesh erosion into the vagina, bladder, or rectum, mid-rectal stricture, rectovaginal fistula, and chronic pelvic pain due to pudendal nerve irritation or chronic inflammation around the mesh. In most studies, the frequency of mesh-related complications seems to be low [55], but long-term follow-up is still limited.

Gracilis Muscle Transposition

Muscle transposition is usually performed with the gracilis muscle due to ease of harvest. The gracilis is located superficial in the medial thigh and can be transposed without any sequelae for the patient. The muscle has a single vascular pedicle in the proximal part of the muscle, facilitating its transposition around the anus.

The transposed muscle can be stimulated with an intramuscular electrode linked to an impulse generator in subcutaneous tissues. This induces contractions, and the initial fast-twitch fatigable muscle is retrained to become a slow-twitch, fatigue-resistant muscle. The technique demonstrated good effect in some patients, but complications were common [56–58]. Complications included surgical site infection, pain, device problems, erosion, and outlet obstruction. Dynamic graciloplasty is currently not available.

Magnetic Anal Sphincter Augmentation

The Fenix™ Continence Restoration System (MAS) was approved by the FDA under a humanitarian device exemption for patients with FI who fail medical and other surgical management. MAS includes placement of a number of magnetic beads on a titanium string around the anal sphincter to provide improved outlet resistance of the anal canal. At defecation, the rectal pressure will dilate the

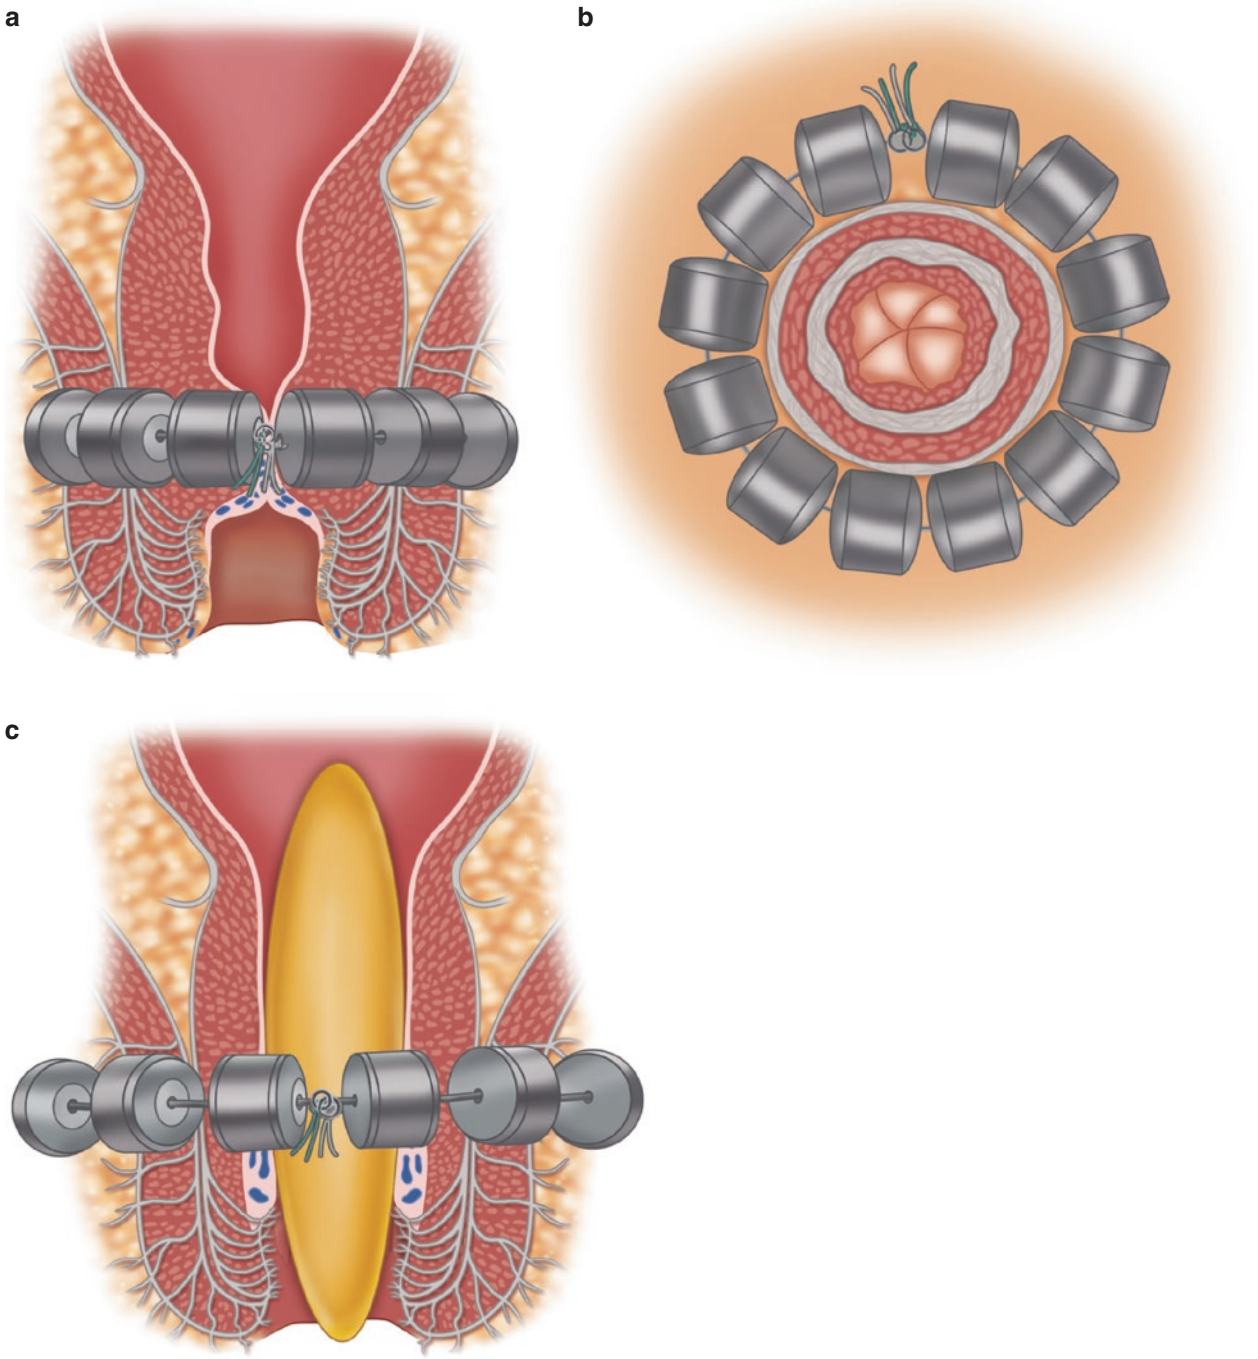

Fig. 61.7 Magnetic anal sphincter: (**a**) In the resting state, the magnets keep the anal canal closed. (**b**) Axial view to demonstrate placement of the magnetic sphincter outside the sphincter complex. (**c**) With bowel movements and Valsalva, the magnets expand to allow passage of stool

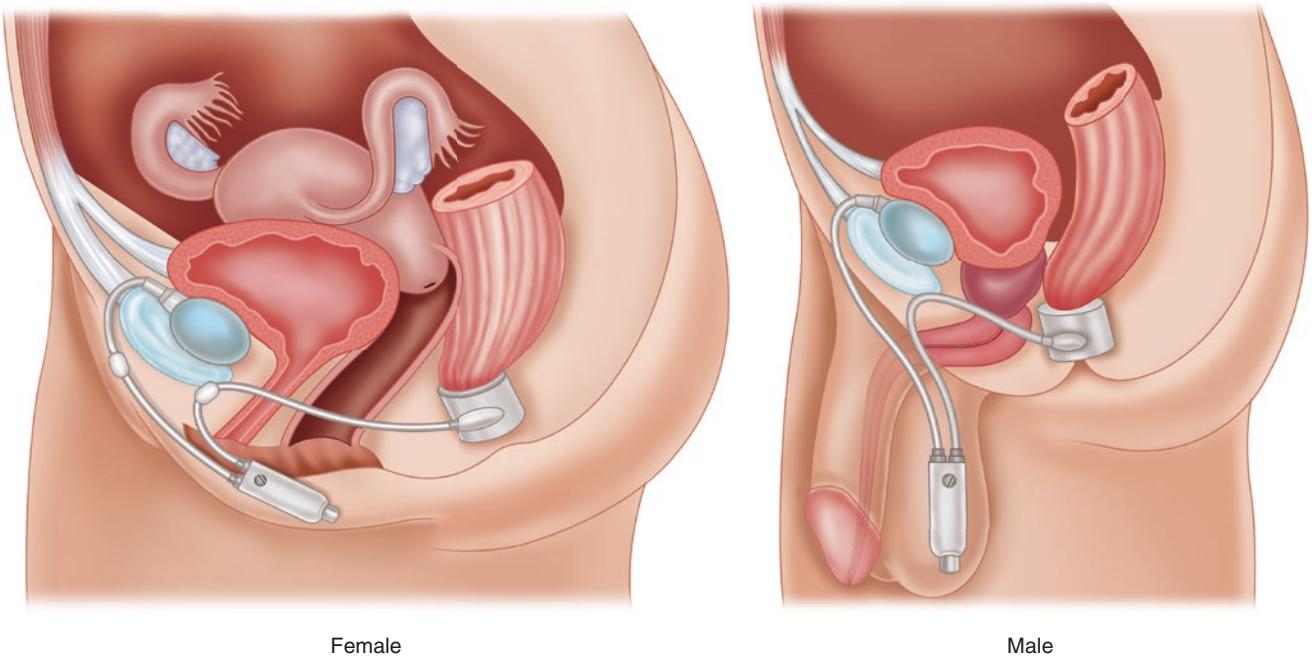

Fig. 61.8 Artificial bowel sphincter placement in males and females. The cuff is placed to encircle the anus, while the balloon is located in the space of Retzius. The button is placed in the labia in females and in the scrotum in males

anal canal with separation of the magnetic beads (Fig. 61.7).

Current literature, while limited, reports favorable outcomes in terms of improvement in FI scores with success in half of the patients at 5-year follow-up [59]. Complications include infection, pain, and gluteal swelling, and some patients will need to have the device explanted. The Fenix™ Continence Restoration System is currently not available.

Artificial Bowel Sphincter

The artificial bowel sphincter (ABS) system consists of an implanted cuff around the anus that is connected to a pump implanted within the subcutaneous tissues of the labia majora or scrotum. When defecation is required, the pump is compressed, deflating the implanted anal cuff and allowing the cuff fluid to drain into a balloon reservoir in the space of Retzius (Fig. 61.8). Though studies demonstrate solid results of approximately 60–70% in patients with end-stage FI, the device is associated with high rates of infection and erosion, which often required revisions and, ultimately, explantation [60, 61]. The ABS is no longer available in the USA.

Treatment Failure

When the above options fail, a well-constructed ileostomy or colostomy can lead to significant improvement in patients' quality of life. For selected motivated adult patients, the Malone antegrade colonic enema (MACE) procedure might be fashioned using a reverse appendicostomy or cecostomy. A catheter is introduced through the ostomy and the colon is flushed in an antegrade fashion.

A systematic review, including 374 patients who underwent MACE for FI and constipation, demonstrated that 47–100% of the patients still used their MACE stoma despite being time-consuming. Some patients report problems with soiling and leakage after usage of the MACE stoma. The rate of stoma stenosis varied from 8% to 50% and may require reintervention [62].

Conclusion

There are a variety of noninvasive and invasive options for the treatment of FI. Treatment should be tailored to the individual patient, based on the severity of the FI, anatomical abnormalities, and patients' expectations.

Low Anterior Resection Syndrome (LARS)

62

Liliana Bordeianou and Craig A. Messick

Key Concepts

- Significant alteration in bowel function altering a patient's quality of life commonly occurs after restorative proctectomy or low anterior bowel resection. This has been termed low anterior resection syndrome (LARS).
- Using a Delphi analysis, experts including patients with LARS have been able to describe the condition as eight symptoms and five consequences.
- No standardized tool exists that determines its severity. Careful questioning starting around 3 months after establishment of intestinal continuity is important to determine treatment options.
- It is important to determine if correctable problems that can mimic LARS are leading to these symptoms.
- Treatment starts with setting expectations, educating patients, and evaluating treatment outcomes. This involves a systematic incremental approach to treatment with precise written instructions and monitoring results.

Introduction

Current rectal cancer treatment involves a complex, multidisciplinary approach with individualized treatment tailored to disease location and its degree of local and systemic spread [1]. Following chemoradiotherapy and/or surgery, the subsequent injury to nerves altering pelvic floor function has become recognized and supported by a significant body of literature that describes their deleterious consequences [2, 3]. The collective bowel symptoms that develop have been grouped together under the eponym of low anterior resection syndrome (LARS). Though largely variable, patient-reported symptoms that develop within the first year include, but are not limited to, fecal incontinence (FI) (20–80%), urgency (30–90%), fragmentation (30–70%), painful defecation (20–50%), and clustering [4, 5]. How best to describe and approach patients who suffer from these symptoms has been generally lacking in the literature, largely due to no uniform LARS definition [3]. This has made meta-analyses and systematic research difficult or of low quality.

Despite lacking a consensus/definition, recent research has provided some insight into the frequency of LARS. LARS is defined as having bowel dysregulation causing a significant alteration in the patient's quality of life. As many as 58% of patients treated with a restorative proctectomy or low anterior resection (LAR), for a rectal cancer (or for benign etiologies), may report major symptoms of urgency, frequency, and clustering at 3 months. An astonishing 46% of patients continue to suffer from major symptoms of LARS at 12 months, and 41% continue to have symptoms at 54 months. This implies that for some, LARS may last a lifetime [6, 7].

Etiology

The etiology of LARS is poorly understood. It is speculated to be a combination of the loss of the rectal reservoir, autonomic denervation, an increase in colonic motility, damage to rectal mucosa from radiotherapy, a reduction of recto-anal sensitivity from pelvic dissection, and a decrease in the anal rest pressure. None of these theories have been properly studied or validated [8].

Definition

Low anterior resection syndrome has previously been pragmatically defined as "disordered bowel function after rectal resection, leading to a detriment in quality of life." Given the

major and long-lasting impact of LARS on rectal cancer survivors, modern efforts are underway to improve its recognition, diagnosis, and treatment [9]. The first step was determining a definition. A recent Delphi analysis consensus effort involving 325 experts (including 156 patients with LARS) successfully distilled the condition of LARS to eight symptoms and five consequences, which together encompass the important aspects of the syndrome and serve as its definition [10].

For a LARS diagnosis, any patient who underwent LAR would have at least one symptom and at least one of the listed consequences (Fig. 62.1). Once LARS is recognized, the next step would be to assess the severity with a validated tool [11]. Unfortunately, none of the existing tools cover all eight LARS symptoms, again highlighting the current difficulties in the accurate measurement of LARS [12]. LARS is the type of entity that we all feel we know when we see it – the measurement of its severity requires in-depth patient conversations at each visit, patience to understand which aspect of the syndrome may be getting better or worse with intervention, and a bowel diary.

LARS: Scope of the Problem

The precise number of clinically affected patients who experience LARS is highly variable as previously mentioned [3]. Laurberg and colleagues originally described LARS from expert physician opinion and developed an online clinical scoring instrument, validated in many countries (see Fig. 62.2) [13]. Though intended to provide a clinical assessment about the severity of recognized LARS symptoms, it does not provide an accurate appraisal of all patients who experience LARS. It is still the mainstay for clinical assessment for patients with LARS symptoms.

Risk Factors for LARS

Patients with LARS must have had some portion of their rectum removed. This is important as other patients may develop similar symptoms but have a preserved rectum. One group are those that undergo definitive chemoradiotherapy for other pelvic cancers as similar posttreatment bowel dysfunction symptoms have been reported from this group. This has mostly been described in women who have undergone chemoradiotherapy for cervical or anal squamous cell carcinoma. Though the number affected remains largely unclear, major bowel symptoms affecting their quality of life have been reported in 50% of treated patients [14, 15].

For patients who have undergone LAR, additional risk factors have been reported. Age, gender (female > male), tumor location from the anal verge, extent of mesorectal dissection, use of neo(adjuvant) pelvic radiation therapy, and having fecal diversion (loop ileostomy) have all been implicated [4, 7, 16, 17]. Acceptable fecal continence does not

APPENDIX 2. LARS Score: Scoring Instructions

Add the scores from each 5 answers to one final score.

Do you ever have occasions when you cannot control your flatus (wind)?

☐ No, never	0
☐ Yes, less than once per week	4
☐ Yes, at least once per week	7

Do you ever have any accidental leakage of liquid stool?

☐ No, never	0
☐ Yes, less than once per week	3
☐ Yes, at least once per week	3

How often do you open your bowels?

☐ More than 7 times per day (24 hours)	4
☐ 4-7 times per day (24 hours)	2
☐ 1-3 times per day (24 hours)	0
☐ Less than once per day (24 hours)	5

Do you ever have to open your bowels again within one hour of the last bowel opening?

☐ No, never	0
☐ Yes, less than once per week	9
☐ Yes, at least once per week	11

Do you ever have such a strong urge to open your bowels that you have to rush to the toilet?

☐ No, never	0
☐ Yes, less than once per week	11
☐ Yes, at least once per week	16

Total Score:

Interpretation:

0-20:	**No LARS**
21-29:	**Minor LARS**
30-42:	**Major LARS**

Fig. 62.2 Low anterior resection syndrome (LARS) scoring system. (Reused with permission © Wolters Kluwer 2020 [13])

protect against developing LARS. Eighty-five percent of patients who have most or all of the rectum removed maintain continence; however 42% of patients still experience LARS [18]. Additionally, inflammation due to an anastomotic leak has been shown to cause irreparable damage to the pelvic floor muscles adding to the severity of chronic bowel dysfunction [19].

Prediction of LARS for Patient Counseling and Surgical Planning

Considering the potential impact of both radiation and surgery for rectal or other pelvic cancers, a discussion of possible outcomes including postoperative bowel dysfunction and LARS is critical in preoperative counseling. Informed consent should not only discuss perioperative complications, but projected alteration in bowel dysfunction. The online Pre-Operative LARS (POLARS) nomogram has emerged as an aid to predict the development of LARS following restorative proctectomy [16]. When patients are confronted with the true risk of fecal urgency and other bowel problems that may dominate their lives, they may opt for a colostomy after proctectomy. Thus, an honest discussion of all surgical options including an end colostomy should be carried out with all patients, not just those who have baseline bowel dysfunction and mobility restrictions or patients confined to a wheelchair.

Prevention of LARS

There are no substantial studies on the prevention of LARS. Having symptoms and a definition will be key going forward to study this issue. The role of pelvic radiation is one area under study. Future research has also started on the effects of chronic diversion with a loop ileostomy (even 3 months) and long-term implications. The use of a mechanical bowel preparation may have an effect in LARS development and is under study [20]. Alternative neo-rectal reservoirs have been considered as ways to prevent LARS and FI. While short-term improvement in bowel function with a colonic J pouch has been documented, by 18 months, the patient-reported outcomes (PROM) are not statistically different

compared to an end-end anastomotic configuration [21]. Overall, no definitive intervention has proven effective to prevent LARS.

Diagnosis

The clinician should start to question their patient about bowel function starting around 3 months after restoration of intestinal continuity. Once suspected, exclusion and treatment of correctable LARS-like conditions should occur. Some of these LARS-like conditions include pancreatic malabsorption, bacterial small bowel overgrowth, or 5-FU-induced lactose intolerance. In addition, patients with LARS-like symptoms could also be suffering from radiation enteritis or fat and bile salt malabsorption from radiation-induced mucosal injury. Thus, patients with LARS or LARS-like conditions may be prescribed a trial of cholestyramine in an attempt to reduce and regulate bowel frequency [22]. Surgical strictures, ischemic conduits, or tumor recurrence can also produce a LARS-like pattern and should be considered. Flexible sigmoidoscopy in patients with LARS-like symptoms during the first 5 years after surgery should always be a consideration. This is particularly important if the patient has not been receiving adequate surveillance or the patient reports sudden worsening of their bowel function. Endoscopic evaluation should be done with the idea to exclude recurrence, stricture, or any correctable anatomical problem. If an intervention occurs, bowel symptoms should be reassessed post treatment.

Treatment Options

There is limited data to guide caregivers regarding the treatment of LARS. Most data are derived from small, nonrandomized trials with varied interventions and post-intervention assessments. Most of these studies did not employ the LARS score or any other validated tool, with most assessing FI only. Surgeons and caregivers should set realistic expectations for their patients. Treatment of LARS requires an individualized treatment plan that will not encompass one intervention, but likely multiple combined modalities in an effort to improve their symptoms. LARS should be viewed as a chronic disease, similar to diabetes or hypertension, and several interventions, adjustments, and modifications may be required over time to maintain and improve their quality of life. Some interventions may require other experts including gastroenterologists, primary care providers (PCPs), and mental health experts.

Despite these major limitations and difficulties, it is reassuring to know that with systematic care, patients with LARS can have meaningful improvements to their quality of life. In a recent study, simple implementation of a postoperative protocol to treat LARS systematically led to a drop in the LARS score from 31 (major LARS) to 18 (moderate LARS), with the rates of major LARS dropping from 51.9% to 26.3% [23].

Another randomized control trial (RCT) compared algorithmic care to routine ad hoc care and showed that algorithmic care demonstrated improved symptomatology and functional status in LARS patients [24]. This care can be administered by surgeons, gastroenterologists, PCPs, or advanced care practitioners. This requires patient education, patience, and a careful empathetic open dialogue between the patient and provider.

Regardless of who delivers care, it should be noted that a significant amount of information may be discussed or recommended per visit. Thus, it is extremely helpful to give precise written instructions for skin care and bowel altering medications so the patient does not rely on memory. Conversely, the provider should document data reported by the patient in a well-maintained bowel diary in an effort to monitor results over time. This will allow a systematic, incremental approach toward treatment.

Nonsurgical Interventions

Medical Therapy

Initial interventions for LARS should begin with dietary fiber and water to improve stool consistency, followed by fiber supplementation (bulking agents) and then anti-diarrheal/motility medications. Many patients remain reliant on these agents over the long term. Thus, patients should be reassured that long-term use of these medications is not detrimental.

Intraluminal bulking agents, such as dietary fiber supplementation and psyllium, are recommended with the idea of improving stool consistency, while simultaneously reducing fragmentation and clustering. If diet and fiber fail to provide adequate relief, antimotility agents like loperamide (non-opiate) and opiates such as atropine/diphenoxylate or tincture of opium may be added to the patient's medical regimen, typically along with continuing fiber and dietary modifications. Opioids function to reduce gastrointestinal propulsion. Loperamide effects only the intestinal muscle, whereas others have the potential for central nervous system alterations and are controlled substances that require longitudinal monitoring. Some patients with a clustering LARS phenotype have reported a deterioration in their LARS symptoms with opioids. When these interventions fail, a trial of amitriptyline is recommended (dose of 10–25 mg at night, as tolerated). Amitriptyline (tricyclic antidepressant) was evaluated in an open-label FI study and shown to decrease FI scores in 85% of patients [25].

Development of new medical therapies for LARS remains limited. This has resulted in clinicians extrapolating and trialing medications normally used to address symptoms of FI or urgency. Serotonin receptor agonists have been described as potentially useful in FI and eventually trialed in patients with LARS with modest effects [26]. Probiotics are postulated to improve GI symptoms by modifying the immunologic, digestive, or nutritional functions of gut bacteria. Treatment with probiotics in multiple formulations has been studied for a variety of GI disorders and is advocated by some authors for LARS patients. However, there is limited convincing data on the impact of probiotics on LARS symptoms. A small RCT study utilizing VSL#3 (probiotic) administration after loop ileostomy closure did not appear to have any effect on LARS symptoms [27].

Topical Treatments

Many patients with LARS report secondary symptoms of anal pain and skin irritation from skin breakdown caused by diarrhea and FI. Thus, counseling about skin care is an important component of LARS management. Barrier creams that contain zinc (such as Calmoseptine, Calmoseptine, Inc., Huntington Beach, California) and lanolin (if not allergic to wool) should be copiously applied up to the dentate line. When fungal superinfection is suspected, antifungal medication can be applied sparingly with a cotton ball, which dusts the powder over the anus. Another dry cotton ball could then be left near anus to wick away the moisture, which would otherwise collect between the buttocks even if the patient has a sanitary pad in their underclothes. Patients should be advised to avoid chemical wipes, abrasive toilet paper, and soaps that would dry out the skin and lead to chemical irritation. Instead, a gentle washcloth or use of wet toilet paper after defecation or a perineal wash using a bidet water sprayer may be advised. Finally, when pain is severe, temporary application of local anesthetic cream (Lidocaine 2%) on top of the barrier cream can be considered, until the anoderm re-epithelializes.

Biofeedback

Pelvic floor muscle retraining (biofeedback) may provide additional benefit to reduce LARS symptoms and should be considered in parallel with medical therapy and other interventions. However, data to support this is sparse. A recent systematic review of various low-quality studies looked at the effects of biofeedback on LARS. These researchers ultimately identified five trials that cumulatively involved 321 patients utilizing biofeedback for LARS, all conducted internationally [28]. Roughly 286 patients followed through with the recommended regimens. Only two of these trials were prospective, and the pelvic floor retraining protocols varied widely. Despite these limitations, 4/5 trials appeared to show an improvement in patients' bowel function. A recent open-label RCT suggested that most improvement appears to be for the symptoms of FI, with other aspects of the LARS remaining unchanged and no overall improvements in LARS score [29]. Clearly, better data on biofeedback and its efficacy in LARS is still needed, but in the interim, biofeedback remains a reasonable option in motivated patients, especially in those whose main symptom is FI. For patients whose main difficulties are incomplete emptying, clustering, or fragmentation, after six to eight biofeedback sessions, if no improvement is noted, stopping this therapy is reasonable.

Retrograde Colonic Irrigation (RCI)

Rectal irrigation is a frequently utilized treatment option for patients with LARS, regardless of their predominant symptom (fragmentation, clustering, diarrhea, or FI). Importantly this is not a simple rectal enema. Appropriate RCI involves retrograde, transrectal infusion of a high volume (500–1000 ml) of tepid water to fill the entire left side of the colon, followed by its evacuation. The treatment lasts approximatively 30 minutes and usually is performed in the evening or early morning based on patient preference. The key principle is similar to the concept used for colostomy irrigation. It is intended to condition the bowel to evacuate at the same time daily and aid in emptying the large bowel contents. This in turn decreases the need for another bowel movement for the rest of the day. The enema can be administered via a simple 28 Fr Foley catheter which is gently inserted into the neorectum. The catheter is then connected to a bag (typically a tube-feeding bag), which is hung high enough to provide hydrostatic pressure for the water to flow into the rectum and colon. The system has a regulator to allow gentle increase in colonic filling. This setup can be assembled from routine supplies found in any surgical clinic or purchased as a kit (e.g., Peristeen by Coloplast).

RCI has been shown to be effective in most cases of FI and is a frequent tool in the arsenal for LARS (see Chap. 61 on fecal incontinence). The data on RCI for LARS is derived from smaller studies, which appear to support its use in this particular group of patients. A RCT of 37 patients (18 treated with RCI, others with peripheral tibial nerve stimulation [PTNS]) found that patients using RCI reported a decrease in the maximum number of stool episodes per day and per night, as well as improvement in their LARS scores and Wexner FI scores [30].

In another two-group, parallel, open-label RCT of 27 patients with LARS patients treated with RCI, a statistically significant improvement in their LARS scores from 35

(major) to 12 (mild) was reported [31]. Martelucci et al. described 27 patients with LARS (19 early LARS and 8 chronic LARS) who reported a decrease in the number of median daily bowel movements and a decrease in their median LARS score while using RCI. Upon discontinuation of RCI, their symptoms returned [32]. Ultimately, 85% of patients who tried RCI asked to resume RCI after the study ended [32].

Initially patients receive education on RCI and are able to perform successful instillations. It is recommended a minimum trial of 6 months after they can successfully instill RCI, before considering escalation to a more aggressive treatment or to surgery. This also allows time to optimize and adjust their medical regimen, complete biofeedback, and allow the body to adapt to their new anatomy. Most patients may then decide that they are satisfied with the newly reached equilibrium and will not be interested in further escalation of treatment. Those who are still struggling, however, should be considered for surgical interventions.

Surgical Interventions

Sacral Nerve Neuromodulation (SNM)

Sacral nerve neuromodulation (also known as sacral nerve stimulation [SNS]) has emerged as an effective treatment for FI and has become a first-line therapy for FI which is not optimized with medical therapy. Although the mechanism by which SNM works remains unclear, it is postulated that its effects are probably mediated in the brain. The advantage with SNM is that it is minimally invasive and has a test phase before permanent device insertion (see Chap. 61 for details on insertion of SNM). There has been encouraging literature on the use of SNM in patients with LARS from small studies. A recent systematic review of SNM in patients with LARS identified ten studies, with variable endpoints [33]. Seven studies measured improvement in FI, while three looked at an improvement in the LARS score. Cumulatively, 94 patients were screened with PNE or tined lead implantation to demonstrate the effectiveness of SNM prior to permanent implantation of the stimulator. Seventy-five patients (79.8%) proceeded with permanent SNM implantation. Overall median improvement in LARS symptoms was 67.0% after SNM implantation. This is lower than success rates reported in the patients with benign etiologies of FI treated with SNM, but still meaningful considering the lack of treatment for this condition.

Given the minimally invasive nature of this intervention and the lack of other modalities before proceeding to stoma, a trial of SNM can be considered in all patients with LARS who have failed other options. Like all other treatments for LARS, SNM should be viewed as an intervention that is performed not as a replacement of prior therapy but rather as an additive to previously instituted treatments and bowel regimens.

Research is underway on other forms of neuromodulation to treat LARS, some of them nonsurgical. For example, there is emerging data on PTNS in either the office or at home [34]. The data on this intervention remains intriguing, but this option is not currently available in the USA to treat any form of bowel dysfunction. It is speculated that the FDA has not approved this for bowel issues due to contradictions in the data on its efficacy and discouraging results after a RCT showed no difference between PTNS stimulation and sham stimulation for patients with FI [35].

Antegrade Continence Enemas (ACE)

Historical data on use of antegrade enemas via an appendicostomy tube, Chait or Malone antegrade continence enema (MACE) tube, or cecostomy tube have been limited to the pediatric population. However, a 2016 meta-analysis of antegrade continence enemas in adults with FI (and constipation) offered initial insight into its potential role for adults with FI and patients with LARS. In their review of 17 observational studies (426 patients, 165 patients had FI), the pooled success rate (defined as continued use at follow-up or successful resolution of symptoms) for patients with FI was 83.6% (95% CI 75.0–92.1) at a median follow-up of 39 months [36]. The authors concluded that following failure of all other options, antegrade enemas should be considered in motivated patients before creation of a permanent colostomy [36]. A systematic review by Patel et al. published in 2015 produced similar outcomes and shared the same conclusions. Though these studies did not report which type of stoma was used to insert the antegrade enema, 1 study from France with 19 patients suffering from FI and an additional 10 patients who had undergone restorative proctectomy had a percutaneous endoscopic cecostomy (PEC) tube for access [35–37]. Antegrade enemas via PEC tubes were reported by the baseline FI and proctectomy patients as successful in 73% and 90%, respectively, with corresponding improvement in baseline CCIS from 14.3 (baseline) to 2.7 (post-PEC) at 6 months. However, by 2 years the scores up trended to 10.4. Other types of tubes such as the MACE tube have much more limited data and at this point are considered investigational as a treatment for LARS.

Fecal Diversion

Fecal diversion is a last resort therapy after all previous treatment options have failed to improve symptoms. Typically, when patients resort to a stoma, they are overwrought with symptoms. Whether a loop or end, small bowel (ileostomy) or colon (colostomy), stoma, fecal diversion undoubtedly offers patients a means to reestablish an acceptable quality of life. Though daunting to consider up front, the discussion of fecal diversion, preferably a colostomy (being cognizant

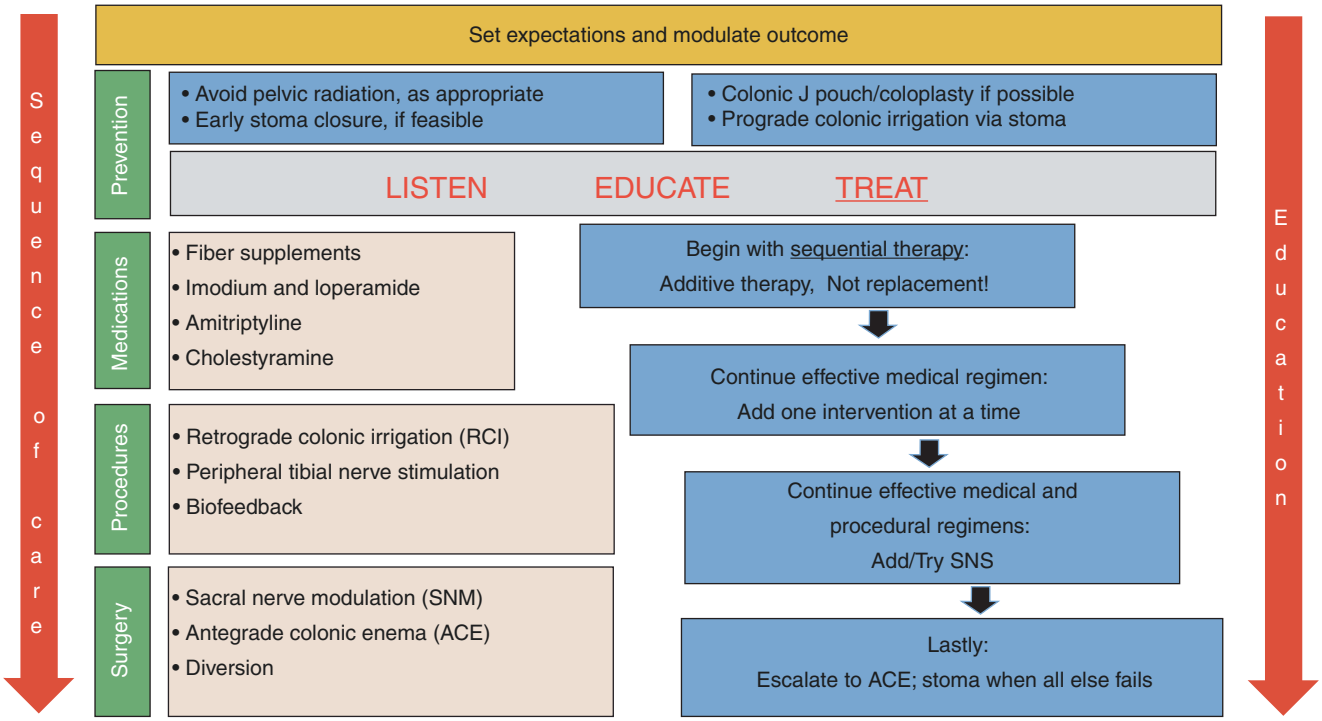

Fig. 62.3 Summary of the treatment algorithm

when constructing of the blood flow disarrangement due to the sigmoid and rectal resection), should be brought up as an option for those with severe bowel dysfunction and/or severe FI. It is imperative for the surgeon to perform the very best stoma possible as the goal is to improve the quality of life, not exchange it for a poorly constructed and functioned stoma. Figure 62.3 summarizes the algorithm for treatment.

Conclusion

Low anterior resection syndrome (LARS) is common. Recognition of this syndrome is increasing. However, treatments for LARS are still rather limited. Further research is underway to guide our understanding and treatment of this condition. In the interim, a real, clinician-patient-informed discussion, rooted in high-quality data and compassionate advice, is required from the very start of our decision-making when it comes to the surgical and medical approaches offered to treat rectal cancer. At the start of this journey, the goal of this discussion – which should include our multidisciplinary team – should calibrate the quest for cure and the quest for organ preservation surgery against the expected functional outcomes, to provide our patients advice and help them make decisions. Careful, consistent, and compassionate patient management will improve patient experience and quality of life. Treatment of these patients is a long-term commitment.

Sexual Function After Colorectal Surgery in Women

63

Deborah S. Keller and Jenny Alex Ky-Miyasaka

Key Concepts

- When considering pelvic cancer in women, the focus has traditionally been on curing the cancer. As therapy has improved and there are more long-term survivors, sexual function and its impact on quality of life has become a key concern of these women.
- Pelvic surgical dissection in women for benign conditions like inflammatory bowel disease can also severely affect postoperative sexual function and affect quality of life.
- Measuring female sexual function can be challenging. The Pelvic Floor Disorders Consortium (PFDC) Working Group (which includes many members from the American Society of Colorectal Surgeons) is a cross-disciplinary collaboration that has evaluated these questionnaires and published recommendations on their use.
- Depending on individual patient's needs, a multidisciplinary approach to improving quality of life for this group of patients is recommended. The team may include the colorectal surgeon; psychologist, psychiatrist, or appropriate counselor; sex therapist; pelvic floor physical therapist; oncologist; radiation oncologist; geriatrician; nutritionist; and exercise physiotherapist.

Background

In the United States, colorectal cancer (CRC) is the third most common and second most deadly cancer in women [1]. However, advances in colorectal cancer awareness and screening, adjuvant therapy, and surgical technique have resulted in improved survival from colorectal cancer [2]. Traditional outcome measures after surgery for colorectal cancer were survival and local recurrence. However, with the increasing rates of survivorship, a new focus must be placed on functional outcomes and quality of life after surgery for survivors. Sexuality is not considered a medical concern compared with the priority of treating colorectal cancer or cancer-related symptoms. However, sexual function has proved to be one of the most common and important quality of life concerns in long-term survivors [3, 4]. In a survey on the importance of discussing sexual issues, over 80% the woman stated it to be important [4].

Accordingly, sexual dysfunction is one of the most common long-term effects after colorectal cancer treatment [3, 5]. Yet studies show the issue is rarely and inadequately discussed among patients and providers and, thus, often untreated [3, 5]. Sexual dysfunction can occur after any colorectal surgery. Study has shown no differences between female patients who had abdominal procedures and those who underwent pelvic dissection in regard to sexual function, self-esteem, body image, and health-related quality of life [4]. Issues can arise after surgery for benign disease as well as cancer, so providers should anticipate and be prepared to address issues. When sexual issues are not addressed, it can have a significant negative impact on the quality of life of patients [6].

There is a need to understand the etiology and scope of the problem and develop standards for how we discuss, measure, and treat sexual dysfunction after surgery and treatment for colorectal cancer. To truly be effective, providers need to have excellent communication skills, an open and nonjudgmental approach, and knowledge of the potential ramifications of disease and treatment of sexuality problems [6]. The stigma needs to be removed from discussing this very private issue to remove the negative influences on the social well-being of colorectal surgery patients. While studies on sexual function after colorectal cancer treatment have been performed, most to date focused on males with a limited number of female patients, are limited by retrospective design, or

have failed to use validated instruments to measure outcomes [7]. As we work toward developing standards, there is also an increasing awareness of the importance of patient-reported outcomes (PROs), the patient's assessment of their own physical, social, psychological, and sexual functioning, for the most valid information on the effects of cancer treatment.

The Scope of the Problem

Sexual Dysfunction After Surgery for Colorectal Cancer

Colorectal cancer survivors often report that their overall quality of life is good. But when asked properly, women report significant problems with sexual functioning and relationships with their partners following treatment [8–10]. In fact, female sex itself is independently associated with lower sexual function and enjoyment after colorectal cancer [11]. Given the anatomical proximity of the genital area to the treatment site, female sexual functioning is often negatively affected [3]. This posttreatment sexual dysfunction is significant, with studies reporting the prevalence rates between 19% and 62% [12]. Furthermore, symptoms of sexual dysfunction can be exacerbated by anxiety, depression, and fatigue which are common after colorectal surgery and in colorectal cancer survivors [13, 14].

The 2019 prospective QoLiRECT study (Quality of Life in RECTal cancer) measured health-related quality of life in Scandinavian rectal cancer patients at diagnosis and 1 year, showing lower rates of pretreatment sexual activity in women than men (29% and 41%, respectively); these rates were further reduced at the 1-year point (25% and 34%) [15]. The extent of the resection and presence of a stoma can also impact sexual function [13, 16–18]. For example, women who had abdominoperineal resection compared to anterior resection for rectal cancer were less sexually active, had sexual intercourse less frequently, and were less likely to achieve arousal or orgasm [17]. While anterior resection patients had better quality of life scores than abdominoperineal resection patients, high-anterior resection patients had significantly better quality of life (QOL) scores and function than low-anterior resection patients [19]. While stoma patients are reported to have significantly worse QOL and greater sexual dysfunction than non-stoma patients, QOL improved greatly for patients whose stoma was reversed [18, 19].

Sexual Dysfunction After Surgery for Benign Colorectal Disease

The issue of sexual dysfunction is not isolated to malignant disease. Surgical treatment for pelvic floor disorders may be "curative" by repairing incontinence but may also have undesired effects on sensation, blood flow, and anatomy that can affect sexual arousal and orgasm or cause dyspareunia [20]. There is particular interest in sexual dysfunction after restorative proctocolectomy with an ileal pouch anal anastomosis (IPAA) or pelvic pouch surgery for inflammatory bowel diseases (IBD), including ulcerative colitis (UC) and Crohn's disease (CD), and polyposis syndromes. IBD has an increasing worldwide prevalence [21], and sexual function is often impaired in female patients, with reported rates of sexual dysfunction of 40–60% [22]. Females with UC who are managed nonoperatively have normal fertility, which suggests that ulcerative colitis and medical therapy do not decrease female reproductive ability, but pelvic pouch surgery has a significant impact on sexual function [23]. Surgery for IBD is aimed to improve QOL, but sexual dysfunction is a frequent complication after the proctectomy, as pelvic dissection may result in injury to the autonomic nerves [24].

Etiology of Sexual Dysfunction

The etiology of sexual dysfunction after colorectal surgery is a multifaceted issue, with both physical and psychological causes, and different causes may concurrently have a role. Recent literature reviews reported that 30 to 40% of female patients who were sexually active prior to treatment became sexually inactive posttreatment. More than half of women experience changes in body image after colorectal cancer treatment, and rates of sexual dysfunction can be even higher from the physiological changes that can result from radiation, chemotherapy, and surgery [14]. Women specifically experienced reduced lubrication, more dyspareunia, reduced vaginal size, and less sexual enjoyment after surgery compared with the time of diagnosis, making intercourse less appealing [11, 15, 25]. Surgery, chemotherapy, radiotherapy, and medication commonly given for symptomatic treatment, as well as the psychological sequelae of the diagnosis and disease itself, can affect sexual function [6]. Table 63.1 shows the common sexual dysfunction caused by radiation, chemotherapy, and surgery.

It is important to acknowledge there are substantial differences in the risks related to treatment for colon compared to rectal or pelvic disease, especially for cancers. Colonic surgery generally does not involve other major organs and is usually a one-stage procedure with an anastomosis after excision of the pathology, while pelvic or rectal surgery involves other organs, such as the vagina and bladder, as well as the pelvic nerves that are very close to the pathology; these structures may therefore be affected by the surgery in a restricted space [26]. Furthermore, rectal cancer treatment may involve a two-stage procedure with the creation and subsequent closure of a stoma. Preoperative chemoradiother-

apy is also an important part of the multimodality treatment of locally advanced rectal cancer, reducing local recurrence [27, 28], and has their own impact on sexual function.

Radiation

Radiation is a key component in the treatment algorithm of locally advanced rectal cancer, reducing the frequency of local recurrence after total mesorectal excision (TME) compared to surgery alone [27, 29]. Radiotherapy plays a role in female sexual dysfunction by damaging the pelvic autonomic nerves, microvasculature, and soft tissue, creating acute edema and inflammation [30–32]. The rapid cell turnover of the vagina and vulva make them very sensitive to radiation effects. Acute effects include erythema, desquamation, and mucositis. The mucosa may demonstrate severe congestion and hyperemia [33]. These effects usually resolve within 3 months after radiotherapy, but in some patients, the radiation effects are progressive and may become symptomatic even after a latent period [32]. There is progressive vascular compromise and tissue hypoxia that may result in epithelial sloughing, ulcer formation, and continuous progression from ulceration and necrosis to eventual fibrosis [32, 33]. With this are the physical symptoms of vaginal wall thinning, atrophy, adhesions, and fibrosis, which can lead to decreased vaginal elasticity, narrowing, shortening, and ultimately vaginal stenosis [34–36]. Radiation-induced endarteritis obliterans can create ischemia, leading in a hemorrhagic, fragile, friable vagina and vaginal entrance, with similar effects possible in the bladder and rectum [33, 35, 37, 38]. As a result, radiation injury can induce ovarian failure in premenopausal women and create the inability for arousal, dyspareunia, inability to achieve orgasm, and even permanent menopause [34, 39]. The degree of vaginal changes and ovarian failure depends on the primary diagnosis, treatment field, and total dose delivered to the vagina and pelvis [40]. Modern radiotherapy modalities are evolving with the aim to decrease the late effects after rectal cancer treatment, as the limiting factor for the total dose delivery of radiation is normal tissue tolerance [33].

There is little controlled data examining the effect of radiotherapy on sexual dysfunction centered on women, and most published work suffers from retrospective design, small sample size, or lack of validated scoring instruments. However, all demonstrate a severe negative effect on sexual functioning in women following radiotherapy, especially for rectal cancer. The landmark Dutch TME trial reported that preoperative short-term radiotherapy (5Gy × 5) had a negative impact on sexual activity and sexual function [16, 41]. Marijnen et al.

Table 63.1 Female sexual dysfunction from radiotherapy, chemotherapy, and colorectal surgery

Physiologic changes	Radiation therapy	Chemotherapy	Surgery
Vaginal vault changes	Shortening of the vagina; decreased lubrication; dyspareunia; risk of vaginal stenosis	Decreased lubrication; dyspareunia; increased risk of vaginal infection from tears; mucositis of the vaginal cavity	Postoperative adhesions from pelvic surgery can cause dyspareunia
Sexual pattern	Decreased lubrication with the need to use artificial lubricant to avoid tears and infection; diarrhea can create apprehension, fear of fecal incontinence	Nausea/vomiting can decrease desire; decreased lubrication with the need to use artificial lubricant to avoid tears and infection	If stoma present, can reduce the spontaneity of sexual activity and cause discomfort and embarrassment during intercourse; loss of rectal sexual pleasuring if proctectomy performed
Skin changes	Texture/color changes can affect body image; tattoos can remind patient of diagnosis	Skin sensitivity can cause an extreme reaction to cold; neuropathy and hand/foot syndrome can affect ability and enjoyment of touch	Surgical scars can affect body image and confidence
Vascular, sensory, and continence	Vascular scarring—decreased genital blood flow, decreased vaginal lubrication	Change in senses—increased sensitivity to smell; peripheral neuropathy impacting touch	Urinary/fecal incontinence risk
Nerve damage	Decreased skin sensitivity and vaginal lubrication	Decreased skin sensitivity and vaginal lubrication	Decreased skin sensitivity and vaginal lubrication
Hair pattern	Alopecia—affects body image; daily reminder of treatment/diagnosis	Alopecia—affects body image; daily reminder of treatment/diagnosis	NA
Delayed complications	Risk of fecal or urinary incontinence due to fibrosis	Peripheral neuropathy may be permanent, can affect sensations/enjoyment	Pelvic pain during intercourse from adhesions; nerve damage can affect sensation
Fertility impact	Premature ovarian failure	Type/dose affect risk	Adhesions can increaserisk of female infertility posttreatment
Fatigue	Affects social interaction, libido	Affects social interaction, libido	Affects social interaction, libido

followed female rectal cancer patients randomly assigned to neoadjuvant radiotherapy and then total mesorectal excision (TME) or surgery only for 24 months after treatment, finding radiation had a significant negative impact on sexual interest, pleasure, and satisfaction, and radiated patients were significantly less sexually active after treatment compared to before treatment [41]. Lange et al. aimed to identify risk factors for sexual dysfunction following this cohort of female rectal cancer patients randomly assigned to neoadjuvant radiotherapy and then total mesorectal excision (TME) or surgery alone preoperatively and at 3, 6, 12, 18, and 24 months postoperatively [16]. The authors found sexual activity levels continued to decline from over 50% before surgery to 18.4% at 2 years posttreatment [16]. Nearly two-thirds of the sexually active women reported newly developed sexual dysfunction after treatment, with neoadjuvant radiotherapy as the only significant risk factor for dysfunction [16]. In investigating the long-term quality of life 14 years after treatment in these cohorts from the Dutch TME trial, irradiated females reported significant sexual dysfunction from more vaginal dryness and dyspareunia compared with the general population [42]. A cross-sectional study by Bregendahl et al. of sexual dysfunction in all women who underwent abdominoperineal resection or low-anterior resection for rectal cancer in Denmark between 2001 and 2007 found a significant association between neoadjuvant radiotherapy and reduced vaginal dimensions, dyspareunia, lack of desire, and sexual inactivity [43]. The authors also found bowel dysfunction in patients that received preoperative radiotherapy, which was associated with lack of sexual desire, sexual inactivity, and sexual dissatisfaction [43]. In a US-based study, Tekkis et al. reported female rectal cancer patients treated with radiotherapy had a fourfold increase in dyspareunia compared to surgery-only patients [17]. Bruheim et al. used the validated Sexual function and Vaginal Changes Questionnaire (SVQ) to assess the impact of radiotherapy on sexual function in 172 female patients from the Norwegian Rectal Cancer Registry [25]. Patients were assessed at a median of 4.5 years posttreatment, finding women treated with radiotherapy reported more vaginal problems in terms of vaginal dryness, dyspareunia, and reduced vaginal dimension, but sexual interest and worries about their sex life were not significantly impaired compared to women treated without radiotherapy [25]. Thyo et al. performed a long-term follow-up study with the validated Sexual function and Vaginal Changes Questionnaire on female colorectal cancer patients between 2001 and 2014 who were sexually active at the time of diagnosis ($n = 2402$), as a basis for comparison [44]. They found in rectal cancer patients, radiotherapy exposure increased the odds for overall sexual dysfunction [OR 1.80 (95% CI 1.02–3.16)] and was associated with dyspareunia [OR 1.72 (95% CI 0.95–3.12)] [44]. Rodrigues et al. compared physical and psychological morbidity, sexual functioning, and relationship satisfaction among women with uterine, rectal, or anal cancers treated with pelvic radiotherapy and comparable controls, finding pelvic irradiation patients reported significantly higher rates of fatigue, weakness, diarrhea, vaginal discharge, and stress, with lower scores of satisfaction with sexual function (all $p < 0.005$). Adams et al. highlighted the late and persistent effect of pelvic radiotherapy in a survey of patients receiving radiation as a primary or adjuvant treatment ($n = 418$, 57.1% response rate) [45]. Twenty-four percent of women stated that the radiation treatment adversely affected their ability to have a sexual relationship. The treatment-related symptoms were as frequent in people 6–11 years after radiotherapy as those within 1–5 years after treatment, showing the late effects are common and continue to reduce quality of life [45].

Chemotherapy

The effects of chemotherapy on sexual dysfunction are less described, as chemotherapy is often grouped with radiation when administered for rectal cancer (neoadjuvant chemoradiation). However, chemotherapy alone is associated with a loss of desire and decreased frequency of intercourse for women. The common side effects of chemotherapy such as nausea, vomiting, diarrhea, or gain and loss of hair can create poor self-esteem, affect an individual's sexual self-image, and decrease sexual interest [46]. For women, chemotherapy may cause a loss of estrogen production from the ovaries, leading to decreased dimension, thinning, dryness, and loss of elasticity of the vagina, as well as dyspareunia and orgasmic dysfunction. A population-based study from the Netherlands assessed the impact of chemotherapy on colon cancer survivors up to 10 years post-diagnosis using the validated SF-36 and the EORTC colorectal module (EORTC-QLQ-CR38) [47]. Though not specific for females, among the sexually active respondents, survivors reported sex to be significantly less enjoyable than the normative population [47].

Surgery

For surgical treatment, knowledge of the anatomy and areas prone to nerve damage that can impact sexual function after surgery is critical. Colonic surgery generally does not impinge on other major organs and is usually a one-stage procedure with end-to-end anastomosis of the bowel after excision of the tumor. However, in pelvic surgery, other organs as well as the pelvic nerves are very close to the pathology and therefore may be affected by both the surgical and radiotherapy treatments.

An extensive autonomic nervous system of sympathetic and parasympathetic fibers supplies the rectum and genitourinary tract, affecting sexual function (Fig. 63.1). The sympathetic autonomic plexus arises from the T12–L2 lumbar sympathetic nerves, passing anterior to the aorta to form

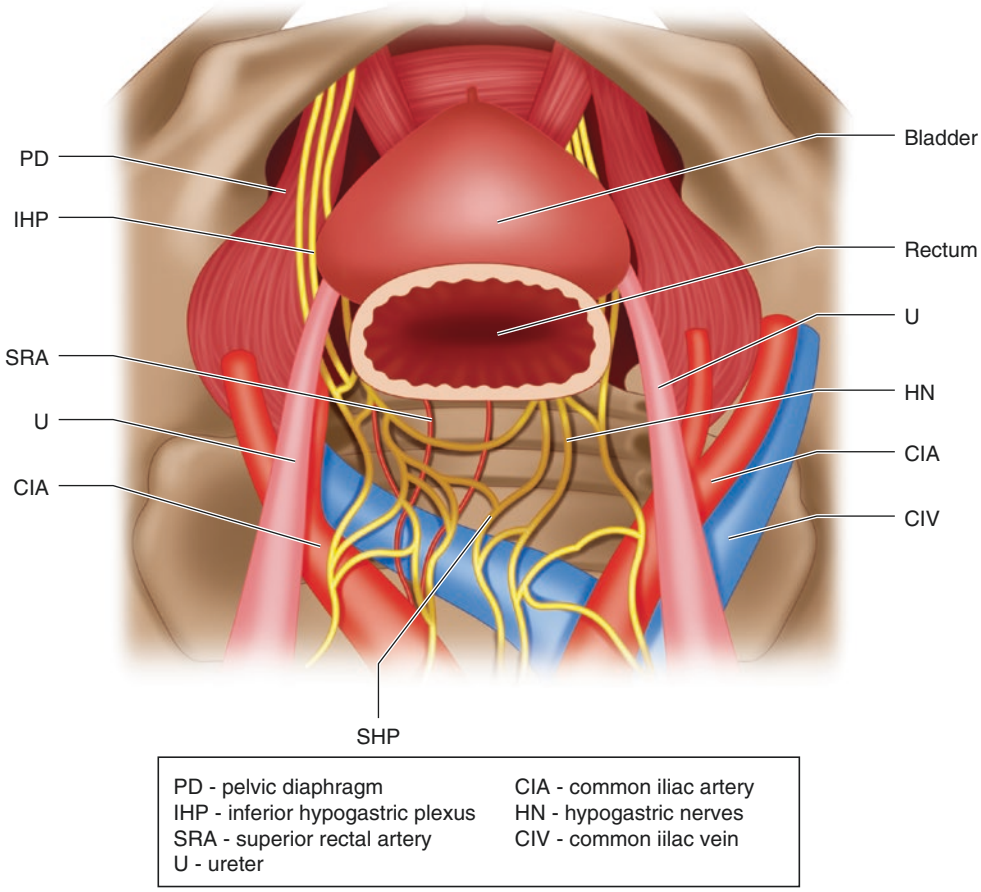

Fig. 63.1 Common sites of nerve injury in colorectal surgery

the superior hypogastric plexus by the origin of the inferior mesenteric artery. It branches into the superior hypogastric plexus as the nerves enter the pelvis, dividing into the left and right hypogastric nerves at the sacral promontory. Damage to the superior hypogastric plexus and hypogastric nerves causes urinary urgency and incontinence in females [30]. The hypogastric nerves course posterolateral to the mesorectum and join parasympathetic nerves running medially along the mesorectal fascia to form the inferior hypogastric plexus. These nerves are responsible for detrusor contractility, vaginal lubrication, and genital swelling during sexual arousal. Damage to these nerves causes decreased blood flow to the vagina and vulva, which can reduce vaginal lubrication [48]. The inferior hypogastric plexus is a network with the paired sympathetic hypogastric nerves and parasympathetic pelvic splanchnic nerves on the pelvic sidewall, with the neurovascular bundle extending anterolaterally to the rectum, passing laterally to the distal ureters, cervix, vaginal fornix, base of the urinary bladder, and lower lateral wall of the vagina [49]. As the inferior hypogastric plexus contains both sympathetic and parasympathetic efferent fibers, damage to this plexus can cause issues in urogenital and sexual function; erection and ejaculation are known issues in men, while the specific disturbance in women is not clearly defined.

Major improvements in recurrence, survival, and quality of life have resulted from the standardization and widespread implementation of total mesorectal excision (TME) for rectal cancer surgery. A TME is a highly precise and sharp dissection along the avascular, areolar tissue plane between the mesorectal fascia and the parietal pelvic fascia under direct vision (Fig. 63.2) [50]. By definition, a TME involves a nerve-preserving dissection which helps to avoid urinary and sexual dysfunction [51]. With a TME, the problem of accidental bladder denervation was reduced from 50% to 60% to less than 20% [52]; the impact on sexual function in women is less described. The surgical approach to the TME may also help reduce nerve injury and subsequent sexual dysfunction. There is no clear evidence of any differences in quality of life regarding bladder and sexual function between laparoscopic and open TME [53]. The robotic approach has been reported to have lower impairment of urinary and sexual function, but the majority of studies have centered on males, and further research is required [54, 55].

Sexual Dysfunction After Surgery for Benign Colorectal Disease

The issue of sexual dysfunction is not isolated to malignant disease. Surgical treatment for pelvic floor disorders may be

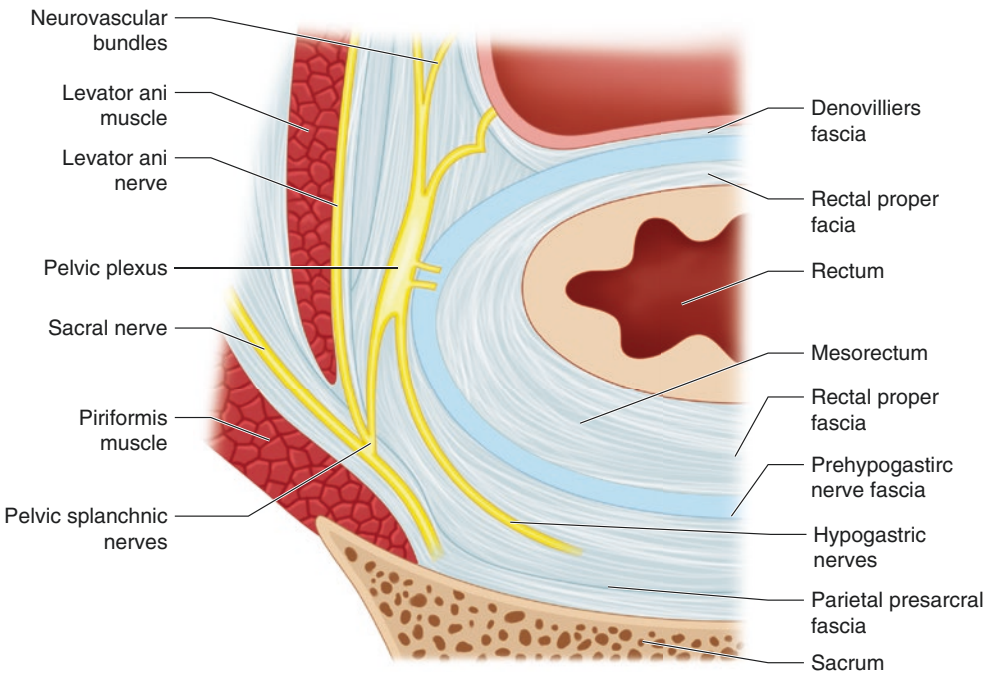

Fig. 63.2 The planes for total mesorectal excision and pelvic surgery

"curative" by repairing incontinence but may also have undesired effects on sensation, blood flow, and anatomy that can affect sexual arousal and orgasm or cause dyspareunia [20]. There is particular interest in sexual dysfunction after restorative proctocolectomy or pelvic pouch surgery for inflammatory bowel diseases (IBD), including ulcerative colitis (UC) and Crohn's disease (CD). IBD has an increasing worldwide prevalence [21], and sexual function is often impaired in female patients, with reported rates of sexual dysfunction of 40–60% [22]. Females with UC who are managed nonoperatively have normal fertility, which suggests that ulcerative colitis and medical therapy do not decrease female reproductive ability, but pelvic pouch surgery has a significant impact on sexual function [23]. Pouch surgery is aimed to improve QOL, but SD is a frequent complication after the proctectomy, as pelvic dissection may result in injury to the autonomic nerves [24]. There are reported reduced fecundity, dyspareunia, and controversy on need for cesarean section post-IPAA to prevent anal sphincter injury [56].

The Impact of Sexual Dysfunction on Fertility

In addition to sexual dysfunction, there is reported reduced fecundity among women who undergo colorectal surgery. Surgical resection for colon cancer likely has no effect on female fertility, but resection below the peritoneal reflection for rectal cancer may adversely affect fertility by damaging the autonomic nerves; this is similar to the risk of decreased fertility after pelvic surgery for conditions such as inflammatory bowel disease (IBD) and polyposis syndromes [57]. In IBD and polyposis syndromes, such as Lynch, a colectomy with ileal pouch anal anastomosis (IPAA) has reductions in fertility rates reported between 44% and 82% [23, 58]. Research has found that the laparoscopic approach results in improved fertility rates when compared to open surgery, likely due to reduced scarring of the fallopian tubes [59, 60]. IBD surgery also appears to have a negative impact on pregnancy-related outcomes, including risks of miscarriage, need for assisted reproductive technology, delivery via caesarean section, and occurrences of stillbirth and preterm births, but there are conflicting results and poor-quality evidence [61]. Specifically, there is controversy on the need for cesarean section post-IPAA to prevent anal sphincter injury [56].

Chemotherapy with 5-fluorouracil is reported to have little influence on fertility, but the impact of agents such as oxaliplatin and irinotecan on gonadal failure is unclear [62]. Guidelines recommend that oncologists discuss the possibility of infertility with their patients, while acknowledging there are insufficient data available to accurately assess this risk in colorectal cancer [63]. The use of radiation in either the adjuvant or neoadjuvant setting may cause premature ovarian failure using current dosing schedules [64]. Methods for fertility preservation include ovarian transposition and embryo cryopreservation, while ovarian tissue cryopreservation and ovarian suppression and the use of apoptotic inhibitors remain investigational with promising results [57, 65]. In general, the effect of pregnancy and female hormones on the incidence, progression, and recurrence of CRC remains unclear, and further research is needed [65].

Defining the Problem for Effective Treatment

The normal female sexual response has four phases, desire, excitement, orgasm, and resolution, whereas sexual dysfunction involves desire, arousal, orgasmic, and sexual pain disorders [66]. The most common sexual issues reported by women include loss of desire for sexual activity, loss of sensation and numbness, a change in genital sensation from pain, and delayed ability to orgasm, often due to medications and/or anxiety. Patients may report emotional or motivational changes, physical concerns including vaginal dryness, inability to climax, and dyspareunia often due to radiation and pelvic surgery, which relate to the desire, excitement, orgasmic, and pain categories, respectively. Sexual pain specifically is reported by as many as one in five women who have pelvic radiotherapy [67]; these patients report continued desire for intercourse, emphasizing the need for better awareness and treatment options. Unlike other side effects after surgery or colorectal cancer treatment, sexual dysfunction may not resolve within the first year or two after treatment and can interfere with the patient's return to a normal function and quality of life. When discussing issues, it is important for the provider to ask appropriate questions to identify the specific issue or issues and best guide treatment with the multidisciplinary team. Treatment interventions by issue or phase of dysfunction are listed in Table 63.2.

Desire

Where low desire is present, it can adversely affect sexual arousal, with the lack of vaginal lubrication and subsequent relationship difficulties [40, 68]. If there is clear treatment-induced menopause or hypogonadism, use of hormone replacement therapy with estrogen and/or testosterone can be effective, assuming there are no oncological contraindications to use [40]. Where the desire loss is due to emotional adjustment difficulties or the side effects of their medical management, a psychological or psychosexual management approach may be most effective. Use of psychological or psychosexual counseling, cognitive behavioral therapy, or mindfulness training alone or in combination with pharmacological or sexual device interventions can help improve sexual functioning from lack of desire for individuals or couples [40, 69, 70].

Arousal and Orgasm

Many women have limited awareness of the objective vaginal changes that accompany sexual arousal. The majority of studies are focused on men, with erectile dysfunction as the primary metric used to gauge improvement. Thus, in females, treatments for arousal and orgasmic difficulties are often grouped with desire, and hinge on hormone replacement for desire, with psychological, psychosexual, and cognitive behavioral therapy recommended for both [40].

Sexual Pain

Despite the prevalence, proactive management of vaginal changes to reduce subsequent sexual pain after pelvic radiotherapy and treatment-induced menopause are not part of routine care after colorectal surgery [71]. This has been explicitly demonstrated in women having neoadjuvant chemoradiotherapy for rectal cancer, where starting post-radiotherapy vaginal dilation is disrupted by surgery, with frequent failure to coordinate the management of multimodal late effects after surgery [72]. In superficial dyspareunia from treatment-induced menopause, the most effective management is hormone replacement therapy and, where feasible, vaginal estrogens [73]. In women already in menopause or when estrogen therapy is contraindicated, nonhormonal vaginal moisturizers can be used to restore vaginal pH and improve moisture content of the vaginal and vulval mucosa [71]. Adding an intimate lubricant to decrease friction during sexual intercourse or vulvar contact can additionally reduce pain. Graduated vaginal dilation and penetration within a framework of sensate focus can help break the cycle of dyspareunia, distress, anticipation of dyspareunia, and sexual avoidance [40, 74]. For women with deep dyspareunia, vaginal adhesions, fibrosis, stenosis, or shortening, vaginal dilation is recommended, though the evidence base and patient compliance are poor [75, 76]. There is an increasing awareness of chronic pelvic floor myofascial pain occurring as sequelae of colorectal surgery or adjuvant treatment [76]; this can be exacerbated during intercourse.

Table 63.2 Female sexual difficulties by phase of dysfunction

Desire	Arousal	Orgasm	Sexual Pain
Hormone replacement therapy ± testosterone supplementation—psychosexual therapy Psychological therapy (mindfulness, cognitive behavioral therapy) Psychosexual therapy Couple therapy	Topical estrogen Psychosexual therapy (sensate focus) Psychological therapy (mindfulness) Guided fantasy/ masturbation	Psychosexual therapy (sensate focus) Psychological therapy (mindfulness) Couple therapy Vibrator therapy Guided fantasy/ masturbation	Vaginal moisturizers Vaginal lubricants Vaginal dilation Topical estrogen

A standardized physical exam and treatment from an interdisciplinary team, including myofascial trigger point release, biofeedback, and electrical stimulation, can aid in diagnosing and successfully treating myofascial pelvic pain [77].

Measuring Sexual Dysfunction

Most studies of sexual dysfunction treatment use validated questionnaire scores as an outcome measure. Validated instruments that reliably measure patient-reported functional status help ensure clear communication between providers, patients, and researchers [78]. This is especially true in treating pelvic floor disorders, which relies heavily on patient-reported symptoms to measure outcomes. In 2020, the Pelvic Floor Disorders Consortium (PFDC) Working Group on Patient Reported Outcomes, a cross-disciplinary collaboration, published recommendations for all practitioners in treatment of female sexual dysfunction [78]. An intensive review of several key instruments with evidence of validity and reliability was performed by the Sexual Function in Women workgroup [79–90]. The consensus selected two instruments for best practice—the Female Sexual Function Index Short Version (FSFI-9), a 9-item questionnaire for women to assess sexual desire, arousal, lubrication, orgasm, satisfaction, and pain domains, and the Pelvic Organ Prolapse/Incontinence Sexual Questionnaire International Urogynecological Association (IUGA)-Revised (PISQ-IR), a 20-item condition-specific validated questionnaire (12 questions in 4 domains if not sexually active) that specifically targets women with pelvic floor disorders (https://static-content.springer.com/esm/art%3A10.1007%2Fs00192-012-2020-8/MediaObjects/192_2012_2020_MOESM1_ESM.pdf) (Table 63.3) [79, 80]. The FSFI-9 has been tested in peri- and postmenopausal women and is best applied where sexual function is a secondary end point and brevity is a priority [78, 79]. The PDFC recommends the PISQ-IR for providers treating women with known pelvic floor disorders and the FSFI-9 for providers seeking to measure and monitor female sexual function outside of patients with pelvic floor disorders [78].

Table 63.3 Items in the Female Sexual Function Index (FSFI) 9 item questionnaire

Number	Item (domain)
1	Level of sexual desire or interest (desire)
2	Level of sexual arousal (arousal)
3	How often maintain lubrication (lubrication)
4	Difficulty becoming lubricated (lubrication)
5	How often reach orgasm
6	Difficulty reaching orgasm (orgasm)
7	Satisfaction with amount of emotional closeness with partner (satisfaction)
8	Level of discomfort/pain during or following vaginal penetration (pain)
9	Satisfaction with overall sex life (satisfaction)

Moving Forward

Given the prevalence and impact of colorectal surgery on sexual function in women, further work is needed to address sexual dysfunction and help incorporate screening for symptoms as standard procedure. Despite clear benefits for patients, providers, and researchers, widespread implementation of patient-reported outcomes and patient-reported outcome measures (PROMs) for recording sexual dysfunction have not yet been achieved [91]. Interviews with colorectal surgery patients and literature reviews were conducted to help define needs for the initial research initiatives and next steps to address sexual dysfunction in women. From this work, the following foundation steps were selected.

Initiating the Conversation

In a survey of cancer patients using the Patient-Reported Outcomes Measurement Information System (PROMIS(®)) Sexual Function measure, nearly 80% reported it was important to discuss how surgery and cancer may impact sexual functioning. However, only 29% asked about sexual dysfunction, and less than half received any information about sexual dysfunction from their provider [92]. The principal reason for the persistent low profile of sexual dysfunction discussions remains the reluctance among patients and health professionals to talk about treatment-induced sexual difficulties [40, 92, 93]. Patients report reluctance to ask questions about sexual dysfunction during appointments. They mention feeling embarrassed or ashamed, as well as unsure on how exactly to broach the subject or describe sexual issues for the first time. Patients also reported that the provider seemed busy and they did not think the subject of sexual dysfunction was important [in comparison to the discussion on surgical or cancer outcomes]. A lack of clinical time to sexual dysfunction has previously been identified as an obstacle by providers, with the argument that follow-up clinics are not a suitable environment for the detailed discussion of treatment-induced sexual dysfunction due to time constraints, the need to prioritize surveillance in cancer cases, lack of privacy, and the absence of clear management and referral pathways [40, 93]. Providers may also be reluctant to discuss sexual dysfunction due to lack of knowledge regarding how to start the conversation, treatment for sexual problems, or concerns about the appropriateness of discussing sexual function. Tools must be used to overcome the reluctance and initiate the conversation on sexual dysfunction, as patients consistently state they feel more comfortable

if providers bring up the topic [92]. Using a combination of physical examination, clinical interview, and validated questionnaires may help to engage patients and initiate the difficult conversation [94].

Developing Options for Diverse Patients

Cultural factors such as age, ethnicity, sexual orientation, and relational status can significantly influence sexuality but are often not taken into consideration in research and clinical practice [95]. Assumptions can also be incorrectly made that sexual dysfunction is "irrelevant" for certain patients due to these cultural factors [5, 13]. Regardless of age, sexual orientation, or partner status, sexual function is an important aspect of QOL. In patient interviews, it was stated that providers assume elderly patients as having less need for sexual function. Assuring that providers appreciate that elderly patients still had the desire for sexual function was stressed. Using a native speaker/translator to facilitate answering questions and involving the sexual partner in the discussions only after asking patient permission was suggested to help overcome cultural barriers. Sensitivity and understanding of the unique challenges to sexual function in women who fall under the lesbian, gay, bisexual, transgender, and questioning (LGBTQ) category or transitioning women should also be considered.

Creating Multidisciplinary Treatment Teams

Providers report that lack of knowledge about treatment options and treating sexual dysfunction within their scope of practice may limit the ability to fully discuss and treat sexual dysfunction with patients [5]. Recognizing the depth and contributions from different members of a diverse multidisciplinary treatment team is key for sexual dysfunction patients. Depending on the individual patient's needs team members can include the colorectal surgeon; psychologist, psychiatristor appropriate counselor; sex therapist; pelvic floor physical therapist; oncologist; radiation oncologist; geriatrician; nutritionist; and exercise physiotherapist.

Conclusions

Sexual dysfunction is common in women after colorectal surgery and has a substantial impact on quality of life. The effects can be long-lasting, especially when chemoradiotherapy is part of the treatment plan. Changes in sexual function can occur after diagnosis and throughout the continuum of care. However, the issue is rarely and inadequately discussed and, thus, often untreated. By understanding the common causes, symptoms, and tools to grade the effects of sexual dysfunction in women, larger-scale controlled trials can be carried out to help providers better understand the needs and best practices for treatment of female sexual dysfunction.

Male Genitourinary Dysfunction as a Consequence of Colorectal Surgery

64

Nathalie Mantilla and Shane McNevin

Key Concepts

- Male genitourinary function can be severely affected after pelvic surgery—even when performed for benign disease. Sympathetic and parasympathetic nerves instrumental to normally functioning neural pathways can be located in close proximity to left colon and rectal structures.
- Many questionnaires are available to measure male genitourinary function. None are perfect and choosing the best tool depends on the outcome being studied.
- Radiotherapy and to some degree chemotherapy both can have detrimental effects on male genitourinary function.
- Selecting interventions to improve quality of life depends on compassionate questioning and building a rapport with the patient. This ideally should begin before starting treatment.
- Sexual function and dysfunction after surgery in LGBTQ patients is often ignored by caregivers and poorly studied. This group of patients can experience unique quality of life problems after pelvic surgery, and awareness is the first step to studying and understanding their needs.

Introduction

Pelvic autonomic nerve dysfunction is a complication of many common colon and rectal procedures. The magnitude of the morbidity is dependent upon the affected nerves, extent of damage, and prior genitourinary function [1, 2]. While direct surgical damage to the nerves is a common etiology of impaired function, it can also be impaired by the adjunctive therapies employed such as pelvic radiotherapy or systemic chemotherapy. Additionally, long-term fecal diversion can impair function due to the psychological impact on body image and its impact on desire. The large and heretofore neglected LGBTQ population also has different but equally important sexual health concerns related to the performance of common colorectal surgical procedures.

Male genitourinary function is relatively easy to describe but has proven much more difficult to quantitatively measure as evidenced by the sheer number of urinary and sexual function metrics available for use. These are often narrowly written and specialty-specific metrics that do not lend themselves well to generalization to the entire patient population and various specialties providing pelvic surgical care. The Pelvic Floor Disorders Consortium is a group of sub-specialist pelvic practitioners (colorectal surgeons, urogynecologists, urologists, gynecologists, gastroenterologists, physical therapists) actively working to define best pelvic metrics and practices so that all practitioners can speak with one voice to enhance the care of these patients [3].

Intimate familiarity with pelvic neuroanatomy and physiology is critical for the practicing colorectal surgeon. Identification of relevant anatomy at specific points of pelvic dissection is important for preservation of functional autonomic anatomy. These neural pathways drive male genitourinary function, which is a major determinate of quality of life especially in younger patients. Injury to these structures can manifest as urinary retention or incontinence as well as erectile dysfunction and/or ejaculatory dysfunction. Studies have estimated the prevalence of male genitourinary dysfunction ranges from 20% to 80% following pelvic colon and rectal procedures [4–7]. Surgeons participating in pelvic procedures should be able to discuss genitourinary function comfortably, putting the patient at ease. Studies have shown that patients and providers alike have difficulty due to embarrassment participating in this discussion. Detailed knowledge of genitourinary function can alleviate these feelings in the provider and mitigate patient's discomfort [2].

Neuroanatomy and Physiology of the Male Genitourinary Tract

Normal function of the male genitourinary system requires functionally and anatomically intact sympathetic and parasympathetic neural pathways. The proximity of these structures to the left colon and rectum makes male genitourinary dysfunction a common morbidity associated with a number of pelvic colon and rectal procedures. Knowledge of sympathetic and parasympathetic anatomic pathways can aid in avoidance of injury to these structures (Fig. 64.1). Additionally, knowledge of sympathetic and parasympathetic neurophysiology is critical to the discussion of potential side effects and consent process of many common pelvic procedures [9–13].

Sympathetic Pelvic Anatomy and Physiology

Sympathetic innervation of the pelvic viscera originates from T12-L2 spinal level manifesting as the superior hypogastric plexus. The superior hypogastric plexus manifests as a group of nerve fibers around the distal aorta to the aortic bifurcation (Fig. 64.2). These fibers coalesce into the bilateral hypogastric nerves at the level of the sacral promontory and course laterally around the rectum (Fig. 64.3) to join the nervi erigentes to form the inferior hypogastric plexus at level of the anterior peritoneal reflection. The inferior hypogastric plexus then courses anterior to Denonvilliers' fascia to supply the genitourinary system (Fig. 64.4).

Sympathetic inflow in males predominately regulates ejaculation and to a lesser degree penile erection. Ejaculation can be separated into two phases. The first, expulsion, is the sympathetically mediated movement of seminal fluid in the prostatic urethra. The second phase, emission, is the somatically mediated contraction of penile musculature resulting in delivery of seminal fluid out of the urethra. Damage to the sympathetic inflow to the pelvic viscera predominately results in retrograde ejaculation. Aberrant sympathetic innervation of the bladder results in bladder atonia with urinary retention and overflow incontinence.

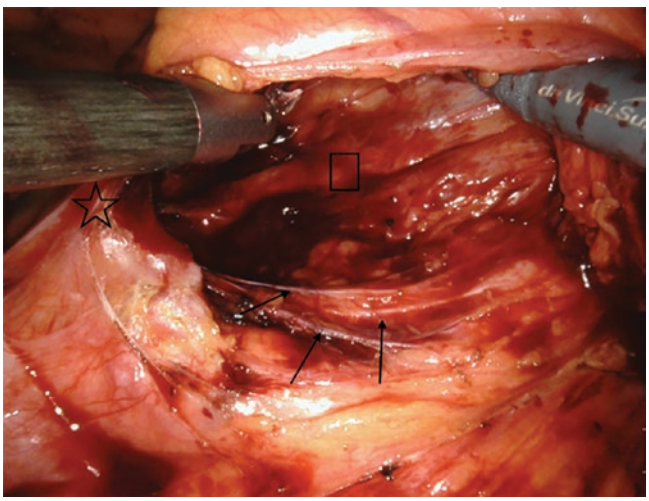

Fig. 64.2 Interoperative photo of superior hypogastric plexus, arrows are on hypogastric nerves, box is on the ureter, star is on the inferior mesenteric artery

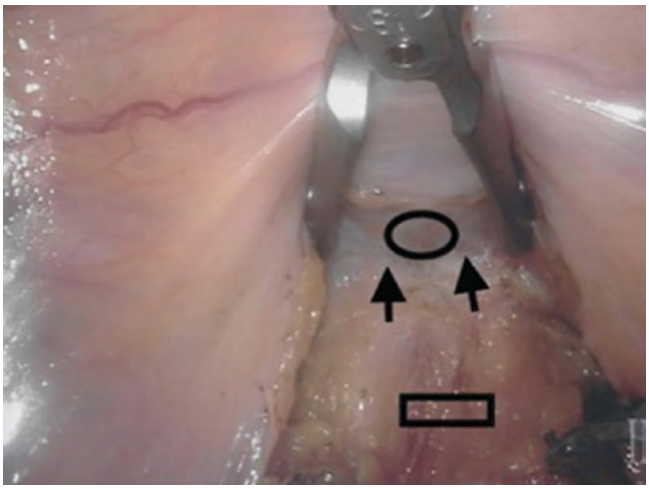

Fig. 64.4 Interoperative photo of Denonvilliers' fascia, arrows are on Denonvilliers' fascia, circle is on the prostate, rectangle is on the rectum

Parasympathetic Pelvic Anatomy and Physiology

Parasympathetic innervation of the pelvic viscera originates from the S2-S4 levels with predominance from the S3 level. These fibers coalesce into the pelvic splanchnic nerves or nervi erigentes that ascend bilaterally to the inferior hypogastric plexus that contains both parasympathetic and sympathetic fibers via the superior hypogastric plexus. The inferior hypogastric plexus courses along the pelvic sidewall and at the level of the prostate courses deep to Denonvilliers' fascia to supply the seminal vesicles/prostate and posterior bladder (Fig. 64.4).

Parasympathetic innervation regulates male erectile function by precipitating vasodilation and engorgement of the penile vascular sinuses. Injury to the nervi erigentes or inferior hypogastric plexus predominantly results in male impotence. Injury to the inferior hypogastric plexus due to its inclusion of sympathetic fibers can also result in retrograde ejaculation. The "micturition center" is felt to lie within the S2-S4 levels and is highly regulated at the central nervous system level. Damage to parasympathetic bladder pathways results in detrusor sphincter dyssynergia and functional bladder outlet obstruction.

Male Genitourinary Functional Metrics

In order to describe a phenomenon, one must be able to reproducibly and objectively measure it. In men due to anatomic and physiologic reasons, genitourinary dysfunction is easily described and manifests as erectile dysfunction, orgasmic and/or ejaculatory dysfunction, and urinary retention. As with many metrics measuring clinical outcomes, generalizable systems of objective measurement for male genitourinary dysfunction have proved elusive. Many metrics are narrowly written to derive specialty-specific outcomes and are not applicable to the entire pelvic health population. Others are so broad as to prove unwieldy and not usable in the busy clinical practice. The Pelvic Floor Disorders Consortium in a multispecialty effort has worked to standardize pelvic care [3]. Its first task has been to sort through the myriad of pelvic health metrics to standardize measurements such that a description of male sexual or urinary dysfunction has the same meaning to the broad group of practitioners providing care to these patients.

Male Sexual Dysfunction Metrics

The International Index of Erectile Function (IIEF-15)

The consortium recommends the use of the International Index of Erectile Function (IIEF-15). This is the most cited instrument for assessing sexual function in men. One of the major advantages of the IIEF is that it includes five separately validated domains: erectile function (six questions), orgasmic/ejaculatory function (two questions), sexual desire (two questions), intercourse satisfaction (three questions), and overall satisfaction (two questions). It is also validated in ten different languages [14–16].

Sexual Health Inventory for Men (SHIM or IIEF-5)

The IIEF-5 or SHIM (Sexual Health Inventory for Men) is brief, practical, and highly cited in the scientific literature. The questionnaire includes five questions from the more comprehensive IIEF. Like the longer IIEF, the IIEF-5 was validated in male patients with erectile dysfunction due to a variety of causes. The IIEF-5 consists of question from the erectile function domain (items 2, 4, 5, and 15) and the intercourse satisfaction domain (item 7). The other remaining three domains (orgasmic/ejaculatory function, sexual desire, and overall satisfaction) are not represented in the IIEF-5. The erectile function domain was shown to have independent validity in the assessment of male sexual function.

Expanded Prostate Cancer Index Composite (EPIC)

EPIC is a comprehensive 50-question instrument that assesses health-related quality of life in 4 separately validated domains including urinary function (12 questions), bowel function (14 questions), sexual function (13 questions), and hormonal function (11 questions) each of which can be scored independently. The strength of this questionnaire is also its weakness in that it is through but impractical to use in clinical practice. It has also only been validated in men with prostate cancer.

Male Urinary Dysfunction Metrics

The Pelvic Floor Consortium has also examined metrics describing male urinary function. This is summarized in a 2004 review article by Naughton et al. that weighted the various metrics according to the strength of evidentiary support. The following were the highest ranked [17].

Urogenital Distress Inventory/Urogenital Distress Inventory-6

The UDI examines 19 lower urinary tract symptoms and the degree to which those are distressing. It is validated only in women but is used also in the male population. The UDI-6 is an abbreviated form of the UDI and has been validated in both men and women. It is useful only for English-speaking populations.

King's Health Questionnaire

The King's health questionnaire has been validated in men and women. It examines ten factors related to urinary symptoms and their impact on quality of life. It is useful in multiple different languages.

Danish Prostatic Symptom Score

The Danish Prostatic Symptom Score is a metric assessing the degree to which men are distressed by their urinary function. It includes 12 symptoms assessing both frequency and distress to result in a composite score that is valid and reliable in the general population.

International Continence Society Male/ International Continence Society Male Short-Form Questionnaires

The ICS male questionnaire assesses 20 urinary symptoms and the severity of distress each of the symptoms causes. An abbreviated form of the ICS is available. The questionnaire was reduced to two major sections: the ICS male voiding subscore, which contains five questions, and the ICS male incontinence subscore, which contains six questions. The two sections are totaled equaling the final score.

Colorectal Procedures Resulting in Genitourinary Dysfunction

Anterior Resection vs Low Anterior Resection vs Complete Proctectomy

Patients undergoing procedures involving the left colon and rectum are at the highest risk for development of genitourinary dysfunction postoperatively. The risk of genitourinary dysfunction increases as procedures go lower into the confined spaces of the pelvis. Genitourinary dysfunction tends to be greater after oncologic than non-oncologic surgery—although some literature is contradictory.

The superior hypogastric plexus and right and left hypogastric nerves are at highest risk when mobilizing the sigmoid and upper mesorectum away from the retroperitoneum and isolating the origin of the inferior mesenteric artery. These structures are typically readily apparent and easy to preserve at this level when dissecting. Therefore, genitourinary dysfunction after anterior resection is quite limited.

As dissection progresses to the mid- and upper rectum, the risk of injury to the inferior hypogastric plexus and nervi erigentes increases as the anatomy is less apparent and the narrow workspace impairs exposure. The nervi erigentes course along the pelvic sidewall and at the level of the seminal vesicles and prostate course anteriorly deep to Denonvilliers' fascia. Adherence to proper techniques and dissection planes specifically staying superficial to Denonvilliers' fascia when mobilizing the anterolateral rectum will minimize, but not eliminate, the genitourinary dysfunction seen after proctectomy. The highest risk of dysfunction appears after abdominoperineal resection and is multifactorial involving damage to autonomic nerves, disruption of normal pelvic floor anatomy and function, and the psychological impact of a significant change in body image [18–24].

Minimally Invasive vs Open Techniques

The information regarding sexual function following minimally invasive total mesorectal excision (TME) is limited and controversial. The magnified view available with minimally invasive proctectomy enables excellent exposure of the pelvic cavity and facilitates sharp dissection of the lateral, anterior, and presacral spaces, all being autonomic nerve locations. Despite this advantage, studies have shown a variable impact on male sexual dysfunction after minimally invasive compared to open proctectomy. The studies can all be criticized as small, single center, and with a retrospective design. Comparison of robotic and laparoscopic proctectomy is equally problematic and fraught with poor-quality studies giving variable results in regard to postoperative male sexual function [25, 26].

Genitourinary Dysfunction Related to Pelvic Radiotherapy

Pelvic radiotherapy is an adjunct in the management algorithm of many pelvic malignancies. Pelvic radiotherapy results in cellular death, which is obviously beneficial for cancer treatment but can for years and decades manifest as adverse toxicity of the treated organ and adjacent organs. Erectile dysfunction and infertility are common long-term complications of pelvic radiotherapy for male patients, and the causes are felt to be multifactorial. Urinary dysfunction is also a common complication of pelvic radiotherapy and includes urinary urgency and incontinence, radiation cystitis, ureteral and urethral stricture, and fistula. Systemic chemotherapy also can have a detrimental effect on genitourinary dysfunction but not to the same degree as radiotherapy or surgical treatments. With cancer patients having increased long-term survival, management of these therapy-related complications will be recognized more frequently as an important factor for quality of life in cancer survivorship [27–32].

Psychological Impact and Counseling

The first step in providing care to men with sexual dysfunction following pelvic surgery is to develop a rapport with the patient preoperatively that allows for frank discussion of intimate matters. In patients undergoing surgery that could potentially affect genitourinary function postoperatively, a thorough history of preoperative function is key to predicting the risk of aberrant postoperative function. The informed consent process should also have a detailed discussion of the potential for genitourinary dysfunction and specifically what types of dysfunction might be experienced.

Patients returning after pelvic surgery or radiotherapy should be actively questioned and encouraged to discuss symptoms of genitourinary dysfunction. Acknowledgment by the surgeon that a problem exists and support and encouragement that function typically improves with time can be extremely beneficial to the distressed patient. Early discussion of potential treatment pathways can allay patient anxiety. Cultivation of a relationship with a urologic colleague with an interest in male genitourinary dysfunction can also provide an early avenue to rehabilitation and long-term treatment [33, 34].

Management of Male Genitourinary Dysfunction

Vacuum Constriction Device (VCD)

The oldest and most widely used device for erectile dysfunction as well as the least expensive is the vacuum constriction device or the so-called penis pump. A cylindrical reservoir is applied to the shaft of the penis, and negative pressure is applied resulting in engorgement of the corpora. An elastic band is then slid off the base of the cylinder constricting the penile base. The sexual act is completed and the constricting band is removed resulting in disgorgement of the penis.

This modality has minimal associated risk, predominantly bruising at the penile base. Patient satisfaction with this modality ranges from 50% to 80%. The most common complaint is interruption of intimacy to use the device, an unnatural feeling erection, blocked ejaculation, and anorgasmia [35].

Intracorporeal (IC) Injections

Until the introduction of oral therapy, intracorporeal injection of vasoactive drugs into the corporal tissue of the penis

was a mainstay in the treatment of erectile dysfunction and remains an effective management option for patients with neurogenic erectile dysfunction after pelvic surgery.

Most commonly alprostadil is used as a single agent. It requires patient education in the office and then dose titration at home to optimize the erection quality. Other injectable treatments which are a combination of medication include Bimix (papaverine/phentolamine) or Trimix (alprostadil/phentolamine/papaverine). While these are more effective, the complication rate is higher than single-agent alprostadil.

The predominant complications associated with intracavernosal injection are pain at the injection site, penile hematoma, penile fibrosis, and priapism. Despite this, successful erection is achieved in 90% of patients, and patient satisfaction with this modality consistently approaches 80%. Interestingly, 30–70% of patients will cease use of this modality over time [36–38].

Intraurethral Alprostadil

Introduction of vasoactive drugs via the urethra or as a cream applied to the penile shaft obviates the need for penile shaft injections. The success rate with these modalities is lower than injection therapy (60%), but this method of therapy has a wider acceptance among patients combined with a lower complication rate (versus injection therapy). The primary complaint is penile pain and mild urethral bleeding [37].

Oral Medications

Due to direct to patient marketing, the oral phosphodiesterase inhibitors used to treat erectile dysfunction are well recognized among patients and the general public. These drugs result in a systemic increase in the nitric oxide concentration such that when the penis receives appropriate neurologic impulses, vasodilation is increased resulting in penile erection. These drugs require appropriate neurologic impulses; hence they are less successful in neurogenic impotence that is encountered after pelvic surgery [39].

Penile Prosthesis

For patients who have failed medical options for erectile dysfunction, there are several surgically implanted devices that can achieve a degree of penile rigidity sufficient for penetrative intercourse.

The implantable devices come in two varieties, the inflatable prosthesis and the semirigid rod. The inflatable prosthesis gives the most natural erection and allows for penile deflation. The device is however more complicated leading to higher rates of device malfunction requiring revisional surgery. Patients also require a certain degree of manual and mental dexterity to operate the device. The semirigid rod while easy to operate leaves the penis in a permanent semi-rigid state, which can be difficult to conceal. As with any implantable device, both modalities are at risk of infection and erosion requiring device explantation. Additionally, penile fibrosis and scarring may impair penile length and efficacy of the device [40–42].

Retrograde Ejaculation/Anejaculation

Retrograde also termed a dry orgasm results from an inability of the urethral sphincter to close during orgasm resulting in all or part of the ejaculate entering the bladder. The condition is not harmful and the sense of orgasm is preserved. It does however result in male infertility. Patients with this condition related to pelvic surgery do not typically respond to medical therapy such as pseudoephedrine. Most unless seeking to father children do not seek treatment. If trying to father children, then the assistance of a fertility specialist is required. Semen can be harvested from the urine and washed, and then assisted fertilization techniques can result in a successful pregnancy [43].

Chronic Intermittent Catheterization vs Indwelling Urinary Catheter

Long-term urinary dysfunction as a result of pelvic surgery is unusual and manifests as urinary retention with or without overflow incontinence. In the short term, bladder decompression with an indwelling catheter and treatment with alpha-blockade usually results in relief of urinary retention. Patients with urinary retention that persists despite these measures are typically offered chronic intermittent catheterization. Chronic intermittent catheterization is the scheduled decompression of the bladder usually performed by the patient after office-based instruction. Long-term indwelling catheters or a suprapubic catheter may be offered to patients with non-recoverable bladder function or who cannot participate in chronic intermittent catheterization [44].

LGBTQ Populations

Sexual function in LGBTQ populations is regrettably unexplored and poorly understood. Most available data is found in the urology field, documenting functional results and psychological impact after prostatectomy. Despite the rising amount of research in gay and bisexual men (GBM), it seems that surgeons are disregarding the fact that the anorectum can serve as a sexual organ and that more than 30% of the general population sees the anus and rectum as sexual organs [45–52]. Increasing awareness of the sexual health needs of

the LGBTQ community has precipitated a rising interest toward understating how changes in sexual function after pelvic surgery can affect sexual roles, satisfaction, relationships, quality of life, and identity in GBM.

Many GBM show sex-specific situational anxiety upon learning about diagnoses whose treatment might imply dramatic anatomical and functional genitourinary changes, such as prostate cancer management. Experiencing a decline in sexual function elicits the same confidence issues in GBM as it does with heterosexual men. Patients experience identity problems with decreased sense of masculinity and loss of sexual self-esteem. Profound impacts on relationships are documented when one partner undergoes treatment affecting genitourinary function.

Data focused on mental health and behavioral aspects as a consequence of pelvic surgery in GBM shows greater mental health challenges and less emotional support post-treatment when compared with heterosexual men. LGBTQ patients experience more mood and anxiety disorders, more depression, and an elevated risk for suicidal ideation and attempts compared with heterosexual adults. These problems are highly associated with discrimination by the general population along with less familial and social support and less partner involvement in treatment compared to the male heterosexual population. GBM experiencing erectile dysfunction and urinary incontinence suffer from decreased intimacy resulting from loss of spontaneity and sexual self-esteem, lack of confidence in their own sexual functioning (performance anxiety), and fear of dribbling during sex. As a result of functional changes related to pelvic surgery, gay couples may need to adjust their sexual practice by changing the role from insertive to receptive intercourse [53]. These changes are not only related to the position during sex but also to the role concerning initiation of the sexual act, the type of affection related to the relationship, and sexual identity. It has been assumed that gay couples or bisexual men can easily change their role in a sexual relationship, but this has much deeper implications than previously considered. Anodyspareunia or the experience of pain with receptive anal intercourse is a recognized consequence of anorectal and pelvic surgery. A metric validated in GBM has established a clinical diagnostic criterion of anodyspareunia. Patients who met the criteria for anodyspareunia reported having avoided anal sex for periods of time (82%), and some restricted their role in the relationship to insertive anal sex only (49%). About one-third (31%) reported disruption of their sexual relationship, and 15% conveyed inability to have new sexual partners. For all these reasons, gay or bisexual men engaging in anal intercourse and undergoing pelvic surgery have an increased risk of social isolation, depression, and suicide due to the detrimental effect of abnormal sexual function. Some will describe their conditions as impending relationship breakers and consider that doctors underestimate the value of sex in gay relations [46, 54].

Male Sexual Dysfunction Metrics in the Gay Population

Gay Sexual Functioning Inventory

In 2019, Rosser et al. develop an innovative and comprehensive tool to assess common sexual behaviors between men, including both insertive and receptive anal sex, "The Sexual Functioning of Gay and Bisexual Men Following Prostate Cancer Treatment: Results from the Restore Study." This instrument incorporated 37 items developed after 39 in-depth interviews, including 19 with GBM treated with radical prostatectomy, 6 with radiation, and 6 with a combination or advanced treatment. Also included were three male partners and six caregivers. Items were scored using a 5-item Likert-type scale. This is the first report in the literature quantifying the incidence of sexual and urinary problems in GBM treated for prostate cancer and describing the consequences on their health-related quality of life [55].

Genitourinary Dysfunction Related to Fecal Diversion

An unfortunate reality for many patients with colon and rectal disorders is loss of gastrointestinal continuity. While a functional and productive life continues, the psychological impact for many patients with a permanent stoma cannot be underestimated. Validated quality of life metrics for ostomates exist and have shown nearly universal alterations in body image, lifestyle changes related to the ostomy (80%), and impaired sexuality (40%). In general, studies comparing patient's quality of life in ostomates versus non-ostomates show improved quality of life independent of bowel function for non-ostomates. Studies have also documented an increased risk of suicide in ostomates [56–58].

Conclusions

In treating pelvic malignancies, long-term cure is the primary goal. Significant issues involving gastrointestinal and genitourinary dysfunction plague patients who undergo pelvic surgery. It is incumbent upon the treating surgeon to understand the complications of therapy and the factors that may minimize them. These treatment-related side effects can have a profound negative impact on quality of life in our can-

cer survivors. Knowledge of treatment options related to these adverse aspects of treatment can have a significant positive impact on patient quality of life.

Middle and Anterior Pelvic Compartment: Issues for the Colorectal Surgeon

65

Danielle Patterson, Susan L. Gearhart, and Elisa Birnbaum

Key Concepts

- When considering pelvic organ prolapse, the pelvis is divided into anterior, middle, and posterior compartments. The anterior and middle compartments are typically more susceptible to pelvic organ prolapse.
- When considering surgical intervention, looking at the pelvis as a whole and considering all compartments is desired. Therefore a multidisciplinary approach offers the chance to coordinate testing and plan treatment.
- Urogynecologists use a designation called the Pelvic Organ Prolapse Quantification (POP-Q) exam to objectively describe and stage middle compartment prolapse.
- From the gynecology, urogynecology, or urology standpoint, addressing the middle and anterior compartments can be performed via transvaginal route when indicated. For posterior compartment surgeons, this may be combined with a perineal approach to rectal prolapse.
- An abdominal approach, either open, laparoscopic, or robotic, can combine surgeons with technical expertise from all three compartments and allow addressing all prolapse issues at the same operation.

Definition, Etiology, and Epidemiology

Female pelvic organs are classically described in three compartments: anterior, middle, and posterior. The anterior compartment contains the bladder and urethra, the middle compartment contains the uterus and vagina, and the posterior compartment contains the rectum and anus. Pelvic organ prolapse (POP) is an anatomical alteration in the pelvic support structures which results in the downward descent of any of the pelvic organs through the muscular pelvic floor [1]. Patients with POP describe their symptoms as a feeling of vaginal or perineal bulging or pressure most commonly experienced with standing, exercising, and straining which resolves when the activity is discontinued [1]. It is best understood by patients as the development of a pelvic floor hernia through which her pelvic organs are slipping. Since prolapse of the uterus and vagina is twice as common as other organs, the focus of POP is often on these structures [2]. It is important for the colorectal surgeon to recognize the proximity of the pelvic organs and the likelihood that more than one compartment can be affected in patients with POP.

The etiology of POP is multifactorial. It is likely that a combination of anatomic, physiologic, and lifestyle factors contributes over time to the development of POP. Established risk factors for primary POP exist and are listed in Table 65.1. Observational studies have found that increasing number of vaginal births (vaginal parity) was the strongest predictor for POP in women <60 years of age [3]. When compared to nulliparous women, women who delivered two children vaginally had an 8.4 relative risk for POP, and women who had delivered four or more children vaginally had a 10.9 relative risk for POP [4].

Table 65.1 Established risk factors for primary and recurrence pelvic organ prolapse

Primary POP	Recurrent POP
Vaginal parity	Age younger than 60 years at time or primary vaginal repair
Advancing age	Obesity
Obesity	Stage III or IV prolapse at initial presentation

Primary POP is defined as symptomatic POP with clinical evidence of prolapse beyond the introitus. Recurrent POP is defined as the need for surgery following primary repair

Advancing age increases the risk for POP. Studies have suggested that the prevalence of POP increases by 40% with each decade of life with a peak age of 71–73 years [5]. A higher body mass index (BMI > 25 in most studies) was associated with a higher risk for POP [6]. It is not clear if having a hysterectomy for non-POP conditions increases the risk for POP. One cohort study suggested that undergoing a hysterectomy increased your cumulative risk for developing POP by 5% [7].

The published prevalence of POP in the USA varies from 3% to 50% depending upon the definition utilized [8]. However, it is commonly accepted that POP is a disorder seen more frequently in the older adult between the ages of 70 and 79 years. The lifetime risk of surgery in the USA for POP by the age of 80 years is 12.6% [9]. Given the aging US population, there may be a dramatic increase in health services required for POP. Wu et al. [9] predicted that by the year 2050, the number of women in the USA suffering from symptomatic POP will increase by a minimum of 46%. Others believe this is an overestimate because it does not take into account decreasing parity and increasing elective Cesarean section rates [8]. Already in the USA, POP surgery accounts for more than 300,000 surgical procedures per year, and ambulatory costs for visits for POP have increased by 40% from 1996 to 2005 [10]. The risk of recurrence following repair of POP is significant. Earlier studies prior to the year 2000 suggested that following a primary repair, women have a 30–50% risk of needing a second repair [4]. However, more recent studies suggest the risk of failure of primary repair requiring a second repair is lower, 6–30% [11, 12]. The improvement in outcomes may be the result of better surgical technique or the redefining of POP recurrence. In general, primary repairs are performed without mesh unless a sacrocolpopexy is performed so there is limited data on the use of mesh to lower the risk of recurrence. However, suspension of the vaginal apex, as is accomplished with a sacrocolpopexy, is associated with a decreased reoperation rate [13]. Established risk factors for recurrent prolapse requiring repeat repair are listed in Table 65.1 and include age younger than 60 years for those patients with a previous vaginal repair of POP, obesity, and undergoing a prior repair for higher-stage POP (III, IV; see below for staging). Other risk factors for primary or recurrent POP that have not been studied as well include chronic constipation, connective tissue disorder, menopause, smoking, hormone replacement therapy, physical activity, family history, ethnicity, pulmonary disease, diabetes, education, and pelvic floor defects imaged on ultrasound or MRI [14].

Evaluation of the Anterior and Middle Compartments

Evaluation of the patient with POP is driven by the presenting symptoms. The most common symptom that patients complain of is a bulging or pressure feeling within the vagina. Other common symptoms are listed in Table 65.2. Urinary symptoms are often associated with POP. These can include urinary frequency, urgency, and incontinence with activities such as coughing, laughing, or sneezing (stress incontinence). Patients may also have a feeling of incomplete emptying or find it more difficult to initiate voiding and describe pushing on the bladder *splinting* to aid in voiding. Bowel function should be assessed as well since patients may have a history of straining, splinting to complete defecation, or experience fecal incontinence. Finally, it is important to address issues of sexual dysfunction including dyspareunia. There are many validated tools available to examine these symptoms and their impact on quality of life. Some of the common assessment tools used by urogynecologists include Pelvic Floor Distress Inventory (PFDI), Pelvic Floor Impact Questionnaire (PFIQ), and Pelvic Organ Prolapse/Urinary Incontinence Sexual Questionnaire (PISQ). The PFDI is a 20-question validated questionnaire that addresses prolapse and anal and urinary distress symptoms [15]. The PFIQ is a 7-question validated survey that assesses life impact in women with pelvic floor disorders [15]. The PISQ is a 12-question validated survey which has been shown to measure sexual function in women with pelvic floor disorders [16].

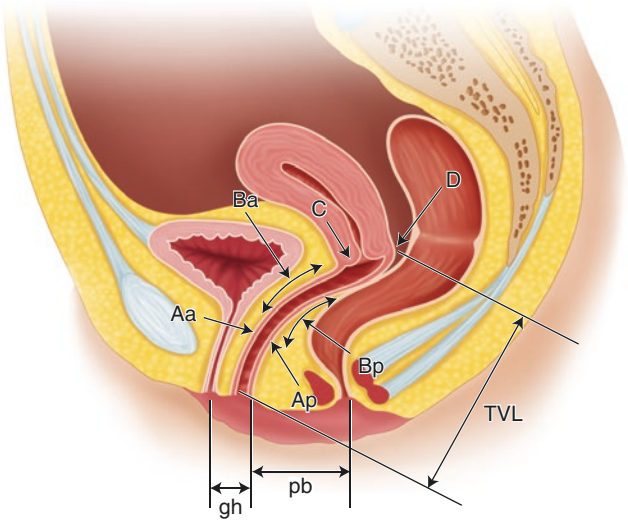
The examination of the pelvic floor can be performed in either the left lateral, standing, or lithotomy position. Findings are more consistent if the bladder and rectum are empty. If a patient has a pessary or a tampon in, these should be removed. A routine pelvic exam as well as a rectal exam should be performed at rest and with strain. To assess for defects within the muscular floor of the pelvis, the levators can be palpated through the rectum or vagina. If the full

Table 65.2 Symptoms associated with pelvic organ prolapse

Pelvic organ function	Symptoms
Sexual function	Bulging, heaviness, pressure, pain, decreased pleasure, decreased body image
Urination	Leaking, urgency, frequency, weak stream, feeling of incomplete emptying, splinting, positional voiding, pain
Defecation	Stool or flatus leakage, feeling of incomplete evacuation, straining, urgency, splinting or digitizing to evacuate, pain

extent of the prolapse is not seen on exam in lithotomy, it can be repeated in standing position with Valsalva. For the best demonstration of POP, give time for the prolapse to protrude, and consider repositioning the patient and asking the patient if they believe the maximum extent of the prolapse is felt or seen.

Urogynecologists use the Pelvic Organ Prolapse Quantification (POP-Q) exam to objectively describe and stage POP (Fig. 65.1). The POP-Q exam measures the opening of the vagina (genital hiatus, GH), the perineal body (PB), the total vaginal length (TVL), and each compartment of the vagina (anterior, apical, posterior). It is important to note that all measurements are all taken during Valsalva, except for the total vaginal length. The anterior and posterior walls and uterus (or vaginal cuff if prior hysterectomy) are measured in relation to the hymenal ring. Point A is located 3 centimeters proximal from the hymenal ring on the anterior and posterior vaginal wall. On the anterior wall, this location correlates to the bladder neck (Aa). Point B is the most distal point of the anterior and posterior vaginal wall with Valsalva between the A point and the vaginal apex. The A and B points can be negative (if inside the hymen) or positive (if outside the hymen). The C point represents the cervix (or vaginal cuff if prior hysterectomy), and the D point is the posterior vaginal fornix (only present if a cervix is present). Each compartment of the vagina is then given a stage based on the measurement. An overall stage is also assigned correlating to the highest degree of prolapse from any compartment. The stages are as follows: Stage 0 (Aa, Ba, Ap, Bp all = −3 and C or D ≤ (TVL-2)), Stage 1 (Stage 0 criteria not met and leading edge <−1), Stage 2 (leading edge ≥ −1 but ≤ +1), Stage 3 (leading edge > +1 but < (TVL −2)), and Stage 4 (leading edge ≥ + (TVL-2)) (Fig. 65.2). The American Urogynecologic Society website provides a free interactive and downloadable app that can be used to educate patients about exam findings [17].



Anterior wall Aa	Anterior wall Ba	Cervix or cuff C
Genital hiatus gh	Perineal body pb	Total vaginal length TVL
Posterior wall Ap	Posterior wall Bp	Posterior fornix D

Fig. 65.1 The POP-Q examination with staging

In general, a complete history and physical exam is sufficient to determine an operative plan for anterior and middle compartment prolapse. Other investigations can be performed if the findings on physical exam do not concur with the patient's symptoms and include ultrasound imaging of the pelvic floor, dynamic magnetic resonance imaging (MRI), or cinedefecography. The most common indication for further work-up is a patient's history of urinary symptoms. Patients are referred for urodynamics should they have symptoms or urinary leakage, frequency, or difficulty with voiding. Urodynamics is a functional study of the lower urinary tract and is performed with a comfortably full bladder to determine uroflowmetry and post-voiding residuals. Common findings during urodynamics are seen in Table 65.3. Office-based ultrasound imaging is commonly performed at the time of urodynamics to confirm post-void residual volumes and evaluate levator ani function. Finally, MRI and cinedefecography images the rectum during evacuation and can assess for the presence of intussusception, rectocele, and enterocele. MRI defecography allows for detection of ligamentous and muscular pelvic floor structures as well as providing a good assessment of the anterior compartment and confirmation of POP-Q findings.

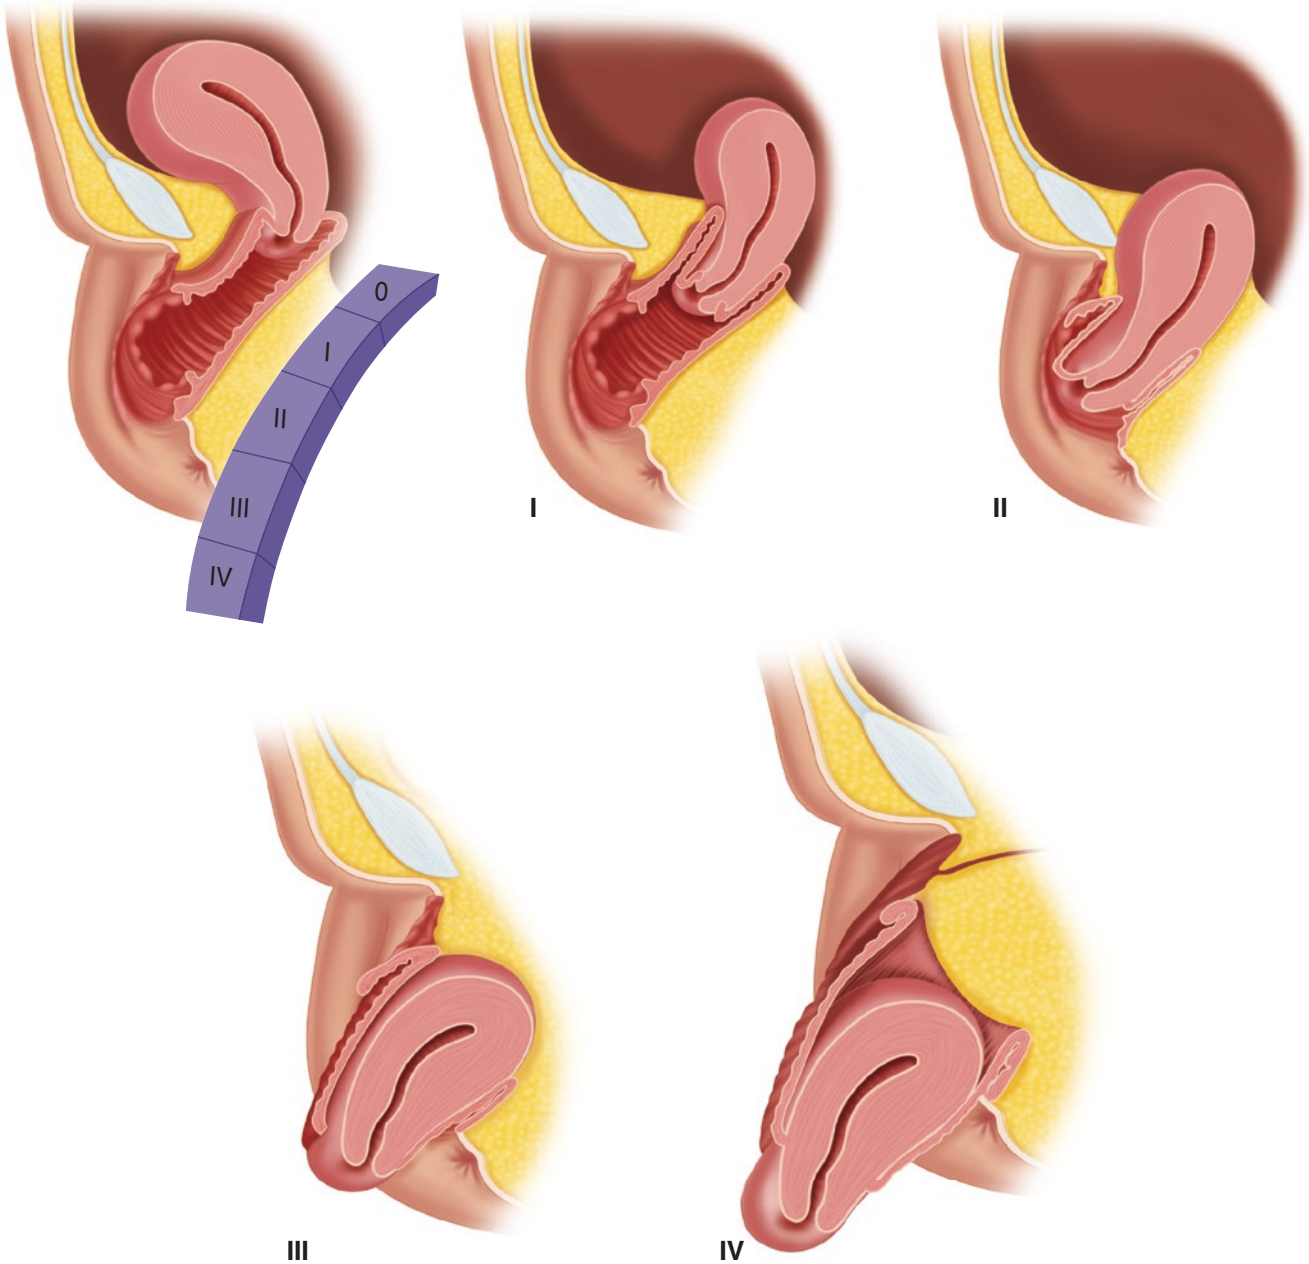


Fig. 65.2 Pelvic organ prolapse staging

Indications and Outcomes for Common Nonoperative and Operative Approaches for Anterior and Middle Compartment Prolapse

Asymptomatic patients with POP should be educated about symptoms associated with POP and be reassured about treatment options. Nonoperative options for symptomatic patients are limited. However, many symptoms related to POP can be managed initially with lifestyle modifications. The sensation of bulging may improve, or the progression of prolapse slowed by performing pelvic floor strengthening exercise either alone or with a trained professional therapist. However, pelvic floor retraining has not been shown to prevent the need for corrective surgery in patients with symptomatic POP [18]. There is limited evidence to suggest that local or systemic estrogens may also help prevent progression of POP [19]. Finally, a pessary can be offered

as an alternative to a surgical repair. A pessary can be fitted well into the vagina and is an effective, short-term, low-risk option for up to 90% of women [20]. A pessary is generally used for Stage II through IV prolapse; however, it is less successful in Stages III and IV [20]. It is best if patients can maintain their own pessary hygiene by removing, cleaning, and replacing the pessary every 3 months. Up to 9% of patients can experience a mild ulceration of the vaginal wall secondary to the pessary [20]. Resolution of the tissue injury occurs with local estrogen therapy.

Table 65.3 Common findings on urodynamics with uroflowmetry and assessment of post-void residual

Diagnosis	Findings on urodynamics
Incomplete bladder emptying	Large post-void residual
Stress incontinence	Involuntary leakage of urine with increased intra-abdominal pressure and no detrusor contraction
Increased bladder sensation	Increased perceived bladder filling with an early desire to void at a low volume with no abnormal increase in detrusor pressure
Detrusor overactivity	Involuntary detrusor contractions during bladder filing
Detrusor underactivity	Poor detrusor contractions during voiding

Operative interventions for POP are reserved for Stage II–IV symptomatic patients. It is imperative that the patient's symptoms match their clinical findings if an operation is to be performed. The goal of any operation related to POP is to restore normal anatomy. Operative indications, techniques, and outcomes are listed in Table 65.4. There is a lack of consensus which approach is best for identified anatomical defects, and the risks and benefits of each approach should be considered carefully with the patient. The first decision that must be made is whether an obliterative or reconstructive approach should be taken. In older women who are no longer sexually active, an obliterative surgery (colpocleisis) can be successfully performed. In the presence of a uterus, a Le Fort partial colpocleisis can be performed by denuding a strip of epithelium from the anterior and posterior vaginal walls and suturing them together. This approach allows for the drainage of secretions from the cervix. A pap smear should be performed and found to be normal prior to this procedure. In the absence of a uterus, a colpectomy or tight

Table 65.4 Operative indications, techniques, and outcomes for anterior and middle compartment pelvic organ prolapse surgery

Indication	Surgical technique	Outcomes
Apical uterine prolapse (Grades II–IV)		
1. Shortened vaginal length, intra-abdominal pathology, high risk for recurrence, young age	1. Supracervical or total hysterectomy + abdominal sacral colpopexy	1. Recurrence rates of 7% (synthetic mesh) vs. 38% (cadaveric fascia) at 5 years [51]
2. Poorer surgical candidate, does not want mesh in prolapse repair	2. Vaginal hysterectomy + uterosacral ligament suspension	2. 35% recurrence rate at 2 years [48]
3. Poorer surgical candidate, does not want mesh in prolapse repair	3. Vaginal hysterectomy + sacrospinous fixation	3. 36% recurrence rate at 2 years [48]
4. Desire uterine preservation	4. Abdominal sacro-hysteropexy	4. No benefit of uterine preservation with prolapse repair [49]
5. Elderly, poorer surgical candidate, not sexually active	5. Le Fort colpocleisis +/− midurethral sling	5. High patient satisfaction, low recurrence rate [50]
Apical vaginal prolapse (Grades II–IV)		
1. Shortened vaginal length, intra-abdominal pathology, high risk for recurrence	1. Abdominal sacral colpopexy	1. Recurrence rates of 7% (synthetic mesh) vs. 38% (cadaveric fascia) at 5 years [51]
2. Poorer surgical candidate, does not want mesh in prolapse repair	2. Uterosacral ligament suspension	2. 35% recurrence rate at 2 years [48]
3. Poorer surgical candidate, does not want mesh in prolapse repair	3. Sacrospinous fixation	3. 36% recurrence rate at 2 years [48]
4. Elderly, poorer surgical candidate, not sexually active	4. Colpocleisis +/− midurethral sling	4. High patient satisfaction, low recurrence rate [21]
Anterior vaginal wall prolapse (cystocele)	Anterior colporrhaphy with native tissue vs. mesh	40–60% success in RCT, improved durability with mesh but 10% erosion rate [52]
Posterior vaginal wall prolapse (rectocele)	Posterior colporrhaphy and perineorrhaphy	80–95% success rate, no improvement with mesh repair [53]
POP and stress urinary incontinence	Sacrocolpopexy and retropubic midurethral sling Midurethral sling +/− anterior colporrhaphy	50% reduction in the risk of postoperative stress urinary incontinence [54] 80% mid- and long-term success rates [23]

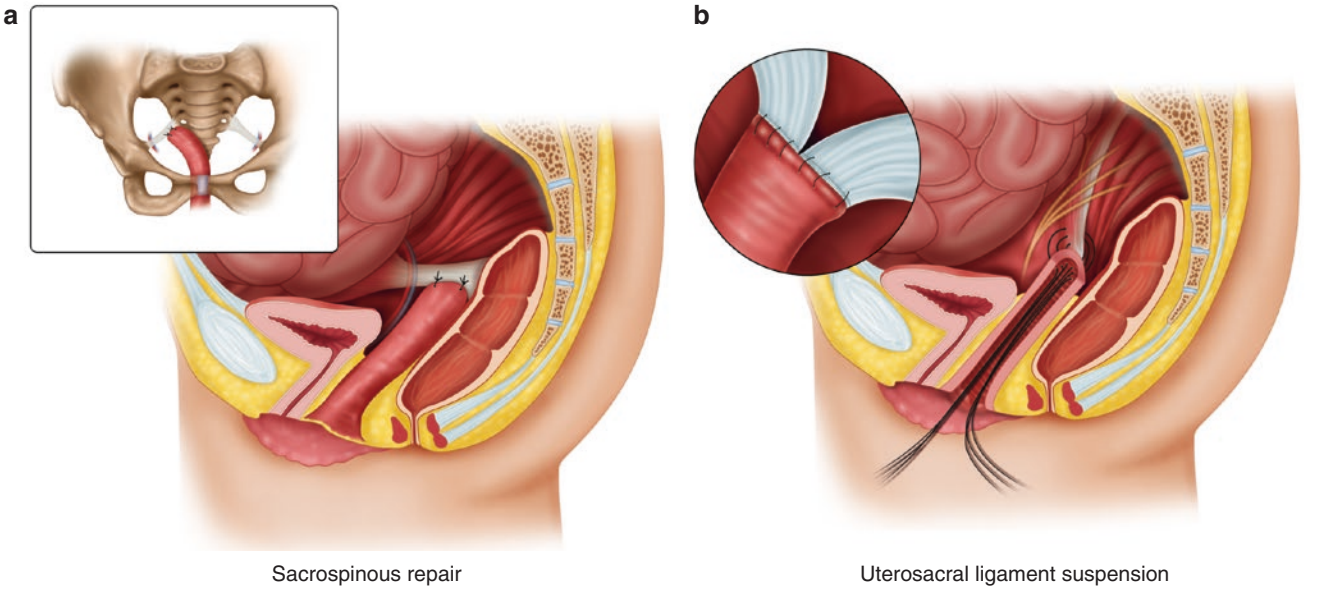

Fig. 65.3 Sacrospinous ligament fixation (**a**) and uterosacral ligament suspension (**b**)

anterior and posterior colporrhaphy can be performed. The operation is performed by completely excising the vaginal mucosa from the urethrovesical junction to the vaginal apex. The prolapse is then reduced with sequential interrupted sutures until the prolapse is above the levator plate. A wide perineorrhaphy is then performed to incorporate the levator muscles and reduce the genital hiatus to 1–2 cm in size. It may be necessary to address urinary symptoms at the time of colpocleisis as this is a common cause for poor quality of life postoperatively [21].

If reconstructive surgery is planned, the second decision which must be made is whether a transvaginal or transabdominal approach is best. Most urogynecologists approach women who are ≥80 years with a transvaginal approach as studies have shown that this approach is associated with a low incidence of serious postoperative adverse events [22]. The most common postoperative complication following the vaginal approach is a urinary tract infection. The third decision that must be made is what defects should be repaired concurrently. Anterior vaginal wall prolapse is often associated with apical prolapse and stress urinary incontinence, and concomitant repair should be considered as this may improve outcomes for findings of more severe prolapse.

Transvaginal reconstruction of POP includes apical vaginal suspensions with either sacrospinous ligament fixation (SSLF) or uterosacral ligament suspension (USLS), anterior colporrhaphy, and posterior colporrhaphy (Fig. 65.3). Vaginal vault apical suspension can be performed either at the time of vaginal hysterectomy or in patients with post-hysterectomy vault prolapse. SSLF and USLS can be performed only if there is adequate vaginal length. The sacrospinous ligament can be palpated through the wall of the vagina tracking from the ischial spine posteriorly, as a thick cord, toward the sacrum (Fig. 65.3a). To begin, the vagina is everted and opened, and any enterocele, the bladder, and the rectum are mobilized to prevent injury. The sacrospinous ligament is identified on one side and attached to the full thickness of the fibromuscular layer of the undersurface of the vaginal apex. The peritoneum is not entered in a sacrospinous ligament fixation so this procedure may be preferred in women with suspected pelvic adhesions. A USLS is performed in a similar fashion; however, instead the vagina is attached to the uterosacral ligaments intraperitoneally (Fig. 65.3b). These ligaments can be found posterior and medial to the ischial spine. The uterosacral ligaments can be joined in the midline to increase the strength of the repair. A USLS is most commonly performed in conjunction with a vaginal hysterectomy, although the hysterectomy can also be performed laparoscopically.

The objective of an anterior colporrhaphy is to plicate the layers of the muscular wall of the vagina and the paravaginal tissue to reduce the protrusion of the bladder into the vagina. While grasping the vagina with well-placed Allis clamps, a transverse incision is made from the urethrovesical junction to the apex of the vagina. The bladder is mobilized, and then plication sutures are placed to reduce the cystocele. Excess vaginal epithelium is then trimmed and the vaginal incision is closed. During a posterior colporrhaphy to treat a rectocele, the posterior vaginal wall is incised in the midline, and the perirectal fascia is mobilized laterally as far as possible. Small defects in the rectovaginal fascia are repaired with vertical mattress sutures. For larger defects, the puborectalis muscles are plicated. Care must be taken to not plicate too much tissue or the vaginal lumen may be narrowed.

Stress urinary incontinence (SUI) is commonly associated with anterior vaginal wall prolapse and should be initially managed with conservative therapies. These therapies include pelvic floor physical therapy directed at returning strength and muscle tone to the pelvic floor. Another nonsurgical option for SUI is an incontinence pessary. If patients have overactive bladder associated with SUI, physical therapy and behavior modifications are the first-line treatment. Antimuscarinic therapy can be tried if these conservative measures fail. The most effective surgical approach to stress urinary incontinence is midurethral slings. These procedures were first introduced in the 1990s. The slings have been made of autologous tissue or polypropylene mesh. The repair is associated with a very low risk of mesh infection (2%) and mesh repair has a lower rate of failure [23]. The two most current techniques are placement of mesh through a retropubic or trans-obturator approach. In the retropubic approach, mesh is passed through a small vaginal incision and through the retropubic space hugging the pubic bone and exits the abdominal wall in the suprapubic location. In the trans-obturator approach, mesh is passed through a small vaginal incision into the obturator foramen to exit lateral to the labia majora. Both repairs have good long-term subjective and objective success rates that approach 80% [23].

The most common abdominal approach to POP is the sacrocolpopexy (Fig. 65.4). Women who are best candidates for this procedure include those with a shortened vaginal length, intra-abdominal pathology, or risk factors for recurrent POP (age < 60 years, Stage III–IV prolapse, and BMI > 26 kg/m^2) [24–26]. This procedure can be performed laparoscopically or robotically safely and effectively [27, 28]. If a sacrocolpopexy is to be performed, hysterectomy is usually recommended if the uterus is still present. Alternatively, a hysteropexy can be performed in a similar fashion as sacrocolpopexy. Supracervical hysterectomy is generally performed because securing the mesh to the cervical tissue provides a more durable hold and avoids a vaginal incision. A vaginal incision increases the risk of postoperative mesh exposure in the vagina. Once the hysterectomy is complete, the bladder and rectum are dissected off of the vaginal apex, and the mesh is sutured to both the anterior and posterior cervix and vaginal wall. This mesh is then attached to the longitudinal ligament of the sacrum just below the sacral promontory. The best results have been achieved by using synthetic polypropylene mesh [11].

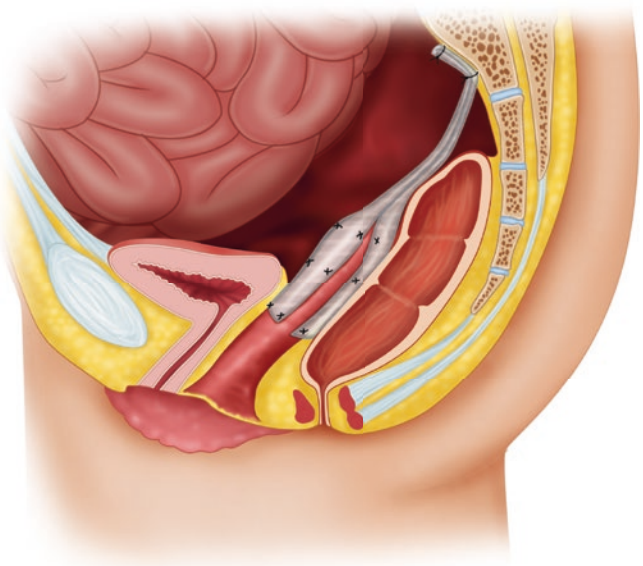

Fig. 65.4 Placement of mesh for sacrocolpopexy

The use of mesh for POP has greatly declined. After the FDA issued a warning in 2008 and in 2011, mesh is no longer placed vaginally during an anterior or posterior repair. However, mesh is used routinely for apical support only during a sacrocolpopexy or hysteropexy. The Colpopexy and Urinary Reduction Efforts (CARE) trial demonstrated that the use of mesh in intra-abdominal procedures was associated with an overall mesh erosion rate of 10.5% [11]. As a result of this finding, it is recommended that large-pore polypropylene mesh be used for performing a sacrocolpopexy as this mesh has the lowest rate of mesh infection among the participants in the CARE trial [11]. In addition, Chughtai et al. demonstrated that placing vaginal mesh for both a sacrocolpopexy and for a midurethral sling had the highest rate for mesh infection (OR 2.13, 95%CI: 1.76–2.56) [29]. The authors suggested a dose-response relationship with the use of mesh. However, D'Hoore et al. demonstrated similar findings of increased rate of mesh infection when a ventral rectopexy with mesh was performed with a posterior colporrhaphy using mesh. He attributed this increased rate of infection to the creation of a vaginal wound resulting in mesh exposure [30].

Multidisciplinary Approach to Pelvic Floor Prolapse

While surgery is indicated for patients with Stage II POP or greater who are symptomatic and who have failed conservative therapy, there is no consensus about which surgical approach is superior. Anatomic failure rate can be as high as 25% [11]. Of those that undergo surgery, 13% will require a repeat operation in 5 years, and 30% may need repeat surgery for POP in their lifetime [31, 32]. Large-scale, community-based research regarding POP failures is lacking, and the follow-up in many trials is only 1–2 years. Failure rates for vaginal and native tissue repairs are higher than those for mesh sacrocolpopexy, and many recurrences are attributed to the posterior compartment. A recent study showed an 82% symptomatic improvement after laparo-

scopic sacrocolpopexy [33]. Of those patients not improved, two thirds had mid vaginal recurrent prolapse, and one third had urinary and bowel dysfunction. Of the patients that were physically examined, 28% had posterior anatomic failure. In a randomized study comparing three different rectocele repairs, 21–51% of patients continued to have symptoms of straining, incomplete evacuation, or defecatory dysfunction despite overall symptom improvement [34].

It is important to review the anatomical relationships of organs in the posterior pelvis to understand how best to manage POP in a multidisciplinary approach. The most distal support of the vaginal wall is provided by the perineum, the lower rectovaginal septum, and the levator ani. The mid vagina is supported laterally to the fascia of the levator ani muscles. The upper vagina is supported by the cardinal-uterosacral ligament complex [35]. The rectum is a retroperitoneal structure which has a short mesorectum and begins at the sacral promontory. The mesorectum allows the rectum to pull away from the sacrum during defecation and notably is elongated in patients with significant intussusception and prolapse. The lateral ligaments are located on the posterior lateral sides of the rectum close to the coccyx. These lateral ligaments are connective tissue structures containing nerves and the middle rectal artery and support the lower rectum above the levator ani. The most distal support of the rectum is provided by the levator ani, the internal and external anal sphincters, and the perineum. The anterior low rectal wall and the mid vaginal wall are typically fused, and continued excessive pressure from the rectal side can cause bulging of the rectal wall into the mid vagina creating a rectocele. There is an interdependence of load-bearing structures of pelvic support (levator ani muscles, connective tissue, nerves) which can affect all of the pelvic compartments to varying degrees.

Addressing symptoms of posterior vaginal wall prolapse with a more thorough initial evaluation and management of constipation and obstructive defecation may help to improve outcomes after surgical management of pelvic organ prolapse. Bulging, pelvic pressure, vaginal splinting, obstructive defecation syndrome, dyssynergic defecation, tenesmus, and rectal bleeding are common patient complaints and have all been described to occur with posterior compartment defects. Other than splinting and stool trapping, many of these symptoms do not correlate with physical findings or the POP-Q exam. A wide genital hiatus and/or perineal defect is often found in patients with posterior vaginal prolapse and can occur with rectal intussusception, posterior enteroceles, and sigmoidoceles. Symptoms from intussusception and enteroceles are nonspecific and cannot be explained by physical examination alone. Internal rectal prolapse (intussusception) may simulate rectocele or enterocele and result in obstructive defecation [36]. These entities can also occur in isolation or in conjunction with each other. Dynamic studies (dynamic MR or cinedefecography) should be obtained when the patient complaints do not agree with the findings on physical examination. Defecography (dynamic MR or cinedefecography) may identify occult pelvic floor issues (e.g., significant rectal intussusception) which can progress after a single-compartment approach. Currently, there are no studies that address how intussusception and enteroceles coexist and how their presence impacts surgical outcome.

The condition of posterior prolapse (rectocele, internal intussusception, and full rectal prolapse) has historically been treated as a separate entity from middle and anterior prolapse despite similar etiological factors. This type of compartmentalization may lead to suboptimal outcomes, worsening of prolapse in the other compartment, and defecatory dysfunction. Whether significant symptomatic rectoceles occur in isolation is a matter of debate and requires further studies. Barium trapping and rectocele size have not been shown to reliably correlate with patient symptoms and should not be used as criterion for surgery in patients with constipation and rectoceles [37, 38]. There is also no correlation between posterior vaginal wall prolapse, constipation, and measurements of anorectal function [39]. Rectoceles may be the result of obstructive defecation rather than the cause [40]. Initial management of rectoceles and ODS with biofeedback prior to surgery can show a 71% response rate [41]. Correcting the rectocele bulge does little to relieve symptoms of constipation and intussusception. If straining at stool is allowed to continue in the postoperative period, pressure on the anatomic repair may result in recurrence of prolapse.

A multidisciplinary approach with urogynecologists working with colorectal surgeons allows for evaluation of all three compartments and a more thorough preoperative assessment. Several reports have suggested that a multidisciplinary surgical approach may improve surgical outcomes for patients with POP [28, 42]. The sutured rectopexy and mesh rectopexy help to elevate the mid and low rectum out of the deep pelvis treating the internal rectal prolapse that is frequently found in conjunction with rectoceles and help to eliminate symptoms of obstructive defecation. A combined sacrocolpopexy and rectopexy for mid and posterior prolapse has been reported to be safe with a low risk of recurrence improving bowel function (constipation and fecal incontinence) and quality of life for most women with pelvic organ prolapse and rectal prolapse [43]. Early reports suggested that combined surgery would improve patient satisfaction and be cost saving by utilizing a single surgery for management of a complex problem [44]. The addition of a rectopexy (sutured or ventral mesh rectopexy) does not add significant morbidity or mortality or time to the sacrocolpopexy [28, 42].

The approach to combined operations can be open, laparoscopic, or robotic and is based upon the surgeon's preference. The order of the procedures depends on the surgeons' choice and experience. If a uterus is still present, a supracervical hysterectomy is generally performed first. The urogynecologist will typically do the hysterectomy, perform the anterior vesicovaginal dissection, and begin the posterior dissection along the cervix and posterior vagina. The sacral dissection starts with the identification of the sacral promontory, the common iliac artery/vein, and the right ureter. The middle sacral artery originates from the aorta and is a midline structure seen on top of the anterior longitudinal ligament. The colorectal surgeon opens and dissects the rectovaginal space down toward the pelvic floor. The lateral stalks to the rectum are preserved to minimize postoperative constipation symptoms. A ventral rectopexy is performed with polypropylene mesh sutured to the anterior rectum or the perineum. Some authors have advocated the use of biologic mesh to avoid the risk of mesh erosion [45]. This mesh is then sutured to the sacral promontory along with the sacrocolpopexy mesh. A sutured rectopexy may be as effective as a mesh rectopexy in this situation and is done with permanent suture placed through the lateral ligaments of the rectum and sutured below the sacral promontory stitches [46]. The mesh is covered by the peritoneum at the end of the case, and cystoscopy is frequently performed to ensure that there has not been injury to either ureter during dissection and closure. Evaluation of the anterior and posterior vaginal prolapse is done by the urogynecologist, and the decision for a posterior repair or perineorrhaphy is made at the end of the case. Oftentimes, there is no need for a formal posterior repair once the upper vagina and the mid and low rectum are supported. Although not commonly done, resection rectopexy combined with sacrocolpopexy is reported to be safe, but some have reported a higher complication rate [47]. Avoidance of constipation and straining in the postoperative period is recommended, and the use of stool softeners and laxatives is encouraged.

Conclusion

The three compartments of the pelvis are intertwined. Knowledge of anatomy and physiology aids in taking care of this patient population. A multidisciplinary approach should be considered if the history and physical point to multicompartment problems. Evaluation and treatment planning may also involve a team effort. Surgery on all compartments at the same setting requires coordination and patience but can be in the patients' best interest.

Key Concepts

- The major principle of operative therapy for Hirschsprung's disease is to bring ganglionated bowel to within 1 cm of the dentate line.
- The ideal surgical treatment of a duplication depends on length and location of duplication, age of child, and relationship to surrounding structures with complete excision being the goal, though not always possible.
- Constipation and fecal incontinence need a full history and physical examination but are managed often successfully by medical management.
- Anorectal malformations often occur with other congenital defects and a mainstay for surgery is an ano rectoplasty.

Hirschsprung's Disease (HD)

Patients with HD present classically during three different periods of life. The first time of presentation is the neonatal period when infants fail to pass meconium in the first 24 hours of life. These infants can present with vomiting, distention, and failure to tolerate feeds as the most common symptoms. Some infants marginally tolerate their first few weeks of feeds (usually breastfed) and subsequently present with enterocolitis, the signs and symptoms of which are explosive and/or bloody stool, vomiting, and fever. Lastly, there are late presenting patients who usually come to attention when either weaning off breast milk or transitioning to solid food. These patients will have significant abdominal distention and significantly dilated colon on contrast studies and usually have a history of requiring laxatives of some sort to assist with bowel movements.

When suspected, the diagnosis of HD rests with the pathologist. An absence of ganglion cells more than 1 cm proximal to the dentate line is diagnostic of the disease. Suction rectal biopsy, partial-thickness punch biopsy, and full-thickness biopsy are all acceptable means of retrieving tissue depending upon the age of the patient and the need for anesthetic support. With the widespread use of calretinin, which stains ganglion cells, the need for second opinions to locate ganglion cells (or more precisely confirm the absence of ganglion cells) on a hematoxylin and eosin (H&E) slide or assaying for acetylcholinesterase is no longer necessary [1]. For late presenting children over the age of 2, a general anesthetic will be required to obtain tissue for pathologic evaluation. Thus, anorectal manometry can be a triage tool to help determine which patients require rectal biopsy. Failure to demonstrate the receptive relaxation reflex of the internal sphincter is suggestive of HD but not adequate to make a definitive diagnosis.

When diagnosed, the treatment of HD can and should be tailored to the individual patient. Whether to do a primary pull-through (colorectal resection with hand-sewn coloanal anastomosis), a leveling colostomy (colostomy at the level of beginning of ganglion cells), diverting ileostomy, or delay surgery by utilizing rectal irrigations (high colonic saline enemas) should be individualized based upon the patient's signs, symptoms, and age of presentation. Patients presenting with systemic signs of illness due to enterocolitis are at increased risk for significant postoperative enterocolitis, and thus primary pull-through in this population should not be the default [2]. In addition, patients with long-segment disease (especially total colonic HD) are also at increased risk for postoperative enterocolitis, and primary pull-throughs in this population are also not recommended [2]. If diversion is recommended, an experienced pathologist will be required to perform a leveling colostomy as calretinin staining is not available on a frozen specimen. If an experienced pathologist is not available and there is no means to transport the patient to an institution with expertise, a diverting ileostomy will

S. R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, https://doi.org/10.1007/978-3-030-66049-9_66

suffice in most cases (even in total colonic/total intestinal HD). Lastly, rectal irrigations can be very effective in relieving symptoms and also be effective treatment for enterocolitis. This can allow surgery to be electively scheduled and, in many cases, avoid diversion for families who are resistant to a stoma. This also has the added benefit of teaching the family how to do home irrigations which can be helpful in the event that postoperative enterocolitis occurs [2].

The principle of operative therapy for HD is quite simple: bring ganglionated bowel to within 1 cm of the dentate line [3]. The details of accomplishing this are numerous and very specific. Most HD patients will also have some internal sphincter dysfunction. Thus, each of the common procedures created to accomplish bringing ganglionated bowel distally attempts to deal with internal sphincter dysfunction via a variety of procedure modifications. Although the three main HD operations (Swenson, Soave, and Duhamel; Fig. 66.1) were developed in "the era of open surgery," all can be performed laparoscopically. The Swenson technique brings ganglionated bowel to the distal 1 cm of the rectum after a full-thickness, circumferential resection of the rectum is performed, usually transanally. The Soave technique (first described by Yancy) [4] involves a submucosal transanal rectal dissection with subsequent full-thickness dissection of the rectal wall followed by an anastomosis at 1 cm above the dentate line, leaving a small cuff of aganglionic rectal wall. The Soave and Swenson can also be formed entirely from a perineal approach/transanally. To combat the distal internal sphincter dysfunction and resultant stricture, the Boley modification of the coloanal anastomosis can be applied to either the Swenson or the Soave procedure. Boley described creation of the anastomosis in an angled fashion with anterior being 1 cm from the dentate line and posterior coming within 0.5 cm of the dentate line, thus elongating the anastomosis by essentially creating an elliptical anastomosis and also building a posterior sphincterotomy into the procedure. The Soave has been additionally modified to include a posterior division of the remaining aganglionic rectal wall from below the levators all the way to the level of the anastomosis, thus building in a posterior division of the internal sphincter [5]. The Duhamel technique leaves a segment of aganglionic rectum, and the ganglionated bowel is then anastomosed in an end-to-back fashion just above the level of the dentate line, thus also performing a posterior internal sphincterotomy into the procedure. A critical step is to ensure that any segment of aganglionic rectum proximal to the end-to-back anastomosis is resected as, over time, this can result in expected lack of peristalsis and lack of emptying of this segment with subsequent dilation and stasis into what is known as a "rectal spur" [6]. A Duhamel anastomosis may be chosen with longer-segment HD where retention of part of the rectum, despite being aganglionic, may be beneficial to achieve continence.

With these modifications, all named procedures have success rates that are equal [7]. There are advantages to minimally invasive approaches as far as length of stay, postoperative complications, and postoperative narcotic usage are concerned [7]. When comparing laparoscopic to transanal (perineal) approaches, there are no significant differences[8]. The complications of constipation, enterocolitis, and

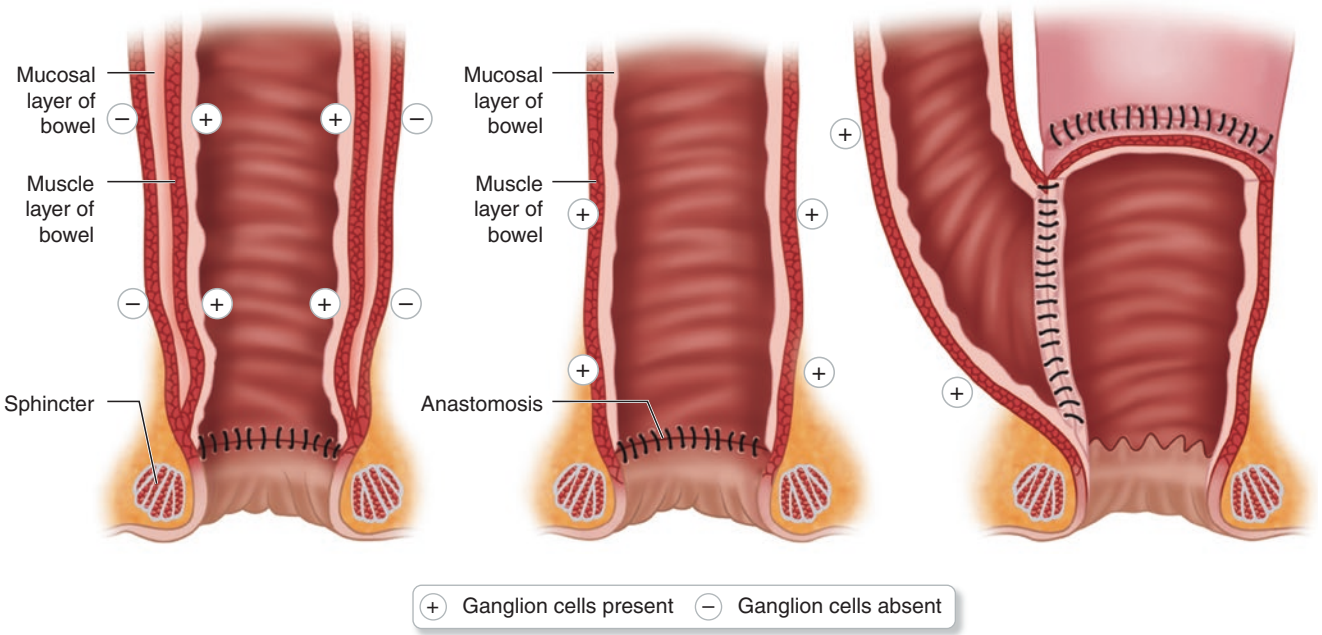

Fig. 66.1 Soave, Swenson, and Duhamel reconstruction for HD

sensory incontinence that limit the success of each procedure have slightly different mechanisms. The Duhamel procedure theoretically is associated with increased stasis of stool in the neorectum due to the remaining distal rectum being unganglionated and the possibility that the proximal end of the rectal portion of the anastomosis will grow into a significant spur. The Swenson and Soave both have risk of circumferential anastomotic strictures (even with the Boley modification) due to some remaining aganglionic rectal wall and will usually require postoperative dilations to avoid development of long-term narrowing which can also lead to enterocolitis.

When complications from HD develop, a systematic approach for each procedure and complication is required. In general, rectal irrigations, dilations, or laxative therapy is the first line of evaluation and treatment. If recurrent symptoms occur, a contrast enema is the first study to be done. Next, a repeat rectal biopsy to ensure that ganglionated cells are present in the neorectum is essential. If ganglion cells are not present due to chronic distention, loss over time, or incorrect pathologic interpretation at the initial procedure, a repeat pull-through (coloanal anastomosis) will be required. If ganglion cells are present within 1 cm of the dentate line and a contrast study shows significant rectal dilation, either anal dilations, internal sphincter Botox injection, or sphincterotomy can be offered [8, 9]. For a significant spur in a Duhamel patient, laparoscopic resection of the spur is required.

In the majority of cases of HD-associated enterocolitis (even significant recurrent disease), patient will overcome their symptoms and "outgrow" most issues by the time they are teenagers. The etiology as to why this pattern of enterocolitis exists is a source of constant study. Theories involving the development and altering of the microbiome are currently evoking the most interest in the scientific community. The composition predisposing microbiota in Hirschsprung-associated enterocolitis (HAEC) is specific to each patient, and total colon resection can change that composition [10]. In addition, relative intestinal immunosuppression could expose Hirschsprung patients to environmental microbes that might not be part of the normal microbiota perhaps leading to a predominance of specific fungi and bacteria that predispose patients to development of HAEC [11].

Adult outcomes in HD are still being elucidated. The main long-term concerns are fecal incontinence which is reported in around 15% and constipation in about 5% [12–16]. Interestingly, bowel quality of life does not seem to be compromised despite these long-term complications of the disease [13–15]. Concerns are higher in those who had longer-segment disease (i.e., standard rectosigmoid aganglionosis vs total colonic aganglionosis) [15]. Also, functionality worsens with increasing age [13, 15], highlighting the importance of care for the aging HD patient. Sacral nerve stimulation is evolving as an adjunctive treatment in some selectively chosen patients.

Colonic Duplications

Enteric duplications are a relatively rare congenital anomaly, occurring in 1 in 100,000 live births and found in 1 of every 4500 autopsies [17]. Sixty to 80% present in the first 2 years of life [18]. Eighty percent are found within the abdomen with the majority being ileal duplications [19]. Twenty percent of patients will have more than one duplication. Genitourinary (GU) anomalies are commonly associated with colon and rectal duplications [18].

Although there are many theories, no exact embryologic cause is known for enteric duplication[20]. Theories include "split notochord" where a traction diverticula is created when the notochord and endoderm split resulting in enteric duplication [20]. This theory explains the associated incidence of spinal cord anomalies and their location on the mesenteric side of the intestinal tract. A second theory is failure of recanalization of the bowel [21]. A third theory is abortive twinning: an incomplete split in the primitive streak which occurs early and late in gestation can explain complete duplication of the colon, bladder, urethra, external genitalia, and upper alimentary tract [22]. Lastly, environmental factors such as hypoxia or trauma could potentially contribute to formation of duplication [23].

Enteric duplications are usually tubular or cystic and closely resemble normal intestinal tract architecture. The duplication cyst may only be partially lined by mucosa, and the mucosa may be different than that of its contiguous bowel. Ectopic mucosa has been described including gastric, pancreatic, transitional, and columnar. Gastric and pancreatic ectopic tissue may cause ulceration, bleeding, and even perforation of the duplication cyst [23, 24]. Hindgut duplications typically contain colonic mucosa and only rarely have ectopic gastric mucosa. As mentioned, they typically occur on the mesenteric side, sharing a blood supply and usually mural elements of musculature and serosa with contiguous bowel. There may be a communication between normal and duplicated bowel, particularly in the longer duplicated segments [25].

Duplication of the colon and rectum makes up 17% of all enteric duplications, ranging from cystic duplication to extensive tubular duplications spanning the entire length of the colon [26]. These can extend to the perineum or vagina as a separate opening. Particularly long duplications and distal duplications are frequently associated with GU and spinal anomalies including fistulae, so this should be investigated preoperatively with contrast and endoscopic studies [27]. Presenting symptoms include constipation, abdominal pain and distention, or stool draining from GU or perineum in the event of a fistula. Rectal duplications can be confused with perirectal abscess and fistula if they become infected. Computed tomography (CT) and magnetic resonance imaging (MRI) are useful to determine the extent of the duplica-

tion as well as the relationship to the spine and GU tract. Ultrasound can be helpful and is the imaging modality of choice in infants, as the cyst will typically have a double layer which is indicative of enteric wall rather than a simple cyst wall [28]. Rectal duplications typically are presacral, rarely anterior, and can be considered as part of a Currarino triad: anorectal stenosis, presacral mass, and sacral anomalies.

Ideal surgical treatment depends on length and location of duplication, age of child, and relationship to surrounding structures. Complete excision is the goal but may not be ideal in all settings, for example, a complete colonic duplication and a small child. Partial resection with long stapled fenestrations to allow normal and duplicated bowel to communicate may be better tolerated in a small child than a total abdominal colectomy (Fig. 66.2) [29]. Fistulae to the GU tract, spine, or perineum must be excised. Isolated rectal duplications often share a common blood supply with normal rectum but can typically be separated from rectal wall and excised in entirety. An infected rectal duplication is recommended to be drained externally rather than internally to protect the operative plane between the native rectum and the cyst wall [30].

For edification, duodenal duplications should not be completely excised due to proximity of the bile and pancreatic ducts. Operative approach should include intubation of the duodenum from above to identify the true lumen, partial excision of the wall opposite the true lumen, and mucosal stripping of the shared wall between the duplication cyst and the true lumen. Any small tears into the true lumen can be primarily repaired and drained. Rarely, cholecystectomy, cholangiogram, and intubation of the CBD into the duodenum are necessary to further identify the anatomy. Cystic duplications of the small intestine usually require intestinal resection as the mesentery adjacent to the duplication cyst is unreliable after cyst excision. Thus, the simplest approach is to resect the bowel with the mesentery and perform a primary anastomosis. As with the large intestine, small bowel tubular duplications can vary in length. In order to avoid lengthy small bowel resections, creating a common lumen with multiple fenestrations or linear division/stapling of the common wall is the preferred approach.

In conclusion, duplications are rare and can present with a variety of symptoms from abdominal fullness to perforation. Ideally, they require complete excision with takedown

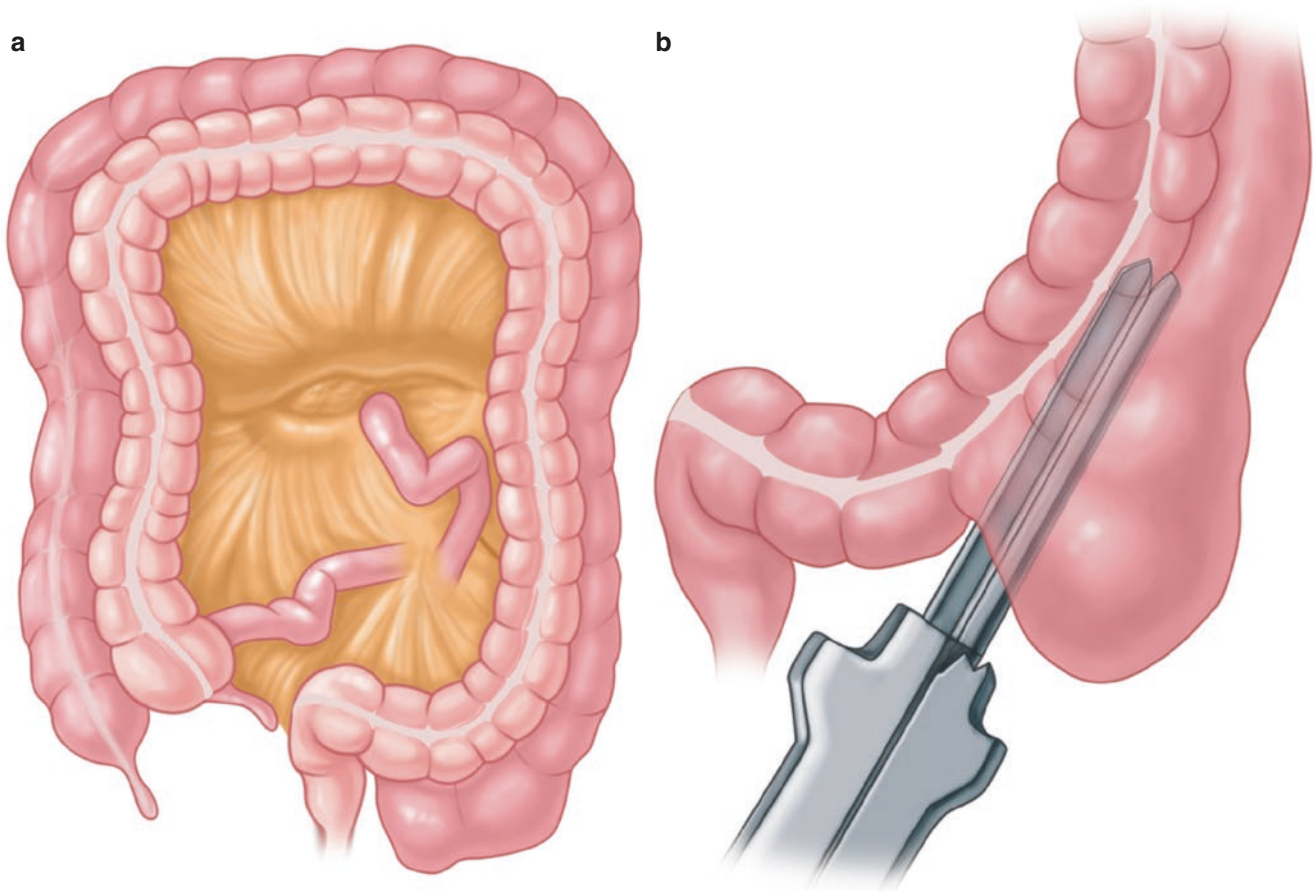

Fig. 66.2 Longitudinal stapling to create common colotomy in long-segment colonic duplication. (**a**) Total colonic duplication. (**b**) Creation of stapled common colotomy for long segment colonic duplication

of any fistulae to prevent symptoms and risk of neoplasm [31]. However, when this would result in intestinal failure, absorptive issues, or damage to critical structures, there are other options including mucosal stripping or wide drainage into a common lumen.

Constipation

Constipation is a common pediatric complaint. It can present with many symptoms including abdominal pain, hard stools, encopresis with fecal incontinence, vomiting, and failure to thrive. Signs can include abdominal distention, rectal prolapse, bright red blood per rectum with anal fissure, and, as a long-term consequence, sigmoid distention with volvulus. Constipation starts within the first year of life in 17–40% of children [32]. Fifty percent of patients referred to gastroenterology for constipation will recover and come off laxatives after 6–12 months. Ten percent will remain on laxatives but be well, and another 40% will need an escalation of therapy beyond laxatives. Fifty percent will come off laxatives after 5 years and 80% will come off after 10 years. If initial referral is delayed and patients present with longer than 3 months of symptoms, recovery is delayed [33]. Common times to present with constipation are in the neonatal period, around the time of toilet training (2–4 years), and after entrance into school where fecal incontinence is more socially pressing. There are many organic problems that can contribute. Celiac and lactose intolerance can commonly predispose to constipation. Any behavioral or musculoskeletal diseases such as autism or cerebral palsy are often associated with a slow transit constipation, anismus and ongoing, refractory constipation. After escalation of medical interventions including osmotic and stimulant laxatives, patients are frequently referred to a surgeon for further evaluation. Also, if there are complications of constipation, a surgeon is frequently enlisted. This section will detail surgical considerations for pediatric constipation.

A detailed history and physical is necessary when evaluating a pediatric patient with constipation. Time to first passage of meconium is an important consideration as Hirschsprung's disease (HD) can present in a delayed fashion. However, if meconium was documented in the first 24 hours, the diagnosis of HD is very unlikely. If no meconium was passed in the initial 48 hours of life, consideration should be given to barium enema looking for a transition zone, and a rectal biopsy should be performed. Anorectal manometry (ARM) looking for a rectoanal inhibitory reflex (RAIR) is unreliable for the first 12 months of life, with a sensitivity ranging from 75% to 90% [34–36]. If HD is discovered, most children who present in a delayed fashion will need diversion to reduce distention of the bowel, allow significant time to treat for enterocolitis, and, ultimately, protect a definitive HD procedure which includes a coloanal anastomosis. If no organic cause of constipation was found but the patient has failed maximal medical treatment, surgical possibilities exist for treatment.

To define the reason for failure of medical management and to direct surgical care, both a sitz marker study to help quantify colonic transit time and colonic manometry in children greater than 2 can be particularly helpful. As in adults, a sitz marker study can help elucidate colonic inertia with a finding of markers remaining throughout the colon or pelvic floor dysfunction where markers are stacked at the puborectalis. Colonic manometry may be useful to predict which patients will respond to antegrade flushes [37, 38]. Identifying and resecting a single dysfunctional segment can improve efficacy of antegrade flushes but may not improve symptomaticity in others [39, 40]. Also, significant bowel dilation will lead to dysmotile bowel that may very well be reversible. Surgical options based on colonic manometry must be tailored to individual patients [41].

Consideration can be given to creation of cecostomy, including a Chait or gastrostomy in the cecum or antegrade continent enterostomy. See the cecostomy portion of this chapter for further information on antegrade flushes. If anismus is a possibility, either by history of withholding, stacked sitz markers along the puborectalis, or anorectal manometry, anal or pelvic floor Botox can be effective in diagnosis and therapy. Anal Botox has been used and studied largely in postoperative HD strictures. Interestingly, there is not always a dose adjustment for size of patient [42, 43]. For medically refractory constipation, consideration can be given to sacral nerve stimulator (SNS), particularly if there are associated urinary symptoms. There are no studies primarily evaluating SNS for constipation in children. Studies in adults do not support implantation for constipation [44–47]. There are retrospective observational studies in pediatrics who note decrease in dependence on ACE flushes and laxatives when the stimulator was implanted for urinary reasons [48, 49]. Of course, if constipation is entirely refractory, fecal diversion is the final step.

Volvulus and perforation of the colon can result from long-standing, refractory constipation. In children, acute and chronic intermittent colonic volvuli are unusual events [50]. Constipation and abnormal colonic fixation are thought to be predisposing factors. Types of volvulus include cecal, transverse colon and sigmoid colon. Presentation varies but usually includes abdominal pain and distention, intolerance to feeds, increased gastrostomy tube output, facial grimace, or expression of pain in the nonverbal population and even peritonitis. Volvulus is diagnosed on abdominal radiograph and confirmed on axial imaging, contrast enema, or colonoscopy. Once discovered, in the case of transverse or sigmoid colon volvulus, the bowel can be attempted to be de-torsed with colonoscopy. This reduces ischemic risk to the colon by straightening the mesentery and may even allow bowel

preparation prior to definitive treatment. Definitive treatment consists of segmental resection and anastomosis. If volvulus is the presenting symptom of constipation, reduction with aggressive medical management may be attempted for transverse colon and sigmoid volvulus, but the rate of failure is high [51–53]. The average age of sigmoid resection in children is 7 years [54]. Postoperatively, due to ongoing dysmotility, the risk of a second volvulus of another segment of the colon should be considered.

If volvulus is present long enough to compromise blood supply to the colon, the presenting symptom may be perforation. Other processes leading to spontaneous perforation include long-standing and increasing dilation of the colon or acute intestinal pseudo-obstruction (Ogilvie's syndrome). Ogilvie's syndrome can present in a postoperative period or occur as a result of any other systemic derangement including but not limited to infection, pancreatitis, electrolyte abnormality, or respiratory process. In the instance of ongoing dilation, the most common site of perforation is the cecum given its proximal position as well as thin wall. This is further supported by the law of Laplace (wall stress = [(transmural pressure) × (radius)]/wall thickness). Should colonic perforation occur, treatment is with segmental resection and primary anastomosis or end colostomy dependent on peritoneal contamination and physiologic status of the patient [55].

Constipation is a common complaint among children, and surgeons are frequently called on to care for the complications of this disease. See the fissure and prolapse portions of the chapter for other complications of constipation in the pediatric patient.

Prolapse

Rectal prolapse is an intussusception of the rectum that by definition involves all layers of the rectum, but in infants and small children with a variety of congenital conditions can involve only the mucosa ("mucosal prolapse"). Prolapse is a common problem in children with a peak incidence in the first year of life and most other occurrences happening under 4 years or around the time of toilet training. Prolapse is a symptom of an underlying condition, usually constipation, but can also be caused by increased abdominal pressure (constipation, staining, chronic cough), acute or chronic diarrhea, parasites or neoplastic disease of the rectum, malnutrition, cystic fibrosis, or pelvic floor weakness.

Most cases of prolapse are mild and resolve spontaneously [56–58]. The initial treatment is typically conservative management of constipation [3]. Parents should be instructed to use stool softeners, or laxatives, avoid prolonged straining, and use proper toilet size to prevent recurrent episodes [4]. If the rectum is prolapsed for a prolonged period of time, manual reduction should occur before edema can make reduction more difficult. Roughly 90% of cases of rectal prolapse that occur in children under the age of 4 will resolve with conservative management and rarely continues after 6 years of age, with children older than 4 being less likely to respond to conservative treatment [3]. Children over 4 years of age are more likely to have neurologic (spinal cord lesions) or muscular defects and require intervention [56–59]. If children fail conservative measures and continue to have rectal prolapse, with ongoing symptoms of pain, rectal bleeding, and perianal excoriation, they may require surgical invention [60–63]. Prior to operative intervention, these children should be screened for cystic fibrosis due to a prevalence of 11.1% in children with rectal prolapse [58–60].

Based on a 2018 survey of the American Pediatric Surgical Association, the most common initial local intervention is the injection of sclerosant [60]. This is thought to be similar to the mechanism of action behind rubber band ligation of internal hemorrhoids, creating scar in the submucosal plane to prevent further prolapse. The methods and content of injections vary highly as some purport a submucosal injection and others advocate trans-serosal injection, scarring the rectal serosa to the perirectal tissues. This is considered the simplest, most benign yet still efficacious intervention [60, 64]. A variety of agents have been described over the years [64–68]. Thirty percent saline was reported with a single injection of 83% and a two-injection cure rate of 97% [65, 66]. Injection of 5% phenol in almond oil results in 91% cure rate after one injection and 100% cure rate after two injections [67]. Ethanol 70% injected results in resolution of 96% of cases after one injection and 98% of cases after two injections [68]. There were few complications seen in these studies including temporary fecal incontinence, temporary limping, bleeding, perirectal inflammation, urinary retention, necrosis of the rectal mucosa, and abscess formation and one death after the injection of phenol [65–69].

Operative interventions are available for refractory cases and can be divided into abdominal or perineal therapies. However, no one operative therapy has been shown to be effective in all cases of rectal prolapse [58–60].

Initially described in 1953 [70], anal encirclement (Thiersch procedure) was recommended as an option for patients with prolapse seconding to weak pelvic floor muscles or associated with cystic fibrosis and is reported to yield success without serious complications [57, 61, 62]. The Thiersch procedure is described as placing an absorbable suture such as a 1-0 PDS circumferentially at the anal opening and securing it over a calibrated Hegar dilator. Another minimally invasive surgical procedure is linear cauterization, which has shown 94% success rate [71]. This is another form of local rectopexy with the submucosal scar being created by electrocautery. Flum, Golladay, and Teitelbaum advocate a combination approach with linear cauterization, sclerotherapy injection, and a Thiersch procedure which they refer

to as a modified Thiersch [62]. In their series they reported a success rate of 67% for patients who underwent a single procedure and a 90% success rate for patients when their patients underwent a combined approach [62].

Patients who continued to experience failures have further surgical options of Altemeier perineal proctosigmoidectomy or abdominal rectopexy. After an Altemeier, some patients did experience temporary fecal incontinence [62]. A posterior sagittal approach rectopexy has been used to treat idiopathic rectal prolapse in children on an ambulatory basis with minimal postoperative pain and normal bowel control. Unfortunately, however up to a 25% recurrence rate was reported [72]. The one study that did not report recurrence was Ekehorn's rectosacropexy which added the placement of a U-shaped suture through the rectal ampulla and tying the suture outside at the sacrococcygeal junction [73]. Ashcraft reported a transcoccygeal rectopexy with puborectalis plication with a success rate of 70%. However, several children developed sigmoid intussusception requiring bowel resection [74]. In one study, children without pelvic floor laxity underwent suture rectopexy to the sacral promontory and suture sigmoidopexy to the left lateral peritoneum without mesh [75]. Laparoscopic posterior levatorplasty has been described for repair of rectosacral hernias where the pelvic floor was lax, treating the prolapse as if it were a true hernia [60, 63]. These procedures were found to be safe and effective with manageable complications.

Currently abdominal rectopexy is thought to be first line for those with irreversible conditions and full-thickness rectal prolapse [76]. As in adults, this can be performed with or without a concurrent sigmoidectomy. Most pediatric surgeons will attempt simple rectopexy with subsequent sigmoidectomy for those that fail pexy alone [5]. Similar to adults, this can be performed laparoscopically or open [58–60, 75]. Laparoscopic rectopexy is a safe and effective treatment for refractory rectal prolapse with approximately a 5% recurrence rate with the only postoperative complication being constipation [58–60]. Laparoscopic sigmoid resection with rectopexy has been controversial in children, but it has been shown to be safe and eliminates the risk of volvulus and has a low morbidity and low recurrence rate [58–60]. Similar to adults, resection rectopexy is preferred in patients with intractable constipation and prolonged transit studies.

Perianal Abscess and Fistula-in-Ano

The treatments of these conditions in children are widely debated in the literature and range from antibiotics and nonoperative management to aggressively probing for a fistula and fistulotomy or fistulectomy. The decision process usually comes down to a weighted belief about attaining adequate source control of an abscess versus creating a fistula-in-ano that can be very difficult to manage surgically and potentially cause recurrence of the infectious process and/or issues with continence. There is currently no consensus as to the best management in the literature [77]. This controversy is in part likely due to the wide range of reported rate of development of fistula-in-ano with a range of 20–85% after perianal abscess management [78, 79]. Further complicating the discussion is the wide range of reports that fistula-in-ano in an infant or toddler can be managed successfully without surgery [78–82].

Perianal abscess and fistula-in-ano are more common under the age of 2, and it is estimated that 0.5–4.3% of all children are affected [79]. Several theories have been hypothesized spanning from gender difference by an androgen excess or androgen-sensitive glands in utero causing a formation of abnormal glands to entrapment of migratory cells from the urogenital sinus during development of the perineum [78, 81–83]. This is a male-predominated disease process; however the ratio of male to female does change with age. In children under 2 years of age, the ratio of males to females is 12:1, while the ratio becomes less extreme after 2 years with a male-to-female ratio of 2–3:1 [80].

The most common positions for perianal abscess and fistula-in-ano are right and left lateral locations [78, 82, 83]. The organisms grown in culture from within the abscess cavities have been found to be gender associated with a significant female predominance growing skin flora (streptococci, *S. aureus*) and a male predominance of enteric flora (*E. coli*, *Klebsiella*, enterococci, *Proteus*) [78]. Although the presence of mixed enteric organisms in the aspirate is suggestive of a fistula, there has been no statically significant correlation between the presence of fistula-in-ano and organisms in culture [80]. There has been a significant increase in the incidence of methicillin-resistant *Staphylococcus aureus* (MRSA) in both the hospital and community settings [84–87].

Remarkably, perianal abscess and fistula-in-ano have not been well-studied in the literature. As a result, there are a wide variety of treatment algorithms among pediatric surgeons. Nonoperative management for perianal abscess including advocating hygiene with good diaper care, sitz baths, and antibiotics has been proposed due to the fact that the patients who undergo surgical drainage have up to a 40% rate of development of fistula-in-ano compared to a 16% rate of development of fistula-in-ano without drainage [79]. Also, it is difficult to predict effect on continence when all babies are incontinent at the time of surgery. Therefore, sparing the sphincter if conservative management is sufficient seems prudent. In addition, the fistula may be a result of other underlying disease processes. For example, Christison-Lagay found 10% of their population to be immunocompromised and treated them with nonoperative management without development of subsequent fistula or the need for

operative intervention [79]. Others have advocated similar approaches with treatment of local hygiene and sitz baths for early-stage perianal abscess and a progressive stepwise approach starting with antibiotics and drainage with an 18-gauge needle for more advanced disease [83]. With this approach, if there was no resolution of the collection within 24 hours, an incision and drainage was performed. The rate of recurrent abscess after needle aspiration was 8%, and subsequent development of fistula-in-ano was 11% [83]. Thus, needle aspiration is a viable treatment technique for perianal abscess in children. In line with this approach, our institution has developed a similar step-up algorithm to manage pediatric patients with perianal abscess and fistula (Fig. 66.3).

Counseling families that one third of abscesses will either recur as an abscess or as a fistula-in-ano becomes important in the care of the child. Recurrence of abscess is not decreased by postoperative antibiotic use, but the subsequent formation of fistula-in-ano is [78]. Reports of recurrence range from 12.5% to 50% with no difference between the different types of antibiotics used [78, 79, 82, 83]. Recurrent fistula-in-ano has also been treated with observation with a spontaneous resolution of 17–80% of fistula-in-ano within 1 year [78, 82]. Antibiotic usage did not affect the spontaneous resolution of the fistula-in-ano [78]. Due to the extreme variation in treatment options reported, there has been no consensus on recommended treatment of abscess and fistula-in-ano for children.

For children under the age of 2 years who undergo surgery for perianal abscess, only 15–25% were identified to have a fistula-in-ano at the time of their primary surgery [80, 87]. Thus, one must question the benefit of an extensive search for a fistula given the potential for sphincter injury in very small patients. In children over 8 years, there were both a high recurrence rate at 50% and a high rate of progression to fistula-in-ano of 25% [80]. As a result, a different strategy should be considered in this population. These strategies can include up-front surgery or fibrin glue application in the fistula after the local sepsis is cleared [87]. In addition, a significant portion of this population should be evaluated for immunosuppressive disorders as well as inflammatory bowel

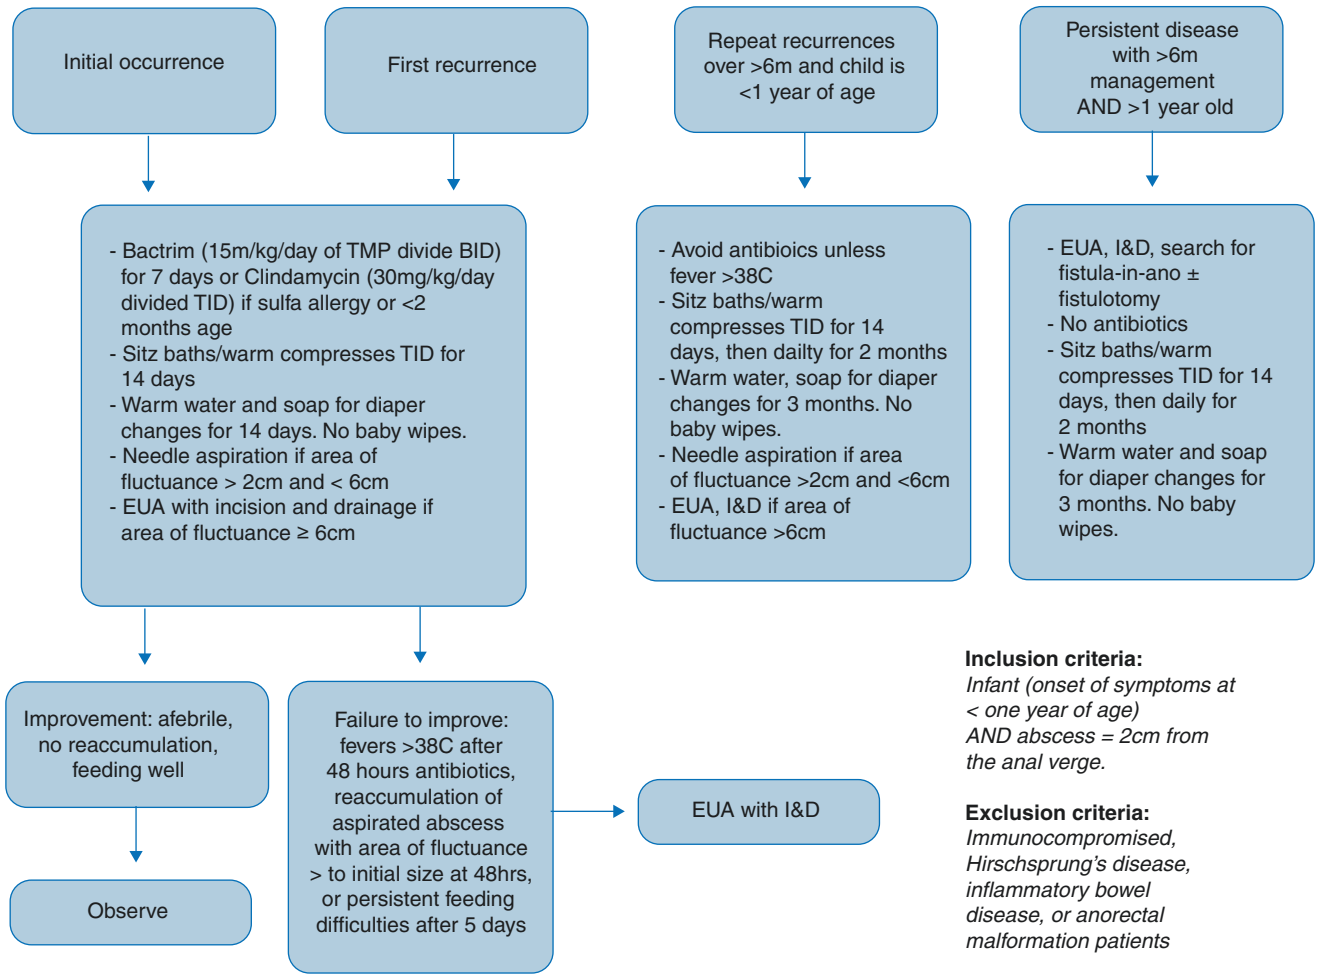

Fig. 66.3 Algorithm for treatment of perianal abscess

disease [77, 80]. Thus, in the inflammatory bowel disease or immunocompromised populations, although perianal sepsis and fistula should be temporized with drainage of the abscess and placement of a draining seton, biologic agents or immunosuppressant therapy should be first-line treatment. As an example, Niyogi successfully used tacrolimus to treat fistulas without the presence of an abscess, and all resolved without operative intervention [80]. Patients as young as 2 years old have been diagnosed with Crohn's disease. Therefore, in a child older than 12 months with recurrent fistula, underlying systemic pathology such as immunosuppression or IBD should be considered and ruled out prior to undertaking any fistula repair.

In summary, perianal abscess is a disease that primarily affects males less than 12 months and should be approached in a stepwise fashion beginning with local therapy and antibiotics, progressing to aspiration, and if necessary incision and drainage. Many of the fistulas-in-ano in this population will spontaneously close without surgical intervention, thus avoiding unnecessary operative interventions. Primary treatment of a fistula-in-ano should be reserved for older children and for those children with a failure to spontaneously resolve as fistula-in-ano seems to be a self-limiting disease in infants [78, 80–82]. While these recommendations are based on current best evidence, prospective randomized trails are needed to further delineate optimum treatment of perianal abscess and fistula-in-ano for infants and children.

Fissures

Anal fissure is a common complication of constipation in children and adults. It represents a longitudinal tear in the distal anal canal and most commonly presents at 2 years of age in children, although it can occur at any age [88]. Pediatric patients present with rectal pain, crying with defecation, hematochezia, or blood on the stools. The fissures in infants may be found anywhere but are more common in the posterior midline. Females, however, more commonly have anterior midline fissures [88–94]. Fissures may also present in association with skin tags or sentinel piles. If the lesions are off the midline or are multiple, a biopsy should be considered to exclude Crohn's disease, malignancy, tuberculosis, sexually transmitted disease, or immunodeficiency [88]. In addition, fissures can be associated with operative management of multiple congenital anomalies including imperforate anus, persistent cloaca, Hirschsprung's disease, ileoanal pull-throughs for polyposis and inflammatory bowel disease, and cystic fibrosis among others [88]. Most anal fissures that appear spontaneously will heal with medical bowel management with recovery rates ranging from 10% to over 95% [88–94]. The higher rate was achieved in a longer study (10 weeks) and with a more intensive bowel regimen with surgical treatment reserved for symptomatic fissures [89–94]. For fissures that do not heal with bowel management and are located within prior surgical fields, nonoperative options such as botulinum toxin injection have become popular [42]. Treatment of constipation in children includes fiber, osmotic laxatives, stimulant laxatives, and rectal suppositories or enemas.

More invasive therapies such as topical nitroglycerin, botulinum toxin injection, calcium channel blockers, anal dilation, anal myectomy, and lateral internal sphincterotomy have all been studied [42, 89–95]. There have been three randomized trials that have evaluated glyceryl trinitrate 2% (GTN). Two of these showed improvement in both the short term (10 days) and at 8 weeks [89–91]. Kenny showed overall 84% healing in both the GTN and placebo groups [89]. Tander and Sönmez separately showed healing in 82–84% of their treatment arm versus 43–50% in the placebo (or lidocaine) groups. They achieved symptomatic relief in 91–94% of the treatment arm versus 10–35% in the placebo (or lidocaine) group [90, 91]. Botulinum toxin can also be used for resolution of anal fissure. Keshtgar showed that children who underwent treatment for anal fissure with transcutaneous botulinum toxin had resolution of their lesion [91].

Anal dilation and anal myectomy of the internal anal sphincter have been performed for constipation with the thought that children with constipation have hypertonicity of their internal anal sphincter and that these modalities would decrease sphincter tone and allow for painless defecation [88]. Double-blinded randomized controlled trials have shown that anal dilation does not benefit children with chronic constipation and that there is no significant difference in outcome with regard to resolution of symptoms [95]. Myectomy of the internal anal sphincter has been used when anal dilation has been unsuccessful. Symptoms were relieved in two thirds of the patients; however, the detrimental effects of fecal incontinence after weakening of the sphincter may not be seen for years [92]. Injection of botulinum toxin into the anal sphincter has been shown to be as effective as myectomy of the sphincter, with resolution of symptoms 94% versus 89%, respectively, without the potential long-term problems [42]. Lateral subcutaneous sphincterotomy was performed for children with a complete resolution of all fissures [93]. A period of inpatient observation and objective evidence of painful defecation is recommended to help avoid misreporting and exaggeration of symptoms and thus unnecessary operations.

In conclusion, asymptomatic lesions are likely to resolve and should be managed expectantly [88, 95]. If intervention is necessary, a trial of topical treatment should be used with reoccurrences again being treated medically and surgery being reserved for continued failures [95]. Any surgical intervention undertaken to the sphincter of a small child or

infant should be done with extreme caution as incontinence and anal stenosis are both reported in up to 30% of children in this age group [95].

Cecostomy

Cecostomy is direct access into the cecum via percutaneous tube or appendix/neo-appendix tacked to the abdominal wall. An antegrade flush is meant to be instilled daily to keep the colon clean and achieve social continence. Cecostomies are used in pediatric patients as an alternative to colostomy as a way to achieve fecal continence.

The antegrade continence enema (ACE) technique was first described by Malone (MACE) in 1990 [96]. He used the appendix to create access to the cecum to provide antegrade enemas. This resulted in controlled stooling with mechanical reduction in fecal burden and ideally reduction in fecal incontinence episodes. Since his original description, the procedure has had several modifications, including creating an antireflux mechanism by wrapping the appendix in the wall of the cecum. This prevents stool from leaking retrograde from the cecum while the catheter is removed. Another modification is the use of laparoscopy for creation of the MACE. If no appendix is available, a conduit can be created using a transverse cecal flap or spiraled piece of small bowel. Other mechanisms of providing access to the cecum to establish an antegrade enema program are via a surgically or radiographically placed percutaneous cecostomy [97, 98]. A surgically fashioned cecostomy involves sewing the cecum to the anterior wall and placing a tube or low-profile gastrostomy through an anterior abdominal wall trephination into the cecum. Gastrostomy or jejunostomy tubes can be used. However, to minimize leakage, granulation tissue, and epithelialization of the cecostomy, Dr. Peter Chait created a low-profile, small-caliber self-retaining coiled tube (Fig. 66.4). Drs. Chait and Shandling first described radiographically

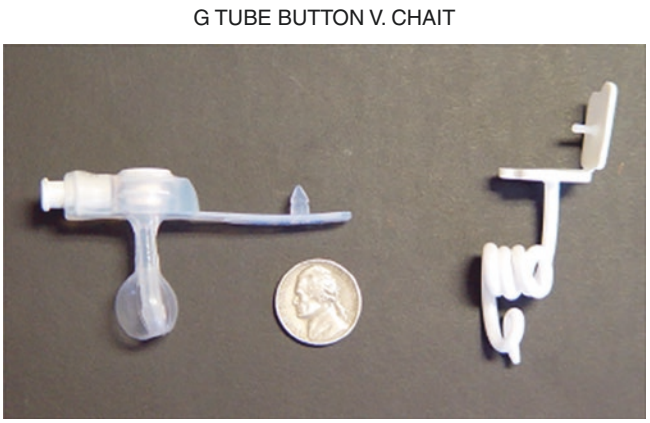

Fig. 66.4 Gastrostomy button versus Chait

Fig. 66.5 Umbilical antegrade continent enterostomy (ACE) site

placed cecostomies [99]. Each approach to cecostomy carries its own risks and benefits. After surgical creation of an appendicostomy (ACE), a catheter is placed in the orifice nightly, the flush is administered typically via gravity, and then the tube is removed. Benefits include ability to remove the tube so there is no permanent foreign body and cosmesis. Because it is typically located within the umbilicus, the orifice is not noticeable once the tube is removed (Fig. 66.5). Potential complications include stenosis of the aperture and tract as well as injury to the appendix resulting in superficial or deep space infection. Intraluminal knotting of the catheter can also occur making removal difficult. Because a percutaneous cecostomy tube typically remains in place, the tract does not have to be manipulated daily. The drawbacks of this approach include permanent foreign body in the abdominal wall, formation of granulation tissue, potential dislodgement, and potential need for sedation to facilitate tube replacement or exchange. Complications common to all approaches include leakage at the skin and skin infection. Both carry equivalent likelihood of continence, and outcomes surrounding superiority of either are mixed [100, 101].

Prior to placement of antegrade enema access, investigation should be undertaken to help gauge if antegrade enemas will be successful at achieving social continence. A retrograde enema program can be initiated. If a temporary retrograde enema program is successful, antegrade access typically will also be ultimately successful. As mentioned, colonic manometry can also be a useful adjunct to help predict success of an antegrade enema program [33,

37, 102, 103]. Those with generalized dysmotility or those who do not respond to a bisacodyl challenge are less likely to be successful with cecostomy. At our institution, postoperatively, flushes are then escalated through the antegrade enemas over the postoperative days to achieve 20 milliliters per kilogram normal saline in a nightly flush. The child will sit on the toilet and begin the flush via gravity drainage through the cecostomy. They will sit on the toilet for an average of 45 minutes, allowing the flush to pass through the colon and anus along with a large quantity of stool. If saline alone is ineffective at achieving fecal continence during the day or if children do not tolerate sitting on the toilet for 45 minutes, additives can be dissolved into the antegrade enemas, including irritant laxatives, lubricants, and promotility laxatives. The percentile success of antegrade enemas is variable dependent on underlying disease process. Some children with cerebral palsy and other movement and communication disorders seem to be higher risk for refractory constipation and soiling due to their potential for significant dysmotility [104].

A new consideration in cecostomies is the adjunctive use of sacral nerve stimulation (SNS). Many patients with cecostomies will receive SNS for urinary indications. Rarely will it be implanted for constipation alone as the failure rate for this indication is quite high [105, 106]. However, in those patients who received SNS for other indications, 45% ultimately had their cecostomy closed [107]. Although interesting, more research is needed around SNS and constipation.

In summary, cecostomy can be created in a variety of techniques, each with its own advantages and disadvantages. Antegrade flushes are a common method of achieving social fecal continence and an attempt to avoid a permanent colostomy.

Transitional Care in the Pediatric Colorectal Patient: Anorectal Malformation, HD

Transitional care for the complex pediatric colorectal patient is becoming more important as this population ages. It is widely known that there is a disconnect as these patients outgrow their pediatric care but do not necessarily seek care at an adult institution [108]. The reasons for this disconnect are still under investigation. It is critical to identify the main patient populations with congenital disease that may seek the care of an adult colorectal surgeon. Facilitating access to adult colorectal surgeons and adult gastroenterologists is a requirement prior to managing the problems that may be encountered.

Anorectal malformation (ARM) has a large spectrum of severity, ranging from congenital anal stenosis to cloaca. ARM presents in the newborn period with a rate of about 1 in 2000–4000 live births. The severity of bowel dysfunction typically correlates with the level of fistula. Those with a higher fistula (e.g., rectal-bladder neck or cloaca) have worse bowel outcomes. This is likely due to the lack of embryologic development of important pelvic floor functionality as well as other associated congenital anomalies. Sixty percent of ARM patients have associated genitourinary, skeletal, and spinal anomalies [109]. Thirty percent will report long-term issues with urinary incontinence. Around 10% of men will report issues with erectile dysfunction and 15% with ejaculatory dysfunction. Unfortunately, female sexual dysfunction rates have not been adequately studied.

In general, these patients will undergo a posterior sagittal anorectoplasty in infancy. To summarize, this operation approaches the rectum from a Kraske (posterior sagittal) approach and separates it from the genital (female) or urologic (male) structures and places it within the identified pelvic floor and external anal sphincters. Of the patients with more proximal fistulas, 30–50% of these patients are constipated [110, 111]. Stimulant laxatives have been the intervention of choice in this disease process as osmotic laxatives are known to increase fecal leakage in these patients with compromised sphincter function. Around 20% of adults with ARM report fecal incontinence (FI) episodes weekly [112]. Intervention for FI includes a fine balance of diet, fiber, and antimotility agents. Implantation of sacral nerve stimulator (SNS) may be a reasonable option if at least one of the S3 nerve roots remains intact as many of these patients will have significant sacral anomalies. After medical interventions have failed, consideration is often given to creation of access for antegrade flushes via cecostomy (see cecostomy portion of this chapter). This is typically a Chait (a percutaneous tube placed in the cecum) or a Malone antegrade continent enterostomy (MACE). A MACE is typically fashioned by using the cecum to create an antireflux valve at the base of the appendix and subsequently attaching the appendix to the anterior abdominal wall, usually at the umbilicus. If the appendix is unavailable, the cecum can be tubularized. The ACE is catheterized nightly for an antegrade flush. The flush can include a variety of agents including saline, polyethylene glycol, glycerin, as well as a variety of other stimulant or lubricating agents. This flush is performed nightly and ideally results in socially acceptable fecal continence during the day. Escalation of fecal leakage indicates that the flush is no longer effective and needs to be changed in some manner.

Issues with cecostomies occasionally will come to an adult colon and rectal surgeon. Excessive granulation tissue at the stoma can be managed with local care consisting typically of either topical steroids or silver nitrate. Stenosis at the ACE is typically improved with a local surgical flap such as a VY advancement flap. Stenosis of the skin around a Chait tube can often be managed with local dilation. Prolapse of the ACE can lead to ongoing soilage. This would need a local revision of the ACE, taking care not to damage the tenuous blood

supply of the appendix/conduit. If there is retrograde drainage of stool from the MACE and the patient is not severely constipated, the MACE would need revision of the antireflux mechanism. MACE flush management in the pediatric sector is typically performed by the surgeon. During transition to adult care, this responsibility is typically taken on by the adult gastroenterologist. Clear and ongoing communication between pediatric surgeon and adult provider is paramount in maintaining continence for these young adults. Another reason ARM patients may seek an adult colorectal surgeon is rectal prolapse, which is usually a symptom of long-standing constipation. The constipation should be addressed prior to limited Altemeier where the redundant rectum is excised and sewn directly to skin as there is no anus.

Hirschsprung's disease (HD) is another congenital diagnosis which requires transitional care and may ultimately present to an adult colorectal surgeon. HD is an absence of ganglion cells in the distal bowel creating a functional obstruction. Early in life, the aganglionic segment is removed and/or bypassed, and the ganglionated segment is brought down to the anus with a hand-sewn coloanal anastomosis (see HD section for further details on variable operative approaches). Eighty-five percent of HD has ganglion cells in the rectosigmoid area resulting in a short-segment resection. Long segment is defined as ganglion cells identified proximal to the middle colic vessels. Short-segment disease can be resected through either a transanal or an intra-abdominal technique. Intra-abdominal approaches are used in longer-segment disease. Many advocate for the use of adjunctive laparoscopy to find the level of transition and mobilize the colon to minimize the trauma to the anal sphincters during a transanal approach. Previous data indicated that long-term bowel functioning was optimistic after repair for HD disease, finding only frequency of bowel movements to differ in HD adults compared to non-HD controls [113]. Many studies have found that initial problems with constipation and FI improve as children enter adulthood [16, 113, 114]. However, this optimistic view has recently been questioned, finding that many adults still struggle with constipation and incomplete evacuation [115]. There is also concern that functional bowel outcomes may deteriorate in an aging population [116]. Further data is clearly needed to further elucidate long-term outcomes, particularly of transanal endorectal pull-through. Hirschsprung-associated enterocolitis (HAEC) is a common postoperative complication of HD regardless of surgical approach. It is thought to be a result of multiple etiologies ranging from internal sphincter achalasia to an abnormal processing of bacteria by HD bowel. The initial treatment, regardless of etiology or age, is with retrograde rectal saline irrigations and antibiotics. About 50% will experience at least 1 episode of HAEC postoperatively and 20% will have >4 episodes. The increasing number of episodes of postoperative HAEC correlates with increasing problems with social continence [113]. Many patients will "outgrow" recurrent HAEC after 5 years of age, and ongoing medical management includes prophylaxis with antibiotics, prebiotics, or probiotics. For those with life-threatening episodes of HAEC or when medical management has no effect, surgical management ranges from injection of Botox or sphincterotomy to creation of a stoma or an ACE. For patients with ongoing fecal incontinence after HD repair, consideration should be given to SNS or creation of ACE when appropriate with the goal of establishing social continence.

Some of the other pediatric bowel management patients that may ultimately seek the care of an adult colorectal surgeon include inflammatory bowel disease, familial adenomatous polyposis, mitochondrial cytopathy, colonic inertia, pelvic floor dysfunction, as well as other behavior and musculoskeletal disorders. Although the pediatric surgeon is heavily involved in the care of these patients as children, they will typically transition to an adult GI provider and be referred to the adult colorectal surgeon via this venue.

Transitional care should begin at age 12 years. The discussion should start with the patient and the family about what will be needed including provider, family, and patient readiness. An appropriately skilled adult provider should be identified. There should be clear communication between the pediatric and adult provider including a joint visit if possible and appropriate. Completion of transition should occur sometime between 16 and 21 years of age with the pediatric provider remaining available to the adult provider for ongoing discussion and questions. Transition of the complex colorectal patient should be a "clearly executed transition rather than a drift away from pediatric care" [117].

Considerations for Geriatric Patients Undergoing Colorectal Surgery

67

Nicole M. Saur and Kirsten Bass Wilkins

Key Concepts

- Frailty affects a large number of our current patients and needs to be assessed.
- Prehabilitation is associated with improved outcomes.
- Enhanced recovery is useful and impactful for older patients and those with comorbidities, though all aspects of the program may not be applicable to each patient.
- Organ-specific recovery, including cognitive function, is critically important.

Introduction

Fifty-six percent of new colorectal cancer diagnoses in the United States are in patients older than 65 years of age [1]. An average 75-year-old male in good health has 18 years of life expectancy, while an 82-year-old has 10 years. However, the presence of severe comorbidities decreases life expectancy to 6 and 2 years, respectively for these patients [2]. While there still exists lack of consensus about the age cut-off to define geriatric patients (65 vs 70 vs 75 years old), there is consensus that patients should not be treated solely based on their age [3]. Despite this knowledge, as surgeons we still struggle to appropriately treat geriatric patients and especially those with cancer who have been shown to be susceptible to inappropriate care, either undertreatment based on their chronological age or overtreatment for their degree of frailty [4]. This chapter will help surgeons evaluate for and optimize frailty and focus on outcomes that matter most to patients.

Frailty Screening

Frailty is a state of reduced tolerance to surgical stress secondary to progressive and lifelong physiological decline [5]. For example, a fit and a frail patient may undergo the same surgery with similar perioperative courses, but a frail patient has a significant functional decline after surgery and requires a prolonged recovery period and has a high probability of dying in the first year. On the other hand, the fit patient recovers quickly from surgery, is discharged from the hospital, and is able to resume all of his/her functional activity as before surgery. Therefore, assessing frailty before surgery is critical for surgical decision making by surgeons, patients, their caregivers, and the multidisciplinary team.

The gold standard for assessing frailty is comprehensive geriatric assessment (CGA), a multidimensional, interdisciplinary assessment of patients, typically performed by geriatricians [6]. The main domains assessed in the CGA are functional status, comorbidities, cognition and mental health status, nutrition, social status and support, fatigue, and assessment for polypharmacy and presence of geriatric syndromes [7]. There are a wide range of tools used for geriatric assessment, but there is currently no consensus on what tools are most useful. There appears to be a rate of frailty between 25% and 46% based on the study and tool used [8]. A study showed that less than a quarter of surgeons routinely collaborate with geriatricians [9]. Moreover, the number of geriatricians is limited with only approximately 7000 practicing geriatricians in the United States [10]. As a result, it is crucial for surgeons to become familiar with components of the CGA and to screen for frailty in the surgical clinic. There are a number of tools available, which are described below and summarized in Table 67.1. The tool chosen is not as important as the universal nature of screening. All surgical patients should be screened for frailty as we have all seen frail patients with Crohn's disease at 30 years of age and fit 80-year-old patients in our practices. With universal screening of older and frail-

Table 67.1 Summary of commonly used frailty screening tests [11]

Test	Acronym	Range of possible scores	Frailty indicator threshold	Purpose
Eastern Collaborative Oncology Group Performance Status	ECOG PS	0–4	≥1	Evaluation of cancer burden on functional status
Katz Activities of Daily Living	ADL	0–6	<5	Evaluation of functional independence
Mini-Cog	Mini-Cog	0–5	≤2	Detection of cognitive impairment in older adults therefore suitable for a more thorough evaluation
Flemish version of the Triage Risk Screening Test	fTRST	0–6	≥2	Detection of hospitalized geriatric patients at risk for frailty
Timed Up and Go Test	TUG	Not applicable	≥20 s	10 feet (3 meters) walking test to determine gait speed
G8	G8	0–17	≤14	Detection of oncogeriatric patients who may benefit from comprehensive geriatric assessment
Nutritional risk screening	NRS	Normal to severely impaired nutritional status	Moderately to severely impaired	Evaluation of nutritional status taking into account BMI, weight loss, and food intake
American Society of Anesthesiologists score	ASA	1–5	Not applicable	Evaluation of preoperative general clinical condition and estimation of anesthesiologic risk
Charlson age comorbidity index	CACI	0–42	≥6	Evaluation of cumulative burden of patient's comorbidities

appearing patients, sparse resources are utilized for patients who need them most, and patients are optimized based on their individual frailty.

Domains of Geriatric Assessment (GA)

Functional Assessment

One of the most important domains of GA is functional assessment preoperatively. Assessing basic and instrumental activities of daily living [12] allow the clinician to determine the patient's ability to care for themselves. Common questions include: Are you able to prepare meal for yourself? Who does the house cleaning? and Do you take your medications on your own? These questions can easily be asked as part of the standard presurgical patient interview. Assessing gait speed and balance is an important objective assessment of patient's functional status. A simple Timed Up and Go (TUG) test [13] can be performed in the surgical clinic in less than a minute. The patient is asked to rise from their chair without using their arms, walk 10 ft (3 m), turn and walk back to the chair, and sit down. A time of greater than 20 seconds has been shown to be predictive of surgical complications. In the PREOP study, a prolonged TUG time was associated with a 50% rate of major complications compared to the rate of complications in the patients with a normal TUG of 13.6%. Furthermore, the authors compared the sensitivity of the TUG vs the American Society of Anesthesiologists (ASA) score to predict development of major complications and showed that the absolute risk for patients with prolonged TUG was 50% while the absolute risk for patients with ASA 3 or 4 was 24.8% [14].

Cognitive Function

Patients who are cognitively impaired preoperatively are at higher risk for postoperative delirium [15]. Many instruments are available to assess cognitive function of older adults. The time needed to complete these assessments range from 2 to 3 minutes for Mini-Cog [16] to more than 20 minutes for tests such as the Mini-Mental Status Exam [17]. The Mini-Cog is a simple test that includes a three-word recall and clock drawing. The patient must place the numbers correctly on the clock and set the time correctly to get full credit for the clock drawing. The test is scored out of 5 points. If the patient is able to recall all three words (3 points) and draw the clock with the appropriate time displayed (2 points), they receive a maximum score of 5.

Polypharmacy

It is imperative to review a patient's medication list. It gives you an idea on comorbid conditions that patient has, the severity (e.g., taking five different blood pressure medications versus one), and the possibility of medications interfering with anesthesia during the surgical procedure. When feasible, consult with a pharmacist for patients having excessive polypharmacy (e.g., more than ten medications).

Nutritional Assessment

With more emphasis on prehabilitation and optimization, assessing nutritional status of patients is essential. This will allow for a timely referral to dietician for improvement in nutritional status of patients while the preoperative workup and optimization are completed.

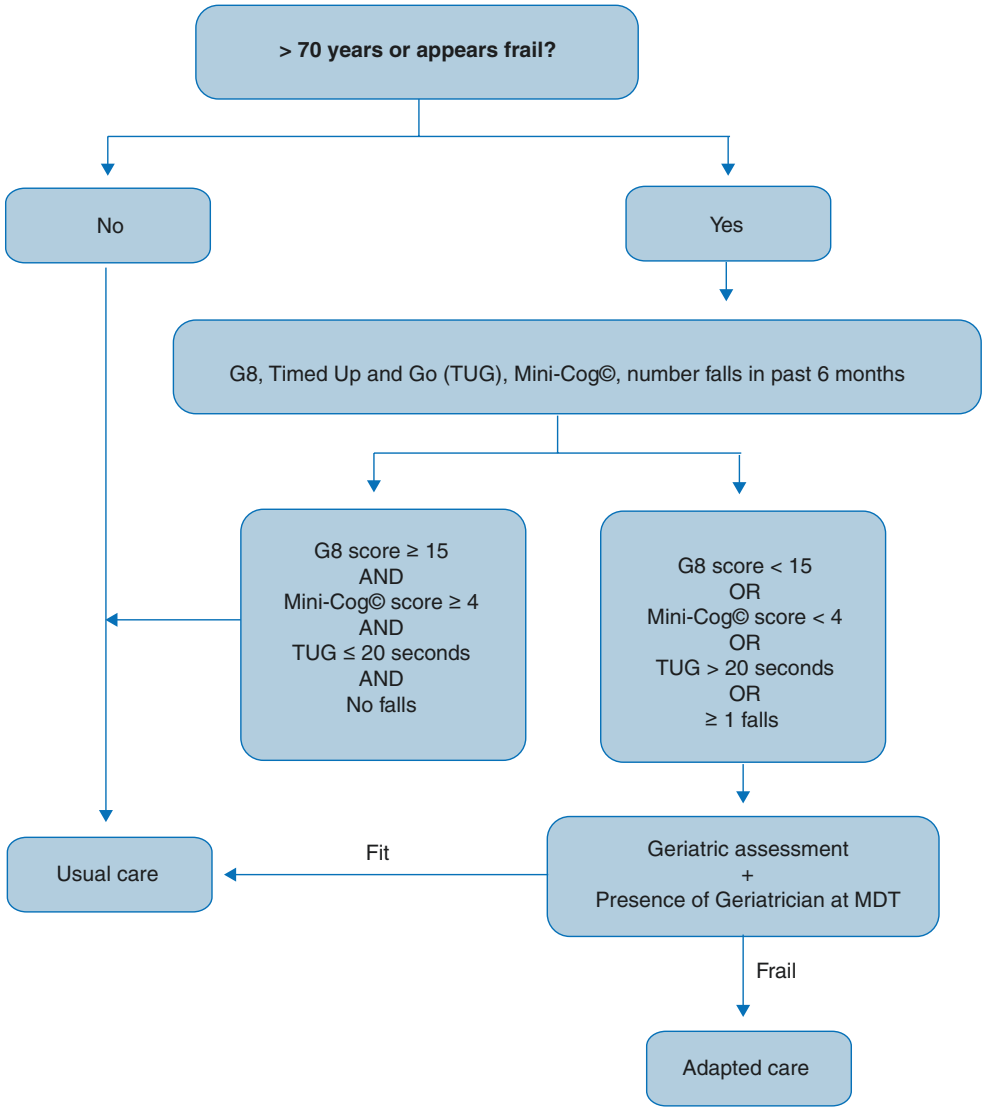

Fig. 67.1 A proposed algorithm to screen for frailty in the surgical office setting. Of note, the tools chosen are not as important as the universal nature of screening [18]

Social Support

Frail patients are more likely to have functional decline after surgery, and, as a result, they rely on their social support to provide care for them. One would assume that a patient living alone is fit. However, we know that they are vulnerable based on their lack of support if they have functional decline after surgery [11]. Assessing social support of a patient before surgery will allow preemptive involvement of the social worker and case manager during the perioperative period. Important questions to address are whether patient lives alone, if the spouse/partner/family member can take care of patient if needed during the perioperative period, how the patient came to clinic, and if they have any issues with transportation.

Patient's Wishes

Another key aspect of the frailty assessment is the discussion of the patient's goals and wishes regarding their diagnosis and their care. This should not be overlooked as it will guide their care from start to finish. If the patient has a cancer diagnosis, their wishes should be presented at the multidisciplinary care discussion [18]. In addition, it should be noted that patients may change their goals throughout treatment and the discussion should be ongoing.

Figure 67.1 presents an algorithm for simple office-based frailty evaluation to trigger additional referrals. Of note, this is an example of tests that can be combined for simple office-based frailty screening in less than 5 minutes. However, there are many frailty screening tools, and the most important recommendation is that *any* tool is utilized to screen for frailty.

Prehabilitation

Prehabilitation refers to interventions in the preoperative waiting period designed to optimize the patient's physical condition in order to reduce perioperative morbidity and pro-

mote an earlier return to preoperative functional status. Due to lack of uniformity of prehabilitation models in the literature, it is difficult to generalize the benefits of the various interventions studied. However, most meta-analyses do point toward decreased postoperative morbidity in geriatric patients who have participated in prehabilitation programs [18–24].

Prehabilitation programs should be multidimensional and include optimization of medical comorbidities, physical strength, nutritional status, and psychological well-being. There is no consensus of the appropriate duration of prehabilitation, but most models suggest that 4–6 weeks of preoperative intervention is sufficient to result in meaningful change [25, 26]. While patients may be anxious to proceed with surgery as soon as possible, it is the responsibility of the surgeon to explain the benefits of prehabilitation to the patient and family when patients have modifiable frailty factors. Furthermore, patients should be assured that cancer and overall outcome will not be compromised by this delay from the time of cancer diagnosis to operative intervention [27]. In fact, as patients become stronger, they may be more likely to be able to successfully complete definitive cancer treatment plans including surgery and adjuvant chemotherapy. Rectal cancer patients undergoing neoadjuvant chemotherapy and radiation are ideal patients to undergo prehabilitation as it may help them maintain strength during the neoadjuvant treatment period and be in a better condition to undergo radical surgery [18]. This is discussed further in section "Personalized Treatment of Rectal Cancer".

Medical prehabilitation includes the management and optimization of comorbid conditions such as diabetes, thyroid function, and cardiopulmonary status. Smoking cessation is paramount in reducing perioperative complications. Reduction of excessive alcohol intake will decrease the problems associated with alcohol withdrawal and delirium. Reduction of polypharmacy should also be a goal in coordination with a pharmacist. All of the above should be undertaken with coordinated care with a geriatrician whenever possible [28].

Preoperative cardiopulmonary fitness has been linked to postoperative outcomes in patients undergoing major abdominal surgery. One objective measure of cardiopulmonary fitness is the cardiopulmonary exercise test (CPET), which determines the ventilatory anaerobic threshold (VAT). Studies have demonstrated an association between a low VAT and postoperative morbidity in major noncardiac surgery. While CPET is considered the gold standard method of evaluation, it may not be readily available in all settings [29]. An easy alternative that can be utilized is the 6-min walk test or TUG. These screening tools require no specialized equipment or training to obtain meaningful results, which can be tracked over time [30].

Prehabilitation exercise programs are not standardized, but may include a combination of resistance and endurance training and breathing exercises at least 2–3 times a week for 30–45 minute sessions throughout the duration of the preoperative period. The exercise program may be completed under the guidance of a physiotherapist and supplemented with exercises to be completed at home. Of course, it is difficult to ensure compliance with the exercise program when it is solely completed in the home setting. Despite the heterogeneity of the prehabilitation exercise programs in the literature, they all aim to improve muscle strength and have been linked with better postoperative outcomes. In fact, Minnella et al. reported that colorectal surgery patients with poor baseline walking capacity were most likely to demonstrate meaningful improvement in physical function from prehabilitation [24]. This highlights the importance of the timely identification of patients with poor functional status so that they can benefit from prolonged physical prehabilitation.

Of note, in a follow-up study, the same group reported that almost 30% of colorectal patients do not respond to the prehabilitation [31], and another recently performed prospective, randomized study showed no benefit when they compared prehabilitation to rehabilitation [26]. Therefore, it remains necessary to identify the factors responsible for poor outcomes and determine what is best utilized to improve these factors. It is unclear if tumor stage or anabolic resistance affect the functional capacity of these patients to respond to exercise or nutritional optimization. There is a need for well-designed prospective studies to evaluate for a metabolic mechanism for failure of prehabilitation in some patients. In addition, the impact of prehabilitation on healthcare systems, timing and type of oncologic treatment, tumor progression, surgical stress response, and postoperative complications needs to be studied further [25].

Preoperative malnutrition is common in geriatric patients and has been linked to worse perioperative outcomes. Sarcopenia is also an important predictor of perioperative outcomes, and sarcopenia can occur in underweight, normal weight, and overweight patients. Thus, nutritional evaluation and supplementation are an important aspect of any prehabilitation program. Patients should be referred to a dietician early in the preoperative period and a full nutritional assessment undertaken. Patients should be given nutritional support with a targeted protein intake of 1.2–1.5 g/kg/day. Whey protein supplementation given prior to exercise may improve functional exercise capacity. Gillis et al., in a systematic review and meta-analysis, found that nutritional prehabilitation alone or combined with an exercise program decreased length of hospital stay following surgery and accelerated the return to presurgical functional capacity [21].

An additional aspect of prehabilitation addresses the psychological needs of patients facing the challenges of a possible cancer diagnosis and a major surgery and life-altering changes that may entail. Therefore, efforts should be made to address the anxiety and depression that is frequently present

in these patients. Anxiety-decreasing and relaxation strategies should be implemented by a psychologist whenever possible. It has been demonstrated that symptoms of anxiety and depression decrease when measured using the Hospital Anxiety and Depression Scale (HADS) when prehabilitation is utilized [22].

In summary, multimodal prehabilitation that focuses on medical optimization, improved functional capacity, optimal nutritional status, and decreased anxiety and depression should be the goal for geriatric patients undergoing colorectal surgery. While programs are not standardized to date, making it difficult to compare different prehabilitation studies, it is clear that prehabilitation does have a positive effect in postoperative outcomes.

Surgical Considerations

Enhanced recovery (ER) pathways have been shown to decrease perioperative complications and promote a more rapid recovery from surgery. This is a multidisciplinary approach that involves participation of the patient, patient's support system, surgeon, anesthesiologist, nurses, dieticians, and physiotherapists. The approach involves the utilization of evidence-based preoperative, intraoperative, and postoperative strategies to achieve these goals. These pathways are addressed in greater detail in this textbook, but some of the key elements are patient and family preoperative education, carbohydrate loading before surgery, early oral intake, goal-directed intravenous fluid therapy, avoidance of drains and nasogastric tubes, early ambulation, multimodal opiate-sparing pain control, and minimally invasive surgery. Studies have demonstrated that ER pathways are feasible to utilize in geriatric patients without an increase in perioperative complications and with the same benefits as those seen in younger patients [18, 23, 32–36]. Of course, care should be taken to modify certain aspects of ER pathways in older patients as in younger patients. For instance, NSAID use and extreme fluid restriction use should be avoided in patients with baseline renal insufficiency. Patients with known diabetes and gastroparesis should be monitored closely with the implementation of early feeding to reduce chances of aspiration.

Minimally invasive surgery should be offered to geriatric patients when deemed appropriate. Age alone should not be a contraindication to offering a patient laparoscopic surgery, and laparoscopic colorectal surgery is feasible in the geriatric population [18, 23, 37–40]. Consideration should be given to the hemodynamic changes secondary to the intraabdominal pressure associated with pneumoperitoneum. In that regard, laparoscopic surgery may not be appropriate for a patient with severely compromised cardiac ejection fraction or severe preexisting pulmonary compromise. However, this is not solely based on age, but on the overall preoperative risk assessment. Redo surgery and rectal cancer surgery is not a contraindication to laparoscopic surgery in geriatric patients, but as in all laparoscopic surgery, only experienced and facile laparoscopic surgeons should offer geriatric patients minimally invasive surgery so as to avoid prolonged time under general anesthesia and to prevent late conversion to open surgery.

If a geriatric patient is not considered a good candidate for minimally invasive surgery, components of the ER pathway should still be utilized as geriatric patients have been shown to benefit from such an approach even when open surgery is utilized [41].

Emergency colorectal surgery in geriatric patients has higher rates of morbidity and mortality. These outcomes are worse as frailty increases. Obviously, emergency surgery does not allow for medical optimization and the other components of prehabilitation which are useful at reducing morbidity. Emergency surgery is unavoidable in certain scenarios, and the patient and family should be informed of the increased risks and the extended time expected for a functional recovery. Zattoni et al. showed that the Flemish Triage Risk Screening Tool (fTRST) could be used in the emergency setting. The fTRST includes just five questions that can be asked of the patient or the caregiver in the emergency department: presence of cognitive decline (2 points), living alone or no help from partner/family available (1 point), reduced mobility or falls in the past 6 months (1 point), hospitalized in the past 3 months (1 point), and polypharmacy (≥ 5 different medications; 1 point). A score of 2 or greater was effective in predicting increased morbidity, mortality, and length of stay [42]. This data can be utilized to help patients and their caregivers decide on a treatment path and have an accurate prediction of their likelihood to survive surgery. As the population ages, there should be consideration for the continuation of "screening" for colorectal cancer in geriatric patients so as to avoid such emergency encounters secondary to advanced colorectal cancer [18, 43].

There are times when palliative surgery may be offered to geriatric patients with advanced disease. For instance, a patient in severe pain from an obstructing cancer with multiple liver metastases may be offered a diverting ostomy or colonic stent. However, "palliative" surgery should be avoided in geriatric patients undergoing surgery if there is a chance for cure. Surgeons should not be biased to do a lesser operation in a geriatric patient based on age alone. For instance, a patient with an obstructing sigmoid colon cancer without metastatic disease should not be simply given a diverting ostomy if the patient could tolerate resection of the primary lesion based on oncologic principles. As in younger patients, there should be the goal to achieve an R0 oncologic resection whenever possible in the medically optimized patient. Geriatric patients with node-positive disease should be considered for adjuvant chemotherapy based on

their postoperative frailty and a personal decision regarding treatment made between the patient and oncologist. While geriatric patients do have overall decreased survival from all causes, disease-specific survival is the same in geriatric colorectal cancer patients when they are offered standard-of-care cancer treatment [44]. There will obviously be situations when the risks of surgery far outweigh any perceived benefits of the procedure. In those situations, it is the role of the surgeon to educate the patient and the family about the futility of surgery and refer the patient to hospice or palliative care. This will be discussed further in section "Personalized Treatment of Rectal Cancer".

Postoperative Management

Geriatric patients, especially when frail, are at risk for postoperative complications. Even with optimal frailty screening and prehabilitation, patients have less chance to return to their preoperative functional status when they suffer complications. In the colorectal cohort of the Geriatric Oncology Surgical Assessment and Functional Recovery After Surgery (GOSAFE) study, patients who experienced one or more Clavien-Dindo complication had double the rate of functional decline when compared to the entire cohort (59 vs 31 percent) [45].

Geriatric comanagement is a system of collaboration between geriatrics and surgery teams with the goal of prevention and management of geriatric syndromes and complications [46]. The benefits of geriatric comanagement have been demonstrated in the orthopedic surgery population and include decreased length of stay, morbidity, and mortality [47–49].

Shahrokni et al. presented data on 1009 patients that were geriatric comanaged versus 846 that were managed by the surgery service alone after cancer surgery. They found that the adjusted rate of 90-day mortality was lower in geriatric-managed group versus the surgery-managed group (4.3% and 9.2%, respectively; 95% CI around difference − 7.3%, −2.5%; *p*-value <0.0001) [50].

Additional benefits of comanagement include early recognition and management of geriatric syndromes, such as delirium and falls. Patients who have experienced a prior delirium, who are dependent on caregivers, or who have cognitive impairment have an increased risk of delirium in the perioperative period. This increased risk should be identified preoperatively and communicated to the patient and caregiver in order to reduce the stress that comes with the development of delirium and to improve communication of early symptoms. When increased risk is present, delirium prevention measures should be taken, including improving orientation and safety, mobilization, and maintaining the day-night rhythm. A recent systematic review and meta-analysis demonstrated that these multifactorial interventions can reduce the risk of delirium, with an odds ratio of 0.47 (95% CI 0.38–0.58) [51].

If needed, rehabilitation can be utilized in older patients to maintain baseline function and slow the functional decline due to surgery. This process should start at admission as part of a multimodality program and continue beyond discharge. In order to maintain functional status, the focus of rehabilitation should be to restore daily living skills and mobility. Bedrest should be avoided at all costs because even a limited time can lead to a rapid loss of muscle mass, which is difficult to reverse [52].

Functional Recovery and Patient-Reported Outcomes

Functional recovery is as important as achieving low morbidity and mortality and good oncologic outcomes in geriatric patients undergoing colorectal surgery. Functional recovery includes distinct aspects including return to preoperative independence as well as organ-specific recovery. These functional aspects are perhaps even more important to geriatric patients than 5-year disease-free and overall survival since the expected life expectancy is already decreased in the very old patients. Thus, patients and families must be adequately informed of the possible functional consequences of surgery in order to make decisions which will lead to good functional recovery and increased health-related quality of life [11, 18].

Regaining functional independence requires the return to preoperative cognitive status and achieving adequate nutritional status, the ability to perform activities of daily living, and the ability to ambulate proficiently. As discussed above, one of the purposes of aggressive prehabilitation is to assure expedited functional recovery. Early hospital discharge and appropriate use of rehabilitation also contributes to the achievement of these goals [18].

Organ-specific functional recovery includes return of bowel, bladder, and sexual function. Bowel functional recovery is multifactorial and should include not only restoration of intestinal continuity but also assessment of function in patients who have achieved that continuity. Of particular concern are problems with fecal incontinence and bowel dysfunction associated with low anterior resection syndrome (LARS). These outcomes should be objectively measured using validated instruments such as the Cleveland Clinic Fecal Incontinence Score and the LARS score. Fecal incontinence in geriatric patients is a frequent reason for nursing home placement [18].

Therefore, a thoughtful discussion should be undertaken prior to surgery in geriatric patients when restoration of intestinal continuity is likely to result in fecal incontinence. For instance, an older woman with poor sphincter tone

would be expected to have better functional outcome with a permanent colostomy as opposed to a coloanal anastomosis following surgery for a distal rectal cancer. There is also evidence that diverting loop ileostomy reversal occurs less frequently in geriatric patients. Readmission to the hospital from ileostomy complications such as dehydration and acute renal insufficiency is not uncommon and potentially less tolerated in the geriatric population. This is not to say that diverting ileostomy should be avoided in geriatric patients, but careful patient selection is required to achieve acceptable outcomes in this population. When it is unlikely that a patient will undergo ileostomy reversal, it is probably better to offer the patient a permanent colostomy. This alleviates the potential complications from the ileostomy itself, but also potential complications from a second surgery to reverse the ileostomy. There is evidence to suggest that geriatric patients are able to tolerate a permanent colostomy as well as a restorative procedure and that geriatric patients with a stoma have the same health-related quality of life (HRQL) as geriatric patients without a stoma [53]. In addition, geriatric patients undergoing treatment for rectal cancer also need to be informed regarding the increased chances of bladder and sexual function that occur not only following pelvic surgery but also from neoadjuvant treatment from chemotherapy and radiation [54].

The prospective, international Geriatric Oncology Surgical Assessment and Functional Recovery After Surgery (GOSAFE) study recently finished enrollment of over 1000 geriatric patients undergoing curative cancer surgery [11]. Early results suggest that complete functional recovery (ADL score > 4, Mini-Cog >2, TUG <20) occurred in 26% of patients. On the other hand, decreased functional capacity was seen in 31% of patients alive at 90 days. In the same cohort, quality of life improved 90 days after surgery (mean EQ-5D index from 0.76 to 0.80) with the main drivers being improvement in pain and anxiety/depression [45]. Final results are forthcoming with the hope of giving patients a real-world prediction of their likelihood of functional recovery and their quality of life after surgery.

In evaluating quality of life, goals, and patient-reported outcomes, the International Consortium for Health Outcomes Measurement (ICHOM) has done considerable work. They aptly point out in Fig. 67.2 that outcomes that matter to patients related to cancer and related to being older often overlap. These overlapping points such as pain, function, and mobility likely have considerable improvement when successful surgery is undertaken [55].

Personalized Treatment of Rectal Cancer

Rectal cancer management is complex, and geriatric patients are complex. In an attempt to mitigate the complexity and offer rectal cancer patients personalized treat-

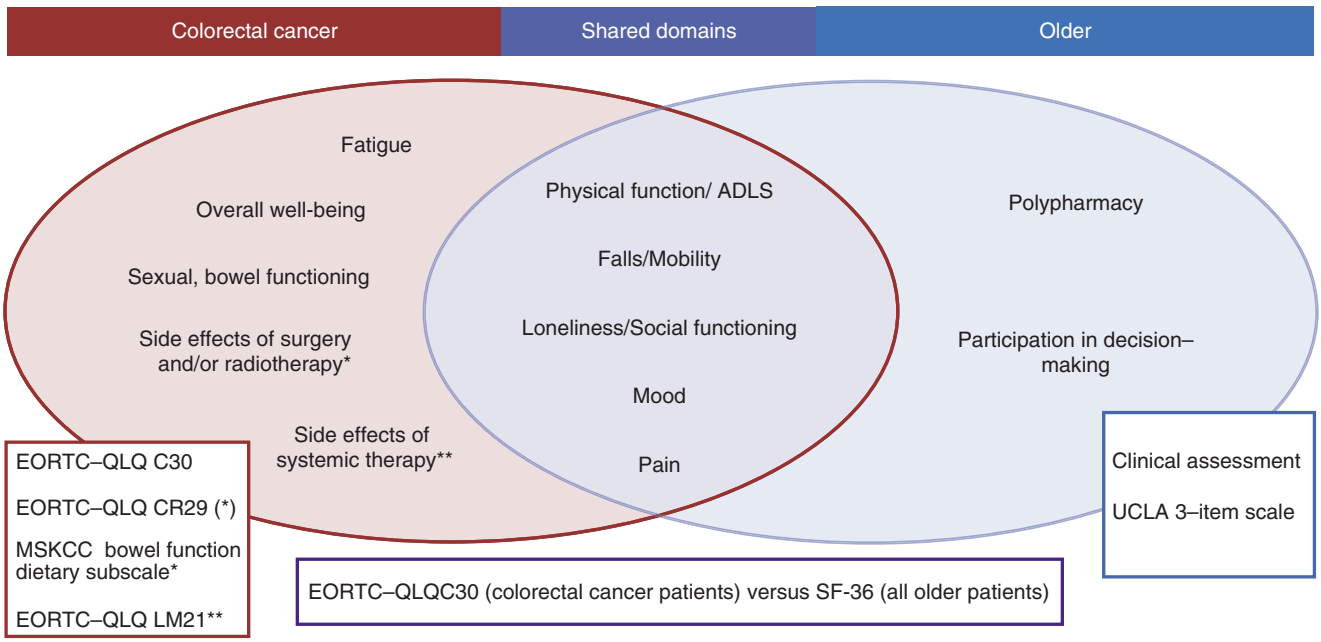

Fig. 67.2 Domains of the International Consortium for Health Outcomes Measurement (ICHOM) patient-reported outcome measures (PROMs) for patients with colorectal cancer and older persons. Several domains are assessed by both outcome measure sets, suggesting the outcome measures for colorectal cancer patients can be adapted to older patients, and with the addition of clinical assessment for polypharmacy and UCLA three-item scale for participation in decision-making, a comprehensive set for older colorectal cancer patients would be achieved. ment of their rectal cancer, an interdisciplinary task force was created. The task force was comprised of 29 members representing the following organizations: the European Society of Surgical Oncology (ESSO), European Society of Coloproctology (ESCP), International Society of Geriatric Oncology (SIOG), and American College of Surgeons Commission on Cancer (ACS CoC) [18]. The recommendations of the group are summarized in Table 67.2, and a treatment algorithm is presented in Fig. 67.3.

Table 67.2 Summary of expert recommendations for the management of geriatric patients with rectal cancer [18]

General recommendations	All management decisions for an elderly patient with rectal cancer should consider: Physiological age Life expectancy Risks versus benefits of treatment vs nontreatment Treatment tolerance Patient goals/wishes Possible treatment barriers
Multidisciplinary team	Frailty and not chronological age should be used in risk stratification Mandatory frailty screening: ex; G8, Mini-Cog, Timed Up and Go, history of falls If frail, geriatrician should be routinely involved in multidisciplinary team If patient is fit, should treat with algorithms developed for younger patients
Patient optimization	Multidimensional prehabilitation should be utilized pretreatment and especially considered in the window for neoadjuvant chemoradiation (nCRT) Required elements include exercise, nutrition, treatment of anxiety/depression
Surgical treatment	Rectal resection with total mesorectal excision (TME): Open/laparoscopic/robotic/transanal TME (taTME) techniques for TME surgery are not contraindicated based on chronological age alone and should be considered in elderly patients Laparoscopy: Laparoscopy is safe and effective in the elderly population and should be utilized as the preferred option by experienced surgeons Robotic approaches can be considered based on surgeon preference, but have not been shown to be superior to laparoscopy and are associated with higher costs taTME: taTME is advised when utilized by expert surgeons as it has shown to be associated with decreased conversion rates. It should be noted that long-term data are lacking Local excision (LE): Clinicians should balance oncologic outcomes with goals of care/frailty LE is not recommended after radiation therapy secondary to increased morbidity Surgical emergencies: Efforts should be made to preempt surgical emergencies (bleeding, obstruction, perforation) and treat them early when they occur
Treatment of locally advanced disease	Neoadjuvant chemoradiotherapy: Can be considered to increase local control but should be noted that increased toxicity can prevent potentially curative surgery Capecitabine is contraindicated in renal failure Contact X-ray brachytherapy can be used as an adjunct for small residual tumors (<3 cm) following external beam radiation therapy (EBRT) or as monotherapy for early rectal cancer (cT1) less than 3 cm, in order to increase rate of complete clinical response, but is only available at selected centers EBRT +/− contact radiation can be considered for patients not suitable for surgery in order to improve local control Watch and wait: Should be considered in elderly patients with complete clinical response, but need experienced MD expertise by surgeons/radiologist/medical oncologist and radiation oncologist to be performed safely No single reliable predictive factor of complete response is available, but can evaluate size and rate of tumor shrinkage as useful prognosticators Required to take into account patient's goals/wishes Adjuvant chemotherapy: Adjuvant chemotherapy after nCRT and surgery is not advised in geriatric patients

Table 67.2 (continued)

Treatment of synchronous liver metastases	Liver metastasis: Liver surgery should only be performed with curative intent Neoadjuvant chemotherapy and radiation therapy (if indicated) is suggested, if primary asymptomatic Synchronous resections should be avoided
Outcomes	Enhanced recovery pathways: Should be applied to elderly patients based on reduced length of stay and overall complications Most important elements to include are early discontinuation of intravenous fluids, early oral intake, timely removal of the urinary catheter (when possible given pelvic dissection), early mobilization, very limited administration of opioids, and adoption of minimally invasive surgery Involvement of both patients and caregivers is crucial to increase compliance Functional recovery: Should be recorded as pivotal posttreatment endpoint, especially in the elderly Consideration should be given to the morbidity of "permanent" diverting loop ileostomy and prediction used to preferentially perform colostomies in patients who are not likely to undergo reversal Patient-reported outcome measures (PROMs): PROMs should no longer be considered secondary outcomes and instead be recorded by the clinical team posttreatment Prospective observational studies are needed to define outcomes Healthcare cost: Recommend shift toward value-based care as target for finance allocation Focus should be on early diagnosis and frailty assessment as tools to help contain costs

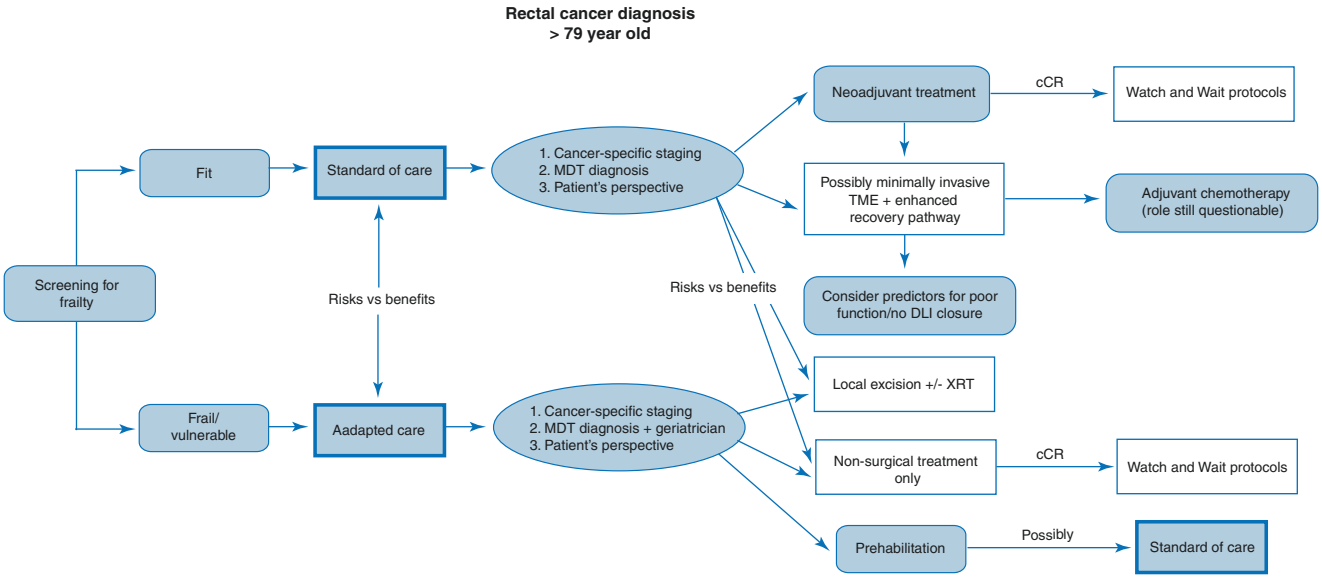

Fig. 67.3 Proposed treatment pathway for geriatric patients with rectal cancer. The treatment pathway is proposed for elderly patients with rectal cancer to guide treatment. It should be noted that treatment should be personalized for the individual patient with input from the patient and the treating multidisciplinary team [18]

One of the key findings stressed by the task force is presented in Fig. 67.4. The long-held historic belief was that older patients could not handle the surgical stress of rectal cancer surgery. However, with a better understanding of frailty and measures to improve fitness, improvement in both open and minimally invasive total mesorectal excision (TME) techniques leading to fewer complications and more efficient recovery, and improved perioperative care, TME surgery has become feasible in well-selected older adults. Therefore, since frailty rather than age has been established as the primary surgical risk factor, TME surgery is currently advised for all rectal patients who can undergo the extensive procedure, independent of their chronological age [18].

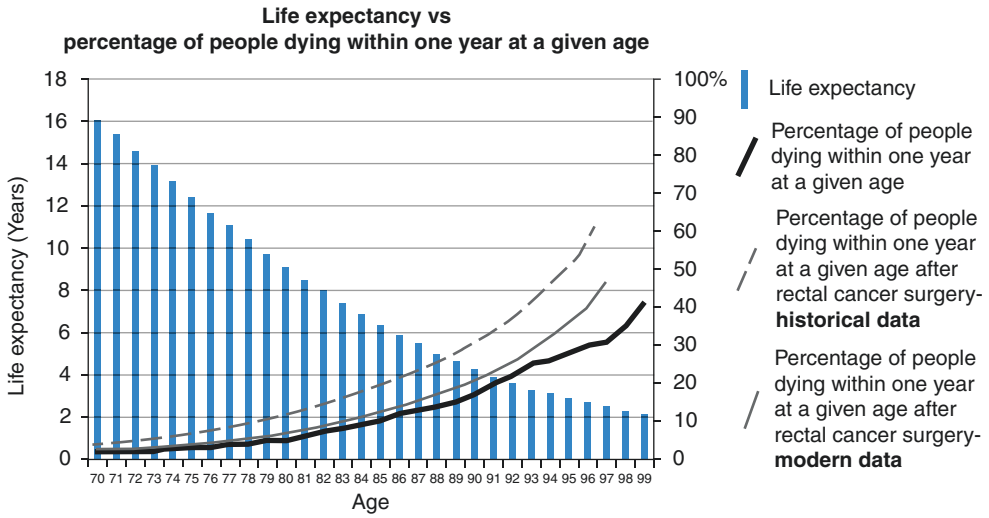

Fig. 67.4 The impact of rectal cancer surgery on life expectancy in geriatric patients. The graph demonstrates life expectancy in the elderly, which is generally higher, at a given age, than previously believed. Using historical data, total mesorectal excision was associated with an increased mortality and was, therefore, not advised. Modern surgical data suggest that elderly patients undergoing surgery today have a similar life expectancy to their peers without rectal cancer. Therefore, in properly selected patients, rectal cancer surgery is advised. (Original Data obtained from: 1. http://opendata.cbs.nl/statline/#/CBS/en/. Central Bureau of Statistics, Dutch life expectancy per year and change of dying within 1 year in the Dutch population 2015. 2. Rutten et al. [56] Reproduced with Permission (ref 18).)

Conclusions

Geriatric patients require multimodality, multispecialty intervention to improve their care. Patient goals and wishes should be identified and addressed early in the course of care. All patients should undergo office-based frailty screening with referral to a geriatric specialist if they are deemed to be frail. Frailty should be optimized with multimodality prehabilitation, and we expect prehabilitation programs to continue to evolve with changing evidence. Perioperative principles applied to all patients should be utilized in geriatric patients as well, including minimally invasive surgery and enhanced recovery programs. Geriatric comanagement has been shown to improve postoperative outcomes and identify and treat geriatric syndromes, such as delirium, early. Functional recovery and patient-reported outcomes are as important as cancer-related outcomes, especially in geriatric patients. These outcomes should be measured and the expected outcomes discussed with patients preoperatively.

Geriatric surgical patients are complex, especially those with rectal cancer. The treatment strategies and algorithms presented here can guide surgeons to provide personalized care and avoid undertreatment of patients based on their age and overtreatment of patients based on their frailty. This is an exciting time in treating geriatric colorectal patients as there has never been more interest in or study of the topic. As the continuing study results continue to be presented, we expect care of older patients will continue to improve and their care will continue to be challenging and rewarding for surgeons.

Healthcare Economics

68

Walter R. Peters and Teresa deBeche-Adams

Key Concepts

- This textbook is dedicated to improving the quality of care provided to individual patients suffering from diseases of the small intestine, colon, rectum, and anus. That care does not occur in a vacuum, but within an incredibly complex healthcare economic environment.
- Decisions made by healthcare systems, insurers, employers, government agencies, pharmaceutical companies, medical device manufacturers, professional societies, and individual providers can often be understood only when viewed in the context of the entire system.
- Our patients make healthcare decisions, including whether, when, and where to seek care, from the perspective of their individual healthcare economic realities.
- This chapter will provide an overview of the complex healthcare environment in which we work, the issues that fuel the healthcare reform discussion, and the current payment system under which US surgeons are compensated.

Healthcare Economics: A Global Perspective

> The U.S. healthcare system is on a dangerous path, with a toxic combination of high costs, uneven quality, frequent errors, and limited access to care. Michael E. Porter, *Redefining Health Care: Creating Value-Based Competition on Results* [1].

Healthcare spending represents a large portion of the gross domestic product (GDP) of the economy in every developed country, but no country spends more on healthcare than the United States. This has not always been the case, but since the 1980s, the growth in US spending on healthcare has steadily outpaced that of all other major economies [2]. US healthcare expenditures in 2018 were $3.6 trillion, which was estimated to represent 16.9–17.7% of GDP, or $11,172 per person [3, 4]. By comparison, Switzerland had the second-highest expenditures at 12.2% of GDP, or $7317 per person. All other major industrialized nations spent a smaller portion of their GDP on healthcare, including Germany (11.2%), Japan (10.9%), and the United Kingdom (9.8%) [5]. While spending less on healthcare, many members of the Organisation for Economic Co-operation and Development (OECD) have achieved universal or near-universal access to core healthcare services. In 2018, only 90.8% of the US population had health insurance coverage, ranking the United States 35th out of 36 OECD countries [5].

Despite massive spending on healthcare, common outcome metrics for the United States are not exceptional. The US life expectancy at birth (78.6 years in 2018) is the lowest of the G7 economies, trailing Japan (84.2 years), Italy (83 years), France (82.6 years), Canada (82 years), the United Kingdom (81.3 years), and Germany (81.1 years). US life expectancy at birth ranks 28th out of 36 member countries of the OECD. Cancer outcomes in the United States are consistently better than the average of the OECD countries, including 5-year survival for colon cancer and rectal cancer, but avoidable mortality rates are higher than average [5].

Why does the United States spend so much more on healthcare than other advanced nations? The two primary determinants of total healthcare spending are the quantity of resources utilized and the prices paid for those resources. It might be anticipated that differences in healthcare delivery systems and the social determinants of disease, such as smoking, obesity, education, nutritional support, and opioid addiction, might result in differences in utilization of resources between the world's developed countries. Numerous reviews of OECD and other data sets have found that utilization of resources in the United States is similar to that of other countries. The United States has similar numbers of hospital beds,

physicians, and nurses as other countries, although there is higher utilization of advanced imaging and some common surgical procedures than the OECD average [6–8].

Prices for healthcare resources, however, are substantially higher in the United States than in other countries. Healthcare is labor-intensive, and wealthy countries, like the United States, generally have higher wages than less affluent countries. Remuneration for generalist physicians, specialist physicians, and nurses in the United States were highest in a comparison of 11 high-income countries, both in absolute terms and relative to the average non-healthcare worker [7]. Pharmaceutical prices are also far higher in the United States than in other countries. The same comparison of 11 high-income countries found that a sample of commonly prescribed drugs cost nearly twice as much in the United States as the average price across all 11 countries [7]. Pharmaceutical expenditures per capita in the United States are more than double the OECD average [5]. The United States also spends more on administrative costs than other countries, due to the fragmented and complex system of healthcare financing. Administrative costs represent 8% of the total healthcare expenditure in the United States, more than double the costs in other high-income countries. In 2015, US administrative costs, $787 per capita, were almost nine times higher than the OECD average of $90 [6, 7, 9].

There are a variety of healthcare delivery models currently in use around the world. The United Kingdom, for example, provides universal care through the National Health Service, which is funded largely through general tax revenues. Canada relies on provinces and territories to plan and co-fund a universal public insurance program. Switzerland utilizes federally mandated health insurance to fund healthcare delivery, but much of the regulation of the system is delegated to cantons and municipalities [10–12]. Financing of the US healthcare system is more complex, with a mixture of payers for specific populations.

US Healthcare Finance

The federal government is the largest single purchaser of healthcare services in the United States. While employer-sponsored health plans provide benefits for 49% of Americans, this coverage is administered through a mixture of private insurance companies and self-funded plans. Medicaid (20%), Medicare (14%), and military programs (1%) provide insurance coverage for 35% of the US population [13]. Total Federal spending on healthcare programs totaled over $1 trillion in 2018, representing approximately 25% of the Federal budget [4, 14].

Medicare

Medicare was one of the signature achievements of President Lyndon Johnson's Great Society legislative agenda in 1965. Passed over the long-standing objection of the AMA, Medicare was created to compliment Social Security in providing a safety net for retired Americans [15]. It is entirely funded by the federal government and provides a broad array of healthcare services for retired individuals over age 65 and patients with end-stage renal disease, amyotrophic lateral sclerosis, and permanent disability. Medicare initially consisted of two complimentary plans, one for hospital care and the other for physician services, but has expanded its offerings over the past five decades. Part A, also known as the Hospital Insurance program, provides coverage to all eligible Americans for inpatient hospital, skilled nursing facility, some home health visits, and hospice care. It is primarily funded through the collection of payroll taxes from both employers and employees. Part B requires voluntary enrollment and offers coverage for medically necessary or preventive services by qualified providers. It is funded through general tax revenues and participant premiums [16, 17]. Medicare Part C, now called Medicare Advantage (MA), was authorized in 1982 to provide Medicare recipients an alternative to traditional fee-for-service Medicare Part B. MA plans are administered by private insurers who receive capitated payments from Medicare to cover all Part A and Part B services. Enrollees in Medicare Advantage continue to pay the premium for Part B and may be required to pay a supplemental premium. These plans typically offer extended coverage for services not covered by Medicare Part B, including dental, vision, and fitness services. MA plans have grown in popularity over the past decade; in 2019, 34% of Medicare recipients were enrolled in MA plans [17, 18]. The Medicare Modernization Act of 2003 (MMA) authorized Medicare Part D, a voluntary program to provide prescription drug coverage. These benefits are administered by private insurers as either stand-alone prescription drug plans (PDPs) or as part of a Medicare Advantage plan. These plans have become very popular, and by 2019, 70% of Medicare beneficiaries had Part D benefits [17, 19].

Medicaid

Medicaid was also established in 1965, as a companion to Medicare, with the goal of providing healthcare insurance for the poor. Unlike Medicare, the Medicaid program is a partnership between the states and the federal government. The federal government sets core eligibility and benefit requirements, while the individual states administer the pro-

gram and have flexibility to expand eligibility, define covered services, and choose the healthcare delivery model. Funding is provided jointly by the federal government and the states with the federal contribution ranging from 50% to 78%, depending on the state's per capita income. Federal matching funds are provided for low-income children and their parents, pregnant women, the elderly, and those with disabilities. In addition, the Affordable Care Act requires the federal government to provide 90% of the funding for newly eligible adults under age 65 with incomes at or below 138 percent of the Federal Poverty Level (FPL) in states that elect to expand Medicaid coverage. The Children's Health Insurance Program (CHIP) is a supplemental program that was authorized in 1997 and provides additional federal funds to allow states to extend insurance coverage to uninsured children whose families have incomes above the Medicaid threshold. Medicaid has become an integral part of the US healthcare system, providing coverage for 20% of the population, and is especially important for certain at-risk populations. In most states, approximately half of all deliveries and over 60% of nursing home residents are covered by Medicaid. Children represent 43% of Medicaid enrollees nationwide [20–22].

Employer-Sponsored Insurance

Many employers sponsor insurance coverage for their workers and dependents, which now covers almost half of all Americans. The practice began during World War II when wage and price controls prevented employers from raising wages, but insurance coverage could be offered as a benefit to attract or retain workers. Because health insurance was very inexpensive at the time, and because the cost was considered a pre-tax business expense, not taxable for the worker, the practice continued after the war. Since 2014, the Patient Protections and Affordable Care Act of 2010 (ACA) mandates that employers with more than 50 employees offer affordable health insurance to their employees or pay a penalty. A recent survey found that 56% of small businesses (<200 employees) and 99% of large businesses (≥200 employees) offered health insurance benefits to at least some groups of employees in 2019. However, only 61% of workers at companies offering insurance benefits were enrolled in a plan offered by the company. As the cost of health insurance has increased over the past decades, employers have begun shifting more of the cost to their employees in the form of higher deductibles and greater cost sharing. The average cost for family coverage through an employer-sponsored plan in 2019 was $20,576 with the employee responsible for 30% of the premium, on average. The portion of the premium paid by the employee has increased more rapidly over the past 5 years (22%) than wages (14%) or inflation (8%) [23].

Individual (Non-group) Insurance

While a robust market has existed for the sale and purchase of large-group health insurance policies, the same was not always true for policies sold to individuals not covered by an employer-sponsored plan. Title I of the ACA established insurance exchanges, or markets, in each state to allow individuals and small businesses a greater opportunity to purchase coverage for themselves or their employees at competitive prices [24]. These individual policies now provide coverage for approximately 6% of Americans.

Healthcare and Politics

The role of government in healthcare finance has been a topic of vigorous political debate for at least the last 75 years. President Truman first advocated for national health insurance in 1945 and 1949. He was met with overwhelming opposition from the Republican-controlled Congress and the American Medical Association. Medicare and Medicaid were hotly debated in 1965 and were enacted only after President Johnson brokered numerous compromises to achieve passage [15]. Healthcare reform efforts by President Clinton in 1993–1994 failed to garner bipartisan support and ended with the loss of the Democratic majority in Congress [25]. The Affordable Care Act was passed on a strictly party-line vote and has continued to engender strong opposition from those who opposed its passage [26]. As our political landscape has become increasingly polarized, several healthcare policy topics will remain in the public discussion for the foreseeable future. These topics are relevant to surgeons because they impact our patient's ability and willingness to seek medical care and they influence a wide range of financial decisions made by healthcare providers.

The Future of the ACA

The Affordable Care Act was designed to increase the number of Americans with insurance coverage by several mechanisms. Employers with more than 50 employees were required to provide health insurance or pay a penalty, the "Employer Mandate." Individuals were required to show proof of insurance or pay a penalty, a requirement known as the "Individual Mandate." Healthcare insurance exchanges

were established in every state to give individuals a market in which to purchase insurance coverage. Finally, states were required to expand Medicaid eligibility to include those earning up to 138% of the FPL in order to continue receiving the federal contribution for Medicaid coverage. The federal government was to cover the entire increased cost of expanding Medicaid coverage for 5 years and at least 90% of the cost thereafter.

The constitutionality of the ACA was immediately challenged, and in 2012 the Supreme Court ruled in *National Federation of Independent Business v. Sebelius* that the Individual Mandate was valid under Congress' taxing authority but that states could not be required to expand Medicaid eligibility, substantially undermining one of the key tactics to expand insurance coverage. Despite this, 36 states and the District of Columbia have expanded Medicaid eligibility, resulting in greater variation between states in Medicaid eligibility and coverage. Medicaid enrollment increased 34% from 2013 to 2019 in states that expanded Medicaid, while non-expansion states saw an increase of only 9.1% [27].

Efforts to weaken or repeal the ACA have increased since the election of 2016. An attempt to repeal the ACA failed by one vote in the US Senate in 2017. Later that year, Congress reduced the penalty, or tax, for failing to purchase insurance as required by the Individual Mandate to $0. This has resulted in renewed legal challenges to the constitutionality of the ACA, arguing that without such a penalty, Congress has no right to mandate an individual obtain coverage. This litigation has pitted states against one another and will ultimately be decided by the Supreme Court [28]. Other efforts to weaken the ACA have included state-imposed work requirements on Medicaid recipients, refusal of 14 states to expand Medicaid, efforts to reduce enrollment through the exchanges, and policy changes intended to destabilize the exchange markets [26]. The debate about the future of the ACA, whether to repeal or strengthen it, will continue following the elections of 2020.

Underinsurance

Even with healthcare insurance coverage, some individuals cannot afford or gain access to healthcare. The National Health Interview Survey found that enrollment in high deductible health plans, defined as those with >$1300 deductible for individuals and >$2600 for families, has increased from 14.8% of employer-based coverage in 2007 to 43.4% in 2017 [29]. Average deductibles for employer-based coverage have increased by 162% from 2009 to 2019. A survey of individuals with employer-based coverage found that 40% reported that they have problems affording healthcare insurance or medical bills. Approximately half said that they, or a family member, had postponed healthcare or prescriptions due to cost within the past 12 months [23].

The ACA relied upon the expansion of Medicaid eligibility to extend coverage to millions of Americans. However, traditionally low fee schedules have resulted in many physicians limiting the number of Medicaid patients they will see. A 2015 survey of primary care physicians found that only 71.6% were accepting new Medicaid patients, compared to 77.4% for new Medicare patients and 92.4% for new private insurance patients [30]. The provision of health insurance, whether through Medicaid or employer-based plans, does not guarantee access to healthcare services if patients cannot afford their deductible or find a provider willing to accept their form of insurance.

Surprise Medical Billing

Surprise medical billing refers to unexpected charges incurred by an insured patient for healthcare services provided by an out-of-network physician or facility. This may occur in the case of a medical emergency but also may occur when patients undergo elective surgery at in-network facilities by in-network surgeons. Other physicians that are not chosen by the patient, such as an anesthesiologist, pathologist, or radiologist, may not be in the patient's network and can bill the patient directly for whatever fee they believe is appropriate. These "surprise bills" may be paid fully, partially, or not at all by the patient's insurance carrier. The provider may then "balance bill" the patient for any amount not paid by the insurance company.

A recent study of 347,000 patients who underwent elective surgical procedures performed by in-network surgeons at in-network facilities over a 5-year period found out-of-network bills associated with 20.5% of cases. The mean potential "balance bill" was $2011. More complex procedures and cases with complications were more likely to result in an out-of-network bill. Anesthesiologists and surgical assistants were the most likely providers to submit an out-of-network charge [31].

Surprise medical bills are a symptom of the fragmented nature of healthcare delivery. They are a source of frustration to patients and can result in significant financial hardship. This issue has attracted bipartisan attention in Congress, and many legislative solutions have been proposed. The debate is likely to continue after the 2020 elections..

Rural Hospital Closures

Since 2005, 170 hospitals in rural counties have closed, including 19 in 2019. A 2020 study found that 354 rural hos-

pitals in 40 states, 25% of the nation's rural hospitals, were financially stressed and at risk of closing unless their financial situations improved [32]. Rural hospitals struggle to survive in today's healthcare economic environment for several reasons. Population declines and a shift to outpatient services have left many hospitals with too many inpatient beds. It is more costly to provide technologically advanced care for a smaller patient base. Patients with the means to do so are often willing to travel to larger facilities for elective care. Rural hospitals are often left with a payer mix including increased shares of Medicare, Medicaid, and unfunded patients. This problem has been exacerbated in states that have not expanded Medicaid eligibility; between 2010 and 2018, approximately two-thirds of rural hospital closures occurred in non-expansion states [33]. Medicaid expansion has been associated with improved financial performance and lessened risk of closure, especially for rural hospitals [34]. The threatened loss of rural hospitals has been the subject of Congressional proposals, but a solution has not yet been found. Possible policy solutions include payment reforms to support rural hospitals, Medicaid expansion, or changes in healthcare delivery models, such as telehealth, to enable delivery of care in rural areas.

Physician Reimbursement: The Quality Payment Program

The processes by which a surgeon's care is described and compensated makes up another complex part of the healthcare economic environment. Because of the federal government's role as the largest single payer for healthcare services, the Centers for Medicare and Medicaid Services (CMS) payment programs are extremely important for surgeons to understand.

Medicare Access and Children's Health Insurance Program Reauthorization Act of 2015 (MACRA)

MACRA was passed with bipartisan support and signed into law on April 16, 2015. It repealed the sustainable growth rate (SGR) approach to Medicare fee schedule adjustments and prepared the way for Medicare to reward clinicians for value rather than volume. Under the SGR approach, an annual physician fee schedule update would be released which carried the threat of a negative adjustment in payments to physicians. Designed as a method to ensure that the yearly increase in the expense per Medicare beneficiary did not exceed the growth in GDP, the fee schedule could be suspended or adjusted by Congress. This temporary "doc fix" only served to defer a permanent solution to the flawed payment system [35].

MACRA created a new payment system, the Quality Payment Program (QPP). It streamlined multiple quality programs under the new Merit-Based Incentive Payments System (MIPS) and provided bonus payments for participation in eligible alternative payment models (APMs). CMS released the final rule governing the QPP in October of 2016 declaring that provider performance during calendar year (CY) 2017 would determine reimbursement for CY 2019. This left little time for physicians to understand the QPP before its implementation and resulted in significant implications for practices that caused concern on the part of many surgeons. Not all physicians are required to participate in QPP; CMS estimated that a low-volume threshold would exempt one-third of Medicare physicians. Physicians seeing fewer than 100 Medicare patients annually or submitting less than $30,000 in Medicare Part B allowable charges were exempt from reporting requirements in 2017; therefore, their Medicare fee schedule remained flat in CY 2019. While an exemption from the QPPs new requirements might have seemed beneficial to providers, in a world where practice expenses and cost of living increase every year, a flat fee schedule is an impractical long-term strategy for success [35].

In September 2018, a new funding opportunity was announced by CMS through the "Medicare Access and CHIP Reauthorization Act of 2015 (MACRA) Funding Opportunity: Measure Development for the Quality Payment Program." Cooperative agreements provided a unique opportunity to partner with clinicians, patients, and other stakeholders to give financial (up to $30 million) and limited technical support to develop, improve, update, or expand measures to use in the QPP. The CMS Quality Measure Development Plan set up initial priority areas to include outcome measures (e.g., patient-reported outcome and functional status measures), patient experience measures, care coordination measures, and measures of appropriate use of services. The goal of these measures is to minimize administrative burden on clinicians, improve outcomes for patients, and drive increased value in care. It is critical that the expertise and insight of those on the front lines be leveraged to develop measures that are relevant and contribute to building a truly value-based healthcare system [35].

To better understand the two value-based payment model pathways developed for the QPP, the Merit-Based Incentive Payment System (MIPS) and the alternative payment model (APS), we will discuss each in further detail.

Merit-Based Incentive Payment System (MIPS)

The Merit-Based Incentive Payment System (MIPS) was designed to connect payments to quality and cost-efficient care, motivate improvement in care processes and health outcomes, increase the use of healthcare information, and reduce the cost of care. This track includes three renamed quality programs (quality, cost, and promoting interoperability) and added a new performance category (improvement activities). The quality element of the score replaced the Physician Quality Reporting System (PQRS). Cost is predicated on the Value-Based Payment Modifier (VBPM), and PI replaced meaningful use. An MIPS score is assigned to each participating provider based on these components. Performance in each category is weighted and used to calculate a final score (0–100). As a reference point, the threshold for the 2019 performance period was 30 points. Payment adjustments are based on performance from 2 years prior (e.g., the MIPS score based on 2017 data was used to adjust the Medicare fee schedule beginning in CY 2019). Initial adjustments ranged from −4% to +4% but will gradually increase to ±9% by 2022 [36].

MIPS is designed to be budget neutral, meaning that the money withheld in penalties will be used to offset positive adjustments to the fee schedule. Whereby CMS made it relatively easy for a provider to evade penalty in 2019, it is unlikely that there will be large sums available in the future to pay incentives. MACRA did set aside an additional $500 million to reward "exceptional" providers based on quality metrics. Exceptional performers that meet the additional performance threshold could receive a further sliding scale positive payment adjustment of up to 10%. The exceptional performance threshold for the 2019 period was set at 75 points. Exceptional performance adjustments occur outside of budget neutrality [35].

Providers can report MIPS data as individuals, as a group, or as both an individual and a group. A group is classified as two or more providers under the same taxpayer identification number (TIN). Reporting as a group may be easier, especially for physicians employed in a large group practice. It is important to note, however, that all providers within the group will receive the same MIPS score and that score may be based on quality metrics that have nothing to do with an individual provider's practice. For instance, a colorectal surgeon employed in a large multi-specialty group practice may have a quality score determined by primary care metrics (e.g., smoking cessation, diabetic retinal eye exam, breast cancer and colorectal cancer screening, etc.) due to the ease in capturing and reporting of this data. Certain eligible providers can report data as an individual and as part of a group holding the same TIN. Under this reporting, the clinician is evaluated across all four MIPS categories on their individual performance and on the group's performance. The final score is calculated for each evaluation as an individual and under the group's TIN. The clinician will receive a payment adjustment based on the higher of the two scores [36].

Advanced Alternative Payment Model (A-APM)

A much smaller percentage of physicians participate in the QPP through an Advanced APM (A-APM). This track offers a 5% incentive for achieving threshold levels of payments or patients through advanced APMs. If these thresholds are achieved, physicians are excluded from the MIPS reporting requirements and payment adjustment. Under the ACA, accountable care organizations (ACOs) were established through the Medicare Shared Savings Program. Although they are an alternative payment model, over 90% of ACOs are not considered to be advanced APMs because they do not accept significant financial risk for the outcomes of their associated patients.

The Executive Summary of the MACRA Final Rule explicitly states that one of the aims of the QPP is to "promote adoption of alternative payment models that align incentives across healthcare stakeholders." It also gives fair warning that "we expect the quality payment program to evolve over multiple years in order to achieve our national goals." Although most physicians will initially participate in MIPS, the incentives will continue to reward conversion to an A-APM, increasing pressure on smaller practices to join larger organizations [35, 36].

Coding Systems

For most surgical trainees, the mundane clerical practice of billing and coding is overshadowed by their desire to master the cognitive and technical skills of surgical care. Their professional education also includes ethical, professional, and interpersonal skill development which further leads to decreased emphasis on billing literacy. Unfortunately, once the young surgeon embarks on their clinical career, the importance of accurate and knowledgeable billing and coding practices becomes immediately apparent. Incorrect coding can result in significant financial penalties by CMS if the claims are ever audited. As the rendering surgeon becomes more proficient in the knowledge of coding systems, they are able to accurately describe the services that were provided using the appropriate language. There is no better person to specify the details of a procedure correctly than the surgeon who performed it.

Billing and coding provide benefit beyond converting clinical effort into financial reward. Employment contracts may include requirements for maintaining appropriate records to support claims for a surgeon's work. Institutions

may also use this data to make employment decisions, career advancement promotions, and resource allocations. Surgical case scheduling and clinical protocol assignment, such as ERP, may be based upon the surgeon's procedure code used for booking the case. Research and quality improvement projects are generally populated within databases based on filters applied in coding systems. For all these reasons, it behooves a surgeon to become familiar with surgical coding and billing practices.

As a basic principle, codes can be broken down into two categories—diagnosis codes or procedural codes. In addition, hospitals and physicians use separate systems of coding to describe surgical services. For example, inpatient surgical procedures are documented by the surgeon using the CPT® coding system, while the hospital will report based on ICD-10-PCS procedural codes (see below). This can prove quite difficult when clinicians realize that hospitals are using a completely different language regarding procedural coding. Here we will discuss the coding systems used in the United States today.

ICD-10

The International Classification of Diseases, Tenth Revision (ICD-10), is an international coding system utilized by clinicians, researchers, governments, and policymakers to accurately describe diseases and health conditions [37, 38]. Responsibility for managing and periodically updating the ICD has been granted by the United Nations to the World Health Organization since 1946 [37]. Under the electronic reporting standards of HIPAA, the Department of Health and Human Services (HHS) requires the use of ICD-10, which in the United States consists of two parts: ICD-10-CM (Clinical Modification) is used for *diagnosis* coding in all US healthcare settings, while ICD-10-PCS (Procedure Coding System) is used to describe *procedures* performed in inpatient hospital settings [39]. When a surgeon performs a procedure in an inpatient setting, the hospital or facility reports that procedure using ICD-10-PCS.

CPT®

Current Procedural Terminology (CPT®) is the coding system that surgeons deal with most frequently. CPT® is a registered trademark of the American Medical Association (AMA). The first set of CPT® codes were published in 1966 and developed to provide a standard method of coding *procedures* for insurance claims, medical records, and statistical tracking. They are copyrighted by the AMA which is responsible for regular revisions and additions to the list of codes. CMS has mandated the use of CPT® codes to report services covered by Medicare Part B and for hospital outpatient surgeries since 1983. All operative procedures, office visits, or hospital encounters with a patient can be described with a five-digit CPT® code to aid in billing purposes. These codes are also designated as a standard for electronic transmission of healthcare information under the Health Insurance Portability and Accountability Act (HIPAA) of 1996 [40].

Given the complexity and variety of the services provided by surgeons, it is not surprising that there are several rules, algorithms, and modifiers that may be necessary to accurately describe a service. Category I codes make up the most numerous group of CPT® codes and describe a wide range of services, including evaluation and management services (E/M codes), and diagnostic or therapeutic procedures. Category II codes are supplemental codes used for data gathering and performance measurement, thereby decreasing the need for record abstraction and chart review. These are not billable codes. Category III codes are used as temporary tracking codes to collect data and assess new technologies or procedures that do not meet the criteria for a Category I code. They are noticeably different from Category I codes with their numeric alpha format. For example, 0249T was used for transanal hemorrhoidal dearterialization (THD) until a Category I code was established—46948. No work RVUs are assigned to these codes, so there is no payment established for these procedures in a payer's fee schedule.

There is a well-defined process for the creation of a new CPT® Category I code or for a Category III code to become a Category I code. The AMA CPT® Editorial Panel, the group charged with maintaining the CPT® code set, is the receiving party for a CPT® code application submission. The panel meets three times per year to review applications for new or revised codes and to delete codes when necessary. The process for approval of a Category I code can take between 18 and 26 months. These procedures must have demonstrated clinical efficacy supported by literature, be commonly practiced across the United States, have FDA approval if a drug or device is involved, and have a minimum of five peer-reviewed journal articles that include US patient populations and a minimum level of evidence. The literature required to obtain such a code is many times incomplete, and without the requisite literature, a request for a Category I code would be summarily denied. The literature requirement is the most common cause for denial of a new code application [40, 41].

Once a Category I code is approved by the AMA CPT® Editorial Panel, the code is turned over to the AMA Specialty Society Relative Value Scale Update Committee, also known as the RUC. This Committee is tasked with assigning a value for the code and includes multiple medical professionals. Most of the members are appointed by major national medical specialty societies recognized by the American Board of Medical Specialties. The remaining members arise

from subspecialties with relatively large numbers of physicians in patient care or specialties that report high percentages of Medicare expenditures. The ASCRS does not hold a permanent seat on the RUC but has held one of the 2-year rotating seats about every 4–6 years. The RUC meets three times a year following the CPT® Editorial Panel meetings to develop recommendations for work relative value units (wRVUs) assigned to new or edited CPT® codes which are then submitted to CMS. Though recommendations are provided by the RUC, the final decision for Medicare payments ultimately lies with CMS [41].

DRG

Diagnosis-related groups (DRG) is the classification system utilized by CMS to determine payments to hospitals for care provided under the Inpatient Prospective Payment System (IPPS). Patients are assigned to the appropriate DRG based upon a primary diagnosis, up to 25 other diagnoses, and up to 25 procedures performed during the stay [42]. Accurate coding of the primary diagnosis and surgical procedure(s) is essential to insure that the hospital will receive the full reimbursement it is due for the care provided. The DRG system is yet another coding language to be understood when identifying populations of patients within a healthcare system's databases [43].

Codes Become Payments

After a billable patient service is performed, from an office evaluation (E/M code) to a surgical procedure, a CPT® code is used to describe the service. The coded service description then makes its way to the payer, where the claim is evaluated on several parameters—if the service provided is covered by the insurance contract, if the claim is supported by necessary documentation, and if the claim has been properly submitted. If the code fulfills the criteria, the payer will transmit payment based on the contractual fee schedule. There is also a "timely filing requirement," ranging from as little as 120 days for some commercial payers up to 1 year for Medicare, which dictates the window of time in which claims must be filed [43].

Surgical procedures as described by CPT® codes may be supplemented by a two-digit modifier to further describe a procedure code without changing its definition. CPT® modifiers (also referred to as Level I modifiers) are used to add information or adjust care descriptions to provide extra details concerning a procedure or service provided. The 2020 CPT® code list includes 35 modifiers that may be joined to a five-digit code to provide greater clarity [44]. The most used modifier in the office would be modifier −57, the decision made for surgery. For procedures that require "substantially greater" than the typical work, modifier −22 may be added to the CPT® code. If the submitted documentation supports the use of the modifier to the satisfaction of the payer, it may result in increased reimbursement to the surgeon. The documentation must specifically indicate the reason for the increased work, for example, a patient undergoing a subsequent laparotomy that is found to have diffuse, dense adhesions. The operative note is obligated to contain the reason for the increased work—"Diffuse, dense adhesions were encountered from previous laparotomies"—and the magnitude of the increase, "… that prolonged the procedure by at least X amount of time." In the case of multiple procedures performed during the same surgery, modifier −51 may be used to indicate the portion that was designated as the secondary procedure. This is usually reimbursed at a discounted rate (50%) as the majority of the work during the surgery was completed for the primary procedure (e.g., placement of laparoscopic trocars, postoperative care) [43, 45].

In addition to modifiers, add-on codes can be used to provide additional detail about a primary procedure. Add-on codes are five-digit CPT® codes that describe procedures commonly performed with other listed procedures. They cannot be billed as stand-alone procedures and are excluded from using the −51 modifier as a secondary procedure [44]. The add-on codes most used by colorectal surgeons are open (44139) and laparoscopic (44213) mobilization of the splenic flexure in conjunction with a partial colectomy. These codes can only be used in conjunction with open and laparoscopic colectomy codes and are not subject to multiple procedure payment reduction (MPPR) [43].

There are still surgical procedures for which no established code seems to perfectly describe the operation. If there is doubt as to the correctness of a listed code, the alternative is to use an "Unlisted Code." These codes are used for procedures that do not fit any of the descriptions provided in the list of CPT® procedure codes. In order to receive payment for an unlisted procedure, submission to the payer of the operative report is requisite to document the service, as well as an explanation of the procedure with suggested comparable procedures. A negotiation with the payer will then be used to determine reimbursement. This is often a labor-intensive process compared to the normal claim submission, and as such, most providers avoid using unlisted codes unless no other code or combination of codes can accurately describe the procedure [43].

Ethical Considerations (Conflict of Interest, Surgical Innovation, and End of Life)

69

W. Donald Buie and Anthony R. MacLean

Key Concepts

- Conflict of interest can take many forms—each are critical to understanding, addressing, and disclosing.
- Reporting conflict of interest can affect study outcomes.
- Introduction of new technologies into practice needs to balance progression of the field of medicine versus placing patients at undue and unnecessary risk.
- Providing excellent and ethical end-of-life care requires attention to three principles: effective communication, accurate prognostication, and sound decision-making.

> Only one rule in surgical ethics need concern you: that action on your part which best conserves the interests of your patient. Martin H. Fischer (1879–1962)

Conflict of Interest in Surgical Research

Conflict of interest (COI) is common within the surgical literature but is neither consistently acknowledged nor transparently reported. COI exists when "professional judgement concerning a primary interest (such as a patients' welfare or validity in research) may be influenced by a secondary interest (such as financial gain)" [1–5]. Researchers are obliged to identify and mitigate the effect of all sources of bias, including COI. While it may be impossible to completely avoid COI, it must be dealt with transparently. This section will explore individual COI as it applies to surgical research including classification, effect on outcomes, reporting, management strategies, relationship to the peer review process, and future directions.

Classification

Individual COI can be classified as financial, intellectual, or professional (Table 69.1) and includes any relationship or belief that may impact an individuals' ability to approach a scientific question with an open mind. While there is some debate as to the relative importance of each of these categories, any type of COI has the potential to have a negative effect on the integrity of the investigators and the veracity of the scientific process.

Financial COI

This is the most easily identified, and the most likely to undermine the credibility of the author(s), the journal, and the science. It usually involves industry and industry-sponsored trials and may include direct or indirect financial support as outlined in Table 69.1. Physician industry relationships are diverse ranging from a sponsored lunch to full research support [6–8]. Interpretation of a significant finan-

Table 69.1 Conflict of interest in surgical research

Financial	
	Grants (for profit and not for profit)
	Employment
	Personal fees (consultant)
	Non-monetary support
	Drugs/equipment, supplies
	Patent(s)
	Stocks, bonds, stock options, other securities (equity)
	Other (gifts, trips, meals expenses, paid expert testimony)
Nonfinancial	
Intellectual	Personal views, ideas, moral convictions
	Strong opinions on theoretic approach
Professional	Personal relationships
	Academic competition
	Peer recognition, public acclaim

S. R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, https://doi.org/10.1007/978-3-030-66049-9_69

cial COI is situational and depends on financial details, the degree of involvement, the timing and place of the relationship, and any attempts to mitigate the effect. Even small gifts or an exchange of services may have an effect on attitudes and decisions [9–11]. The importance of industry investigator relationships is borne out by advances in technology such as laparoscopic surgery, transanal endoscopic microsurgery, and colonoscopy. Preserving these relationships is vital to surgical advancement, but there is a need for regulation to control unprofessional behavior from individuals who are willing to compromise themselves for personal gain.

Non-financial

Nonfinancial COIs, both intellectual and professional, are more subtle and difficult to measure, but are no less dangerous to the scientific process (Table 69.1). Intellectual COIs include personal views, ideas or moral convictions, and strong theoretical opinions. A researcher for example, may be unable to provide an unbiased review of a manuscript that contradicts his/her views. Professional COIs includes personal relationships (friendship or enmity), academic issues, and peer/public recognition and acclaim. Academic pressures including the need for funding, promotion, or publication can affect the quality of scientific investigation. However, there is limited evidence regarding the relative contribution and importance of nonfinancial COIs to scientific bias.

Most authors have argued there is no meaningful conceptual and few practical differences between financial and nonfinancial COIs [12]. The two are often intertwined, influential, and require similar management [13, 14]. Other authors have suggested that nonfinancial interests are virtually always present and should be considered an interest but not necessarily a conflict [15]. However, by definition successful researchers are biased having developed a strong belief in both their ideas and theoretical approach. In addition, there is both sociologic and psychologic evidence that, given the correct circumstances, people are as likely to be influenced to change behavior by nonfinancial incentives as they are by financial incentives. The desire to conform or reciprocate to avoid social disapproval can be a very strong motivator for behavioral change [16–18]. Clearly both external and internal values, goals, and obligations can contribute to nonfinancial COIs.

Determining Conflict of Interest

How do we determine when a conflict of interest is present? In an editorial, Fineberg put forth *the reasonable person standard*; a conflict of interest exists when "a reasonable person would interpret the…circumstances pertaining to a situation as potentially sufficient to influence the judgment of the physician in question" [19]. In other words, would an uninterested observer conclude that the physician is able to make an informed and unbiased judgment or decision? Determination of COI is ultimately subjective and based on the perception of a reasonable person. However, the most important question is not whether a conflict of interest exists but whether it "presents an unacceptable risk of undue influence or bias" [20]. Practically speaking, there is a need for specific guidelines and policies that can be applied universally and transparently to grade significant COI.

It is important to judge every situation on its own merits and avoid being too prescriptive eliminating potentially useful viewpoints. While the opinions and ideas of recognized experts with reported COIs should be carefully vetted prior to acceptance due to the potential for recognized bias, other experts without any financial COIs should be no less scrutinized as they may harbor hidden nonfinancial biases which could subtly affect the framing of an argument or the interpretation of evidence [21].

Reporting COI and the Effect on Study Outcomes

Scientific journals have relied on self-reporting of financial and nonfinancial COIs with varying success [22]. Most journals now require a COI statement to be completed with submission of a manuscript, yet a significant number of relevant COIs still go unreported [23]. To increase transparency and reporting of financial COIs, the Physician Payments Sunshine Act was passed in 2010 which mandated that manufacturers of drugs, medical devices, and biological products report all of their financial transactions with clinicians having a National Provider Identifier (NPI) number. These transactions are publicly available through the Open Payments Database (OPD), which was designed to allow industry-reported COI to be compared with author self-disclosure [24, 25].

There is a significant body of evidence examining the effect of financial COIs on study outcomes. Primary studies that are industry sponsored, both pharmaceutical and medical device, are more often favorable to the sponsor's product when compared to studies with independent sponsorship [26]. This association has also been demonstrated for meta-analysis, systematic reviews, editorials, and letters to the editor [27]. Industry influence includes setting the research agenda, obfuscating important research questions with secondary studies, selective analysis, selective reporting, and selective interpretation of results and conclusions [28–32]. The latter was reinforced in the aftermath of the Vioxx scandal where despite a lack of scientific evidence, an excess of cardiovascular events in the Vioxx arm were falsely ascribed

to a presumed cardioprotective effect of naproxen (control) rather than an increase in thrombogenic potential from Vioxx. Selective interpretation combined with selective reporting and aggressive marketing caused harm to an unknown number of patients prior to the drug being pulled emphasizing the need for oversight and attention to detail when entering into a relationship with industry [33].

Failure to disclose COI is also associated with conclusions that are significantly more likely to favor industry. Cherla et al. used the OPD to investigate the impact of financial COI and found a 70.3% discordance of reported COI between surgeons and industry. Surgeons who failed to disclose developed conclusions that were more likely to favor industry when compared to surgeons without COI [34]. Similarly, a prospective blinded review of 100 consecutive articles on ventral hernia found that authors with COI both self-reported and not reported were twice as likely to report results favorable to industry compared to authors with no COI [35]. Most of the articles (82%) had a relevant COI, and up to one quarter of relevant COIs were not disclosed.

These findings are not confined to primary research. Reporting of individual financial COI in systematic reviews ranges from 17% to 65% [36–39]. Systematic reviews are generally viewed as higher-quality evidence, and thus the potential for disseminating biased conclusions is significant. Recently, a review of opioid practice guidelines published between 2007 and 2013 demonstrated significant unreported financial COI from panelists who produced guidelines that were otherwise judged to be of high methodological quality [40]. The principles of managing COI in guideline panels were outlined in 2011 by the Institute of Medicine but have not been widely adopted [41, 42]. Clearly, guidelines for reporting COI must include primary and secondary research [43].

Management Strategies for Primary and Secondary Research

COI cannot always be avoided, but like all forms of bias, it needs to be managed as transparently and effectively as possible. There are four main strategies: disclosure, elimination, balance, and exclusion. Each strategy is useful in specific situations and has its own strengths and weaknesses [5].

Disclosure

Disclosure is the most frequently used strategy for managing financial COI. It cannot reduce or eliminate bias, but when complete and transparent, the scientific community has the opportunity to evaluate it. Disclosure is usually post hoc and thus is prone to selection bias; investigators disclose only what they want the scientific community to see; thus, financial interests may remain hidden or incompletely reported [22]. Nonfinancial interests including personal views, ideas, and moral convictions are central to an individuals' character and cannot be separated, while other nonfinancial issues, such as previous publications espousing a specific position, may already be a matter of public record. Disclosure of nonfinancial interests may be inhibited by ethical and privacy concerns. Disclosure of a large number of nonfinancial COIs may also distract from a more significant financial COI. For these reasons some authors have questioned the value of extensive disclosure of nonfinancial interests [5].

Disclosure may be associated with several inappropriate assumptions. It does not suggest that the investigators' judgment has been affected nor should it be interpreted to mean that the investigator is biased. Furthermore, it should not be used to interpret the appropriateness or value of a financial relationship [19]. From the investigator's viewpoint, potential unintended effects following disclosure include moral licensing, where the individual, having disclosed their conflicts, feels entitled to say and do what they want. In addition, disclosure of financial COIs by a surgeon in a high-profile advisory role may be interpreted as a sign of expertise inflating their standing and influence as a speaker [44, 45]. Thus disclosure, while necessary, is not always sufficient, and the COI should be judged as any other form of bias when evaluating the validity and generalizability of a study.

Elimination

Elimination works best for financial COIs where the investigator can divest himself/herself of the relationship prior to undertaking the research. Unfortunately, nonfinancial interests cannot be divested from either the investigator or the research for reasons listed above. Elimination is best performed a priori, preferably in the planning stage.

Balance

When planning a study, the participating individuals should ensure that there is balanced representation of financial and nonfinancial biases among the researchers. It may be ideal for two groups with differing viewpoints to participate equally in trial design with a neutral party leading data collection and analysis. Balance is also important in guideline development where all sides of scientific debate can be evaluated and incorporated [46].

Exclusion

Individuals who might be influenced by a secondary interest should be excluded from evaluation and interpretation of results, although they may selectively participate in trial development. Surgeons with a financial interest in a company that would benefit from the recommendations of a guideline panel should be excluded from guideline development and authorship. Again, it is difficult to exclude on the basis of personal views and beliefs which adds to the diver-

sity of scientific discourse and healthy discussion. If all dissenting views are excluded, the homogeneity of the remaining researchers may result in unintentional bias [46]. It cannot be assumed that the remaining investigators are unbiased or without relevant interests or personal beliefs.

COI and the Peer Review Process

Mitigating the effect of COI within the realm of scientific enquiry is the responsibility of all participants including investigators/authors, reviewers, editors, and editorial staff. Investigators must assess the effect of COI during planning, implementation, analysis, and writing.

Disclosure and exclusion are the primary strategies and require transparency to be effective. Authors are required to disclose all financial and nonfinancial COIs that might be perceived to bias their work. The ICMJE form "Disclosure of Conflicts of Interest" has been adopted by most journals including DCR and must be submitted with any completed manuscript.

The review process relies on reviewers and editors to assess and critique manuscripts on scientific merit as free from personal bias as possible. When requesting manuscript review, journal editors will ask the reviewers to assess themselves for any COI that could bias their review with the expectation they recuse themselves when appropriate. At this level, acknowledgement of personal and intellectual biases is extremely important. While some journals have opted for single- or double-blinded review, others have used an open process where the identity of the reviewer and author is known to each other. Each of these potential solutions has merit, but they cannot eliminate the potential for intellectual and professional conflicts which in some cases may be subconscious [47]. When opposing viewpoints exist, a potential solution for the editor is to balance the assignment of reviewers.

Editors must be held to the highest standard and should try to divest themselves of all COI prior to accepting a leadership position at a journal. They must recuse themselves from involvement in any manuscript under consideration when either a potential or actual conflict exists. The editor is also the final arbiter when, despite disclosure, a manuscript remains unpublishable due to bias from financial or nonfinancial COI.

Conclusions

The goal of every researcher is to identify and when possible mitigate the effect of bias on scientific inquiry. Conflict of interest, whether financial or nonfinancial, is one of many types of bias and must be subject to the same level of scrutiny as more traditional forms such as methodologic issues. Continued development and adoption of a comprehensive approach addressing COI requires efforts from individual researchers, societies, journals, publishers, academic institutions, and government. The solution must be multifaceted and includes universal policies and guidelines, robust self-reporting, continued research into quantifying the effect of COI, and increased use of management strategies early in the research process.

Introduction of Surgical Innovation

Innovation is critical to progress. Surgical innovation has been a constant in the history of surgery. Most surgeons are comfortable adapting when faced with a new or unanticipated problem in the operating room, which is a form of innovation, though not the main focus of this section. How one learns new techniques, acquires new skills, and/or incorporates new technologies into one's practice is where ethical issues can arise. The development of new techniques and technologies has been accelerating rapidly. For the practicing surgeon, the challenge and desire to keep pace with these changes and deliver cutting-edge care is compounded by the expectations of patients, hospital administrators, and device manufacturers. Incorporating exciting new technologies and new procedures into practice as they are developed is one of the most exciting parts of clinical practice for many colorectal surgeons. However, *how* we incorporate these novel treatments is fraught with ethical issues.

Incorporating New Techniques and New Technologies

Surgical trainees learn new procedures and techniques under the supervision of qualified mentors. This allows for graduated learning and safe implementation. However, once a surgeon begins independent practice, incorporating new techniques and technologies is far more difficult and complex.

Over the years many promising technologies have been incorporated into clinical practice in a way that resulted in less than optimal outcomes. An early example was the introduction of laparoscopic cholecystectomy and the epidemic of common bile injuries that followed. With time and experience, the risk of bile duct injury decreased to levels comparable to open surgery, only to increase following the introduction of single-port cholecystectomy [48]. In colorectal surgery, the early adoption of transanal total mesorectal excision (TaTME) was unfortunately associated with a high

number of urethral injuries [49], a complication that was virtually unknown with either an open or laparoscopic approach. Add to that the moratoriums that have been placed on TaTME in Norway and the unusual locoregional recurrences in the Netherlands, one could certainly question how well we as surgeons have introduced these technologies and techniques into our practices [50, 51].

What do laparoscopic cholecystectomy and transanal total mesorectal excision have in common? Both are surgical innovations that promise significant benefits to the recovery of patients, and both came highly touted and rapidly adopted among surgeons, frequently after only a minimal amount of "training," often consisting of a weekend course. This was followed by adoption into clinical practice often without proctorship or a means to safely introduce it to our patients and often without any institutional oversight.

As surgeons, new developments and innovations are exciting but can present an ethical dilemma. We want to offer the newest and best to our patients, we want to offer everything that other surgeons are able to offer, and we feel the need to do so with minimal interruption in our clinical practice. Jaffe et al. surveyed 150 faculty surgeons and found that 98% reported learning a new procedure or technology after their formal surgical residency training [52]. They found a large discrepancy between what surgeons actually did to acquire knowledge and learn a new skill or technology (most commonly scrubbing in for cases performed by another surgeon or self-directed study), and what these same surgeons felt would be the most effective strategy to learn a new skill or technology (performing cases under the supervision of a proctor or mentor, or doing a "mini-fellowship"). Barriers to using the most effective strategy included the need for a significant amount of time and the fact that surgeons were confident they could implement the new procedure safely without the need for more rigorous/effective training.

Additionally, while most physicians and surgeons are aware of and accepting of the need for proper IRB approval when introducing new medications or devices into surgical practice, there appears to be far less agreement as to the need for oversight when introducing new technologies or surgical techniques. In fact, a study by Reitsma and Moreno demonstrated that authors who had published on innovative procedures frequently felt that their work was research, and yet the majority did not feel that IRB approval was necessary, and only a minority mentioned the innovative nature of the procedure to the patient in their informed consent process [53].

Oversight

New medications and medical devices are typically heavily monitored and regulated in all countries by regulatory bodies—in the USA by the Food and Drug Administration (FDA). However, new techniques and procedures are mostly unregulated which has led to many advances in surgery through innovation. However, as mentioned above, not all innovations are beneficial, and thus many believe that implementation of new procedures should be regulated to ensure patient safety before widespread adoption.

In order to help surgeons with this very difficult situation, several groups have sought to provide guidance to the clinician on how best to apply surgical innovation into one's surgical practice. Two of these groups are the Society of University Surgeons and the IDEAL Collaboration.

The Society of University Surgeons published a position statement on the responsible application of surgical innovation into clinical practice in 2008 [54] This position statement provides guidance to the surgeon on what constitutes an innovation that should undergo a formal review. In short, if the innovation is planned, AND the surgeon seeks to confirm a theory about the innovation, OR the innovation differs significantly from currently accepted local practice, OR the outcomes of the innovation have not been previously described, OR the innovation entails potential risks for complication, OR specific or additional patient consent appears appropriate, THEN the innovation should be reviewed by a local surgical innovation committee (or institutional review board if there is a plan to publish results), submission to a national innovations registry should be done, and additional informed consent is required of the patient specific to the nature of the proposed innovation.

The IDEAL collaboration is an international group of surgeons and researchers whose goal is to improve the quality of research in surgery. They have proposed that there should be no innovation without study. Their recommendations couple innovation with continuous evaluation based on a five-stage description of the surgical development process [55, 56]. Stage 1 is the proof of concept (or innovation) stage, performed on very few patients by very few surgeons, and is meant to describe the innovation, typically with case reports, to include details of the technique, and outcomes, including adverse events to avoid replication of dangerous methods. Stage 2a is the development stage. A few innovators and early adopters continue with procedure development on a small number of patients, with prospective studies focusing mainly on safety and technical and procedural success. Stage 2b is the exploration stage. Additional surgeons begin to undertake the procedure, broadening the indications to include a larger number of patients. The procedure gets refined, and details on community learning evolve. Patients should be entered into a research database, and the main focus should be on safety, clinical outcomes, patient-centered outcomes, and feasibility. Stage 3 is the assessment stage. At this point many sur-

geons (the "early majority") carry out the procedure on many patients, as the indications expand. Comparison trials or randomized controlled trials (RCTs) would be ideal, and clinical outcomes, middle- and long-term outcomes, patient-centered outcomes, and cost-effectiveness should be the areas of focus. Last is Stage 4, long-term study. At this point the procedure is typically more widely available, and the focus becomes audit, regional variation, quality assurance and risk adjustment, using registry data and available databases. Rare events, long-term outcomes, and quality assurance come to light at this point. They recommend that ethics approval should be considered in stage 1 and should be mandatory for stage 2a, 2b, and 3.

Both of these groups emphasize the critical importance of surgeons taking responsibility for careful evaluation of new procedures or innovations with oversight by either a surgical innovation committee or research ethics board/institutional review board to ensure that patient safety is kept paramount.

Informed Consent

Another ethical challenge to the surgeon incorporating a new technique into their practice is obtaining appropriate informed consent. The consent process is not only a legal requirement; it also is a critical component to the establishment of trust in the surgeon-patient relationship.

Informed consent should include a description of the proposed operation, the indications, material risks and benefits to the patient, treatment alternatives, and who will be conducting the procedure. In the case of a new procedure, a description of the surgeon's training and/or experience with the procedure may be warranted.

Several issues deserve mention here. It is critical that a surgeon's enthusiasm for a new technique does not affect the way that information is conveyed to the patient. The options available to the patient, the potential benefits, AND risks of the new technique must be explained. Patients and surgeons are often under the belief that newer must also be better, which can affect one's judgment. Information must be conveyed in an unbiased, balanced, and honest manner, to allow the patient to make an educated decision regarding their desire to undergo the new procedure.

Surgeon experience with a new procedure is particularly important to consider. In one study, the majority of patients felt that surgeon experience was one of the most important determinants of whether they would want to undergo a new procedure, particularly whether it was the surgeon's first case [57]. While some surgeons feel that they have no choice but to perform a new procedure on a patient in order to gain experience, it is clear that education and appropriate training are critical for safe implementation. Visiting apprenticeships or "mini fellowships" can often be used to gain the required initial experience. Proctorship or mentorship from a more experienced colleague can help optimize the initial learning curve of the surgeon.

Ahmed et al. surveyed 244 surgeons about their knowledge, attitudes, and practice when introducing novel surgical techniques [58]. They found that surgeons often did not discuss the novelty of the procedure, the alternative options, the surgeon's experience with the procedure, or the risks of the procedure. The IDEAL Collaboration has made recommendations regarding these ethical issues across the IDEAL stages of surgical innovation [59]. In stage 1, they recommend sharing appropriate information with patients (including surgeon's expertise, experience with the innovation, and reason to recommend it) and careful attention to ensure true informed consent by providing written information, requiring repeat appointments to discuss the innovation, and taking steps to avoid the surgeon's optimism bias with the innovation.

Lastly, there is sometimes uncertainty about the true risks and benefits of new procedures. This is particularly true for relatively uncommon complications that may not become apparent to the surgical community until the procedure has been adopted more widely. A surgeon's enthusiasm for a new procedure can also subconsciously bias the discussion with the patient, emphasizing the potential benefits while downplaying the potential risks. This bias must be avoided to allow the patient to make a truly informed decision.

Outcomes

As surgeons adopt new or innovative techniques, particularly as "early adopters," they have an ethical obligation to track their outcomes to ensure their patients are not being harmed. While RCTs are considered the gold standard to assess surgical innovations, they are often not felt to be feasible to conduct for a number of reasons. There is the need to establish the learning curve for the procedure and enroll surgeons who are beyond that prior to beginning the trial, so that the study reflects the true effect of the innovation. Without knowing all outcomes and potential risks, it can be difficult to properly design and power a study to assess for those differences. Lastly, once a new technology has been out and adopted for a sufficient period of time, surgeons may lose the "clinical equipoise" needed to feel that they can ethically enroll patients into a trial.

For these reasons, other strategies may be required, including the use of prospective registries or databases to track outcomes. Whether they are personal, institutional, or national, it is critical to capture outcomes and adverse events AND to make that data available to others via publication, to ensure patient's safety.

Industry Involvement

Industry often plays a key role in developing and promoting new technologies. As a critical component of surgical innovation, they are often largely responsible for the widespread adoption of new surgical techniques through the provision of training courses and arranging apprenticeships and/or proctorships. They may also provide grants and other support to enable new technologies to be studied and evaluated. However, it is also important to be aware of the potential conflict of interest that the relationship between surgeons and industry can lead to. Some surgeons working for industry are paid consultants and thus may have conscious or unconscious biases favoring the new technology as outlined in the previous section.

Conclusions

New technologies and innovations are critical to advancing the surgical care of our patients. However, they also have the potential to cause unintended negative consequences. Appropriate training and careful roll out of new technologies is essential, as is clear and transparent communication with our patients and tracking of our results.

End-of-Life and Surgical Care

Advances in medical and surgical care have greatly increased our ability to temporarily interrupt the dying process and prolong life. While recovery to a premorbid state is usually not possible, patients may be able to maintain a quality of life that is consistent with their overall goals of care. The important question often becomes a discussion of not *can we* but *should we*, which raises a number of ethical issues in surgical end-of-life care.

Providing excellent and ethical end-of-life care requires attention to three principles: effective communication, accurate prognostication, and sound decision-making. This section will explore these three principles and related ethical issues as they pertain to the practicing surgeon.

Communication

Effective communication is the cornerstone of ethical end-of-life care. Patients, their families, and their care providers require accurate honest information delivered in an open nonjudgmental environment to enable informed and appropriate treatment decisions concordant with their goals and values. Ethical communication also includes effective listening. Understanding what is important to the patient is the hallmark of patient-centered care.

Communication should occur early, often, and when possible, prior to any acute changes in medical condition which tend to complicate discussion and decisions. When planning a meeting, consider timing, setting, content, context, and key points. Meetings should be private without outside pressure or interference, with ample time and space. As the most responsible practitioner, you should facilitate the meeting rather than run it. Probe for understanding and establish the level of shared decision-making that is expected [60]. Prognostic information must be delivered clearly and compassionately with honesty avoiding false hope. Elicit the patients' goals/values and fears/worries to ensure that treatments are aligned and that expectations are realistic and attainable. Uncertainties between family members and clinicians must be fully disclosed and resolved. When several clinicians are involved in decisions regarding care, a premeeting briefing should be arranged to ensure messaging is clear, concise, and consistent.

Poor communication confers a significant risk for harm [61]. While clarity is essential, the surgeon should be aware of how framing and context affects what the patient hears, understands, and prioritizes. Communication issues are magnified by cultural and language barriers. While it may be convenient to use a family member, the translator may insert their own values and judgments or inaccurately describe a medical situation due to a lack of understanding or verbal facility. The message may be distorted, possibly harmful, and the exact content received by the patient is unknown. When possible, a professional translating service should be used. Pictures and diagrams transcend language and effectively supplement verbal communication.

Prognostication

An understanding of the expected treatment course, potential risks, and possible outcomes is the foundation of ethical treatment decisions. Surgeons must provide accurate and honest prognostic information to patients and their families which addresses functional, cognitive, and psychosocial outcomes. Unrealistic patient expectations coupled with erroneous assumptions regarding acceptable patient outcomes are often the underlying reason behind treatment that is at odds with end-of-life goals of care [60]. The SUPPORT trial demonstrated that half of ICU patients experienced unwanted medical treatment, more than half were undertreated for pain, and many did not have their preferences for care identified or carried out by the management team [62]. Some of these issues can be ascribed to what has been termed "clinical momentum," multiple interventions which

in isolation are standard patterns of care without considering the cumulative effect on an individual's likely outcome or preferences [63].

When prognosticating, the surgeon should consider a range of outcomes and their likelihood, identifying which outcomes are acceptable to the patient and which are not. Although multiple scoring systems exist to predict short-term morbidity and mortality, they are most useful for populations and may not accurately predict functional outcomes and health-related quality of life of an individual patient. Discussion should not focus solely on survival but prognosticate the future clinical course and expected state of health [60]. Acknowledging and discussing expected functional outcomes also sets the stage for any future discussion regarding withdrawal of life support should this become necessary. Elderly patients especially those with an element of dementia require a discussion regarding the possibility of further decline in mental and physical function following surgical interventions especially when emergent.

Use of a time-limited trial is appropriate and ethical when there is prognostic uncertainty or difficulty accepting outcomes. This may include a surgical procedure with time-limited postoperative ICU support, setting specific functional and physiologic parameters to be attained within a specified time frame. Inability to attain these goals within the trial period is evidence that the specified treatment course is unlikely to benefit the patient and requires reevaluation.

Decision-Making

Decision-making is central to ethical end-of-life care. The clinician should be guided by the four primary principles of medical/surgical ethics: respect for autonomy, beneficence, non-maleficence, and justice [64]. These principles are not hierarchical and may seem at odds with one another at end of life. If a situation presents an apparent conflict between two of these principles, every attempt should be made to come to an agreeable compromise. If this is not possible, a consult should be obtained with an expert in ethics or palliative care.

Respect for Autonomy

The right of patients to determine their own goals of care and accept or decline treatments is a basic tenet of ethical end-of-life care. Yet, regardless of the amount of information they receive, it is difficult for patients to fully comprehend the expected outcomes and potential consequences of a treatment decision. Furthermore, acute and chronic effects of an illness may further inhibit reasonable discussion and thought.

Advanced directives enable a competent individual to determine and document their healthcare plan in advance of a future terminal illness or disability. These can be either instructional where a competent individual records their healthcare choices in advance or by proxy where a patient specifies their wishes to their care provider or family to carry out if and when they become incapacitated. Ideally, these documents provide some autonomy to the patient allowing them to receive end-of-life care consistent with their wishes.

Unfortunately, advanced directives are still rare with only 30% of adults having completed them, the majority of whom are over 65 years of age [65]. They are usually completed without contextual background or an understanding of the potential circumstances of a medical crisis and the consequences of many end-of-life decisions. Even when an advanced directive is completed, it may not provide guidance for a specific end-of-life situation such as when an acute potentially solvable problem is superimposed on a chronic terminal illness. A patient's end-of-life preferences may have developed in the absence of a balanced medical discussion, based on previously observed family situations or even movies and television scenarios which may not apply to the current situation. A recent study found that over 70% of surrogate decision-makers thought that survival after CPR was >75%, only 20% understood that brain damage could be present afterward, and only 2% understood that the patient could be dependent on life support [66]. Accurate and consistent communication is important to avoid unrealistic expectations such as these. Patients may also limit their interventions unnecessarily based on a fear of burdening their family in the future [67].

Patients views and expectations are not necessarily fixed and may change depending on the circumstances and disease course. When a situation becomes protracted or there is an acute change in health, it is important to revisit and reassess to ensure alignment with treatment goals. Careful communication is needed to temper unrealistic expectations and ensure that the patient/family understands how an accepted treatment may now be in opposition to previously stated goals and values. When the care provider also functions as the surrogate decision-maker, it may be difficult to perform both roles due to exhaustion and burnout. A study of surrogate decision-makers in end-of-life care found that over 75% of them wished to eliminate or limit their role in medical decision-making [68]. The surgeon must be sensitive to this possibility and rebalance the decision-making process depending on the desires and capabilities of the surrogate decision-maker and patient [69]. It also raises the question of whether the presumed autonomy that we maintain for patient-/surrogate-led decision-making is always meaningful and effective [70].

The concept of shared decision-making (SDM) ensures that the patient's viewpoint is always considered. Although SDM has become standard of care, the nature and optimal strategies for applying SDM have not been fully researched [71]. It is clear that SDM should not be limited to a discussion between a physician and patient/surrogate that is focused

solely on choosing the best treatment option from a list of potential options. From an ethical point of view, it should be a relationship where the patient/surrogate identifies and prioritizes their important goals and values while the physician identifies management options including risks, benefits, and expected functional outcomes, exploring how each option aligns with or opposes the prioritized goals and values. When done properly, the surgeon is well equipped to recognize when a patient is being overtreated or undertreated.

Decision aids are often used to help focus a patient on the issue at hand by reducing extraneous information. A Cochrane review suggested that patients and their families felt they were more knowledgeable and clearer with respect to their values and their understanding of risk and outcomes following the use of decision aids [72]. They should be simple, easy to understand, and generalizable to a number of situations. Another approach to SDM is the best case/worst case framework. Rather than focusing on treatment pathway or acute surgical problem, discussion is centered on outcome by presenting the best case, worst case, and the most likely outcome [73].

Beneficence

Doing what is best for the patient includes actions that improve a situation and those that prevent or remove potential harms. At the end of life, this includes effective symptom control and reasonable attempts at resolving surgical problems. Decisions are based on the patient's disease state, expected course, and the patient's expectations regarding a "good outcome" [70]. When the patient cannot speak for themselves, the clinician may probe family members for anecdotes and previous conversations to obtain a deeper understanding of their views.

What is typically recognized as routine and standard of care may not be appropriate or ethical at end of life. The surgeon must differentiate between ordinary "medicines, treatments and operations which offer a reasonable hope of benefit and which can be obtained and used without excessive expense, pain or other inconvenience" and extraordinary "that which cannot be obtained or used without excessive expense, pain or other inconvenience or which, if used, would not offer a reasonable hope of benefit" [74]. What is reasonable vs. unreasonable requires context, an understanding of the patient's goals and values, and careful interpretation. As the most responsible physician, understand your own biases and take steps to mitigate the effect of them on your decisions. If you feel you are too close to the patient or their problem, you may have to take a step back and ask the advice of or transfer care to an experienced colleague who is removed from the situation.

Aggressive interventions to control symptoms may lead to an inadvertent decline in the patients' overall well-being also called the double effect. For example, aggressive pain management may lead to sedation and hasten death. Provided that the primary intention is to benefit the patient (in this case alleviating suffering), these actions are justifiable and ethical.

As the population ages, increasing numbers of elderly patients require surgery near end of life. Healthy elderly patients may tolerate surgery, but a complication can be devastating due to inadequate reserve. It is important for the patient to maintain realistic expectations especially if the procedure is of limited benefit to quality or quantity of life. Communication errors may compound the problem especially in emergency situations when it may be difficult to ensure that the patient and their family understand the short- and long-term consequences and the expected outcomes [61]. The surgeon should strive to be direct and clear but not callous. While age should not be used as the sole reason for denying treatment to an elderly patient, the surgeon must ensure that any expected benefit far outweighs the risk.

Non-maleficence

To do no harm has long been associated with therapeutic intervention and is at the core of surgical care: "… that it is only the second law of therapeutics to do good, its first law being this – not to do harm" (Bartlett 1844) [75]. A procedure which may be standard of care in a more typical situation may be non-therapeutic or place the patient at significant risk when near the end of life. In complex situations where there is diagnostic or prognostic uncertainty, understanding and evaluating the risk benefit ratio becomes very difficult as the therapeutic window is often very narrow and may change as the patients' condition evolves. Initial interventions may be very reasonable and acceptable to patients and their families in the short term. Frequent reevaluation by the surgical team, the patient, and their family is important to avoid interventions that exceed what would be acceptable to the patient [61, 63].

Central to a discussion of an intervention which is potentially harmful is an understanding of the natural history of disease process given the patients' circumstances. Compounding these situations is the differing perspective of the involved healthcare providers who may submit very different opinions with regard to disease course and thus the value of a specific therapeutic intervention. As individual practitioners we are influenced by our own values, training, and practice environment [76, 77]. A difference of opinion regarding a therapeutic decision that can't be resolved may cause moral distress; the surgeon recognizes the proper course of action but feels they cannot act upon it [78]. This may include a surgical intervention or the persistence of a therapy either of which is seen by one party as potentially harmful. A second opinion from a respected expert who is removed from the situation may be required. An ethics consult may also be helpful to support these difficult decisions and preserve future working relationships within the team.

Removal of life-sustaining interventions once they have been initiated or removal of care following a therapeutic trial is ethically justifiable if one of two conditions are met:

1. The patient/surrogate recognizes that the treatment is no longer consistent with previously identified goals and values.
2. The most responsible physician recognizes that the treatment is no longer medically indicated [70].

The term "no longer medically indicated" should be used for any treatment that will not or has ceased to accomplish the intended goal or deliver the benefit for which it was intended. The term "futility" has also been used in the past, but it has proven difficult to define as it is value based and requires contextual discussion [79]. Difficulties can arise when the patient has an acute reversible issue superimposed on a terminal irreversible disease or when multiple reversible issues occur simultaneously making recovery highly unlikely. In these cases, withdrawal of care is ethically justified to prevent interference with the natural process of the disease. The patient/family and the surgeon should reach mutual agreement by exploring the lack of benefit of the treatment, the inability to change the course of the disease, and any risks of continuing with the treatment.

At times there can be differences of opinion regarding a treatment course between family members. There may also be family members who have some medical experience but not in the area in question who harbor strong opinions about a specific treatment course. These situations can be difficult to navigate and may also create moral distress [80]. Early and frequent communication is required emphasizing that the treatment course must remain consistent with the values and goals of the patient. These differences are often the result of errors in communication that have been magnified due to the stress of the situation rather than a true difference of opinion. Additional input and consultation from senior colleagues, intensivists, palliative care, and ethicists may be necessary. In some cases, the patient may need to be transferred to a colleague whom the patient or family feels has a viewpoint more consistent with their own.

Justice

Justice is a form of fairness where each patient is entitled to the fair distribution of all available medical resources, based on equality and equity. Equality means that everyone has equal access to all available treatments, while equity means that everyone gets the support they need when needed. Both of these concepts are important in end-of-life care as each situation is unique with patients having differing needs.

In every health system demand exceeds available resources. While no patient should be denied a potentially beneficial treatment, in reality access may be limited by a number of factors including available expertise and resources. Healthcare systems without universal healthcare have the potential for limiting access due to variations in private insurance, while systems with universal health coverage may have limitations on expensive treatments due to system and societal costs [81, 82]. Unfortunately, social issues such as age, social status, ethnic background, culture, sexual preference, disability, and insurance coverage also factor into access [83–86]. While many of these issues are unsolvable, the surgeon should be aware of how they may affect the provision of treatment. Any potential solutions to mitigate these effects must be explored and offered.

Many of the social factors present in marginalized communities may lead patients to late engagement and mistrust of the medical system. The surgeon should be sensitive to these issues and make every attempt to understand how they affect end-of-life decisions and acceptance of care. In some cases, cultural and ethnic differences may be an overarching consideration at end of life and may include religion, racial identity, and socioeconomic status. While the surgeon cannot expect to have a complete understanding of cultural nuance, he/she must be open to considering other viewpoints to deliver patient-centered care [87]. For example, in some cultures, end-of-life decisions are made collectively by the family or by a senior member of the family. In this situation, patients could be asked how much information they would like to receive, how involved they would like to be in decision-making, and how much they want their families involved [87]. This approach provides them some autonomy yet respects their cultural needs. Most hospitals have a liaison service which should be involved to help bridge these gaps.

Conclusions

End-of-life care presents a number of ethical issues for the practicing surgeon. The principles of effective communication, accurate prognostication, and sound decision-making are the hallmarks of ethical patient-centered end-of-life care. Central to the decision-making process are the four primary principles of medical/surgical ethics: autonomy, beneficence, non-maleficence, and justice. All decisions must uphold the patient's values and goals, and the resulting actions must be directed toward conserving the best interests of the patient.

Welcome to Litigation

70

Dennis K. Ames

Key Concepts

- In litigation, preparation is the key to a successful outcome.
- Preparation should begin as soon as you become aware of an adverse outcome likely to lead to litigation.
- Don't conduct an independent investigation.
- Never appear at a deposition without consulting an attorney.
- Meet with your attorney early.
- Communicate with your attorney regularly.
- Know what you can expect of your attorney and when.
- Know what is expected of you and when.
- Do your homework, and make yourself available.

The unfortunate reality for today's physician is that he or she will almost certainly be sued for medical malpractice in his or her career. According to data published in *The New England Journal of Medicine* in 2011, general surgeons (the publication does not include a cohort for colon and rectal surgeons) face a 15.3% annual probability of facing a medical malpractice claim. Along with other "high-risk" specialties, 80% of general surgeons are projected to face a claim by the age of 45 years, and by age 65, fully 99% of those physicians in "high-risk" specialties such as general surgery are projected to face a claim [1].

The pertinent question for today's surgeon is not "What should I do *if* I get sued?"; rather, it is now "What should I do *when* I get sued?"

If there is comfort to be taken in this data, it is that while physicians, depending on specialty, face a 5–20% probability of facing a malpractice claim in a given year, the probability of any such claim leading to an indemnity payment is substantially lower.

This chapter is designed to guide the physician-defendant toward achieving the *best result* the facts of the case allow. *Best result* is not measured only in the sense of winning or losing the case. As importantly, *best result* implies minimizing the human toll the process exacts on the physician-defendant, by reducing anxiety and frustration [2].

Anxiety is reduced by education and managing expectations. This chapter is organized to provide a general outline of each of the stages of the litigation process. It will describe each stage of the process and define the role of the attorney and of the physician-defendant at each stage.

Frustration is reduced with preparation and being proactive in your defense. As a physician facing a malpractice claim, you have the right to expect your attorney to be well prepared at each stage of the litigation. As the physician-defendant, you, too, have a significant role in the preparation of your own defense. To be prepared, you must know what to expect during the course of the litigation. You must understand the litigation process. You must understand what you have the right to expect from your attorney, and finally, you must understand what your attorney has the right to expect of you.

In an effort to minimize frustration, *Teaching Points* are provided. These *Teaching Points* include a list of things which the physician-defendant can do proactively at each stage of the litigation to assure himself or herself that everything which can be done in his or her defense is being done and that his or her defense is not unwittingly being compromised.

Preparation: Key to Success

The probability of a successful defense to any claim rests first on the underlying medical facts. Though relatively rare, true, "indefensible" surgical misadventures occur. Wrong-

Portions of this chapter include material from Judicial Council of California Civil Jury Instructions (CACI), Nos. 200, 208, 219, 221, 501, 505, and 506. Permission to reprint CACI instructions in this publication has been expressly granted by the Judicial Council of California.

site surgery is one, for example. In such cases, the relevant medical facts may not be in dispute. If a claim arises from the occurrence of a true surgical misadventure, it may be prudent to posture the matter toward settlement from the outset. But even in these situations, understanding the entirety of the process and advance preparation for it remain critical.

Even if the case involves an admitted surgical error, it remains important for the physician and the lawyer to be cognizant that the litigation process for the physician likely will not end with settlement of the claim with the patient—there is still the matter of a possible future investigation of the case by the state medical board. In such a case, the physician might appropriately ask whether or not the *best result*, when consideration is given for potential medical board investigation, wouldn't be a settlement before a formal complaint is filed or, if the complaint is already filed, before the surgeon or hospital staff is deposed. Preparation in this setting would include an early consultation with counsel to discuss the ramifications to you personally and professionally of an early settlement versus proceeding to protracted litigation.

In the great majority of cases, however, the facts are disputed. The dispute may or may not involve what happened in surgery. The disputed facts may include the indications for surgery; the consent discussion; preoperative knowledge of the patient's relevant medical history, laboratory values, medications, or other contraindications; the substance of discussions with other medical providers, referring physicians, nurses, or radiologists; the existence of alternative therapies or surgical approaches; or the patient's postoperative course.

The reality of litigation is that the "facts" of a case are what the jury says the facts are on its verdict form. Until that moment, there are no facts; there is only evidence of facts. In coming to its verdict, the jury determines the facts after balancing the evidence presented at trial, giving weight to the evidence on either side of an issue as the members of the jury, individually and in their cumulative wisdom, see fit. Experience establishes that evidence which either side believes to be clearly decisive on an issue, nevertheless, may be marginalized or discarded in whole or in part by the jurors.

Effective litigation requires effective accumulation of evidence and effective presentation of that evidence. Effective accumulation and presentation of evidence require thorough and focused preparation. That process begins at the initial meeting between the lawyer and the physician-defendant, if not sooner, and continues through the conclusion of the litigation process.

There are certainly many aspects of the process over which the physician-defendant may have little or no control, but it remains incumbent for the physician to recognize those aspects of his or her defense that he or she can affect and to do whatever is necessary to achieve the *best result*.

Stages of the Litigation Process

The litigation process can be divided into three stages:

I. Initiation of the litigation process
   A. Notice of an occurrence likely to lead to litigation
   B. Notice of events which suggests that litigation is imminent: handling requests for medical records
   C. Service of the summons and complaint: initial meeting with counsel
II. The discovery process
   A. Written discovery
   B. Your deposition
III. Trial

Initiation of the Litigation Process

Notice of an Occurrence Likely to Lead to Litigation

The litigation process may commence in a number of ways. First among them is the unexpected occurrence of something adverse to your patient.

Something happens during surgery or in the postoperative period which you believe may lead to a lawsuit. At surgery, an adjacent organ or vessel is punctured; there is profound blood loss or spillage of bowel contents resulting in significant compromise, or there is even an unexpected patient death. In the immediate postoperative period or even after discharge, the patient becomes septic and decompensates. Imaging demonstrates a previously unappreciated rent in the bowel. The patient is taken back to surgery at which time the rent is identified and repaired, but the patient has a rocky course. Or several months or even years after bowel resection surgery, you notice, for the first time, that the pathology report had identified a potentially malignant lesion for which no additional investigation was conducted.

In these instances, the litigation process may be said to be initiated by you, in anticipation of litigation. When these adverse events occur, the important thing for you to recognize is that there are preexisting protocols and procedures in place for you to access which have been established for just such events. The purposes of those protocols and procedures are twofold: (1) to accumulate and preserve the necessary evidence about the event in a timely manner and (2), as appropriate, to protect the evidence from undue disclosure to the opposition by veiling it within the cloak of one or more legal privileges.

Know the reporting procedures for significant clinical events of your hospital, your medical staff, your risk management department, and your malpractice insurance company. These will typically include voluntary or mandatory

incident reporting which are in place for purposes of quality assurance or for reporting of events which will likely lead to litigation.

Although evidentiary rules vary among state and federal jurisdictions, as a general proposition, when a hospital, medical staff, or even an insurance company has in place a preexisting procedure for reporting such events for quality assurance purposes, any statement or disclosure made in furtherance of that purpose of quality assurance is privileged from disclosure as a matter of public policy [3]. Likewise, statements made to a risk management department or to an insurance company representative in anticipation of litigation are typically protected from disclosure by the attorney work-product privilege (which is different from the attorney-client privilege).

Whether either of these "pre-litigation" privileges will apply to a physician's disclosure depends on *why* the disclosure is being made. For example, the quality assurance privilege belongs to the hospital or its medical staff. The hospital or medical staff is deemed the "holder" of the privilege. It is the hospital and medical staff's obligation to conduct periodic and incident reviews of its staff's conduct and to investigate significant or "sentinel" events. To fulfill those duties, the hospital and its medical staff have procedures in place for these events to be reported. The goal of these procedures and the attendant privileges is to promote candid disclosure and discussion, which may be adversely affected if the participants are fearful that any statement made can or will be used against them later in litigation—thus the privilege. Therefore, *if the reason* the physician discusses or reports an event is pursuant to preexisting hospital protocol to ensure that an adequate investigation of the event occurs, the physician's disclosure is deemed to be in furtherance of the quality assurance process, and generally, that disclosure will be protected from later discovery. Application of the privilege depends on the physician's mindset when the statement is made.

Teaching Points

- By knowing the hospital's or medical staff's quality assurance and reporting procedures, a physician can tailor his disclosures and, later, his deposition testimony to be consistent with those procedures. At deposition:
  - Q. "Did you discuss what happened in surgery with anyone?"
  - A. "Yes."
  - Q. "With whom?"
  - A. "I told the operating room supervisor and the chairman of the department."
  - Q. "Why them?"
  - A. "Because I understood that the hospital quality assurance department requires that these kinds of events be reported and investigated."
  - Q. "What did you tell them?"
  - By defense attorney:
  - "Objection, quality assurance or peer review privilege."

Unless the physician understands that such procedures exist and knows the reporting requirements of those procedures, the physician may not be prepared to provide the necessary foundation to invoke the privilege. The foundational question to establish the privilege is: "Why did you make the disclosure?" The foundation for the quality assurance privilege is established if the disclosure was made in furtherance of an existing and known hospital or medical staff policy.

Similarly, in anticipation of litigation, malpractice insurance organizations and risk management departments have procedures in place for the physician to report adverse occurrences so that an investigation into the matter can occur while memories are fresh and potential witnesses and other evidence are available. The purpose of these pre-litigation procedures is to accumulate reliable evidence that, if litigation does ensue, can then be produced to the assigned counsel to promote the physician's defense. The rationale of these pre-litigation reporting procedures is that it is anticipated that the physician's attorney will need, and therefore will request from his physician client, a *summary of the occurrence*. This request for a summary of the occurrence will be better served if the summary is prepared soon after the event. Memories fade. Reports made to the insurance company early, without waiting for a formal claim to be made, may be more reliable. Thus, insurance companies have established early reporting procedures in anticipation of the attorney's needs. It is recognized at law that the insurance company collects these pre-litigation reports in furtherance of the physician's defense as an ostensible agent for, and on behalf of, the attorney—even though the attorney has not yet been retained.

Because the pre-litigation reports are presumably being collected on behalf of the attorney, the collection of these reports by the insurance company is deemed to be the "work product" of the attorney. Although there are exceptions, generally, these reports are protected from disclosure by the attorney work-product privilege, much like disclosures made by the physician directly to the attorney are protected by the attorney-client privilege.

Summaries prepared by the physician on his own, outside of the medical chart, may be protected if, but only if, the summaries are being made in anticipation of a request from the malpractice insurance company, or in anticipation of a request directly from the attorney, and are kept confidential.

Teaching Points

- To avoid question as to why you are preparing a summary of the events outside the medical chart and thus to bolster your position that the summary is protected by the attorney work-product and attorney-client privileges, begin the summary with, "The following summary is being prepared in anticipation of litigation, to be provided to my attorney when litigation commences." Ask your malpractice insurance company if it has forms for you to use for such a purpose.

Caveat

- Privileges can be waived. Summaries prepared in anticipation of later disclosure to the attorney can only be protected if they are kept confidential. Disclosure of the summary to others who are not in the line of communication with the insurance company or attorney likely will waive the privilege. For example, placing the summary in the patient's hospital or office chart, where it is open to review by hospital or office staff, defeats the presumption of confidentiality. The summaries must be kept separate and apart from the chart and may not be disclosed to others.

Teaching Points

- By knowing the malpractice insurance company's procedures for collecting statements from its physician insureds, the physician can anticipate that request and prepare a summary in a timely manner. By knowing that the statement must be kept confidential, the physician can take appropriate steps to assure that the statement is not disclosed to others or placed in the patient's chart. At deposition:
  - Q. "Did you prepare a summary of the events?"
  - A. "Yes."
  - Q. "When?"
  - A. "The day after the surgery."
  - Q. "Where is the summary?"
  - A. "I gave it to my insurance company."
  - Q. "Did you keep a copy?"
  - A. "Yes."
  - Q. "Have you shown it to anyone else?"
  - A. "Yes."
  - Q. "To whom?"
  - A. "To my attorney."
  - Q. "Have you shown it to anyone else?"
  - A. "No."
  - Q. "Where is your copy?"
  - A. "It is in a locked drawer in my desk."
  - Q. "Why did you prepare the summary?"
  - A. "I was told by my insurance company that when unexpected adverse results occur, I should prepare a summary of the events and maintain it confidentially for later use by my attorney."
  - Q. "Show me a copy of the summary."
  - By defense attorney:
  - "Objection, attorney work-product and attorney-client privilege."

The work-product privilege may also apply to discussions among the physicians in a group practice, if the statements are made in furtherance of an established (and preferably written) preexisting policy of the group which provides that such events are to be reported to the president or general partner of the group, so that they can then be reported to the malpractice insurance company or the group's attorney.

Notice of Events Which Suggest that Litigation Is Imminent: Handling Requests for Medical Records

You may be placed on notice of ensuing litigation for the first time by the patient or her attorney requesting a copy of her medical records from you (as opposed to asking that a copy of the records be provided to another physician for future care) or by the patient asking that a copy of her records be sent to an attorney. These requests must be handled carefully and consistently. The response to the request should include everything that is being requested. If requested, this must include the entire record. Once litigation ensues, you will be asked again to produce your records. The record produced then will no doubt be compared to the record produced to the patient when first requested. Any difference will need to be explained. Additions or deletions to the record which are found in the later production can be devastating to your case.

The law allows the patient to obtain a copy of his medical record from his physician. This may seem to be a simple task; yet, the prevalence of electronic medical records (EMR) has made this task anything but simple. To respond to a request to produce the office patient chart from an EMR, the medical record is "created" by someone sitting at a terminal and choosing which screens to print. That person decides what is, or is not, part of the record. The terminal operator will decide whether to include clinical notes; referral, demographic, or insurance information; and data imported from outside sources (e.g., operative reports or consult notes from referring physicians or hospital consultants). The terminal

operator will decide whether to include billing information or scheduling information.

The operator will also decide whether or not to include metadata. Metadata, or "data about data," exists in the EMR at several levels. The clinical record reflects the substance of the medical record entry—a history taken or examination findings. The metadata will include an entry log for that data, including when it was entered and by whom. At another level, the metadata may include a "comment" section for the entry. Consistent production of records requires a consistent definition of what is part of the patient's "medical record," as opposed to what is merely part of the office "administration" record. The production request and/or the laws of your jurisdiction will define the scope of the request and, therefore, will define the scope of the physician's obligation to search for, create, and produce the "medical record."

In the context of litigation, a party or his custodian of records will be asked to verify under penalty of perjury that the records produced in response to the request are a true and complete copy of the entire record as requested. That verification serves the formal evidentiary purpose of certifying that this is the complete record and that it may be used as such by any party to the litigation from that point forward, up to and including at trial. You or your staff may be questioned about the production or about any perceived inconsistencies or inadequacies of the production in deposition or trial. To be an effective witness, you and your staff must be able to rely on the production. Effective preparation to be an effective witness on this issue requires that consistent procedures be in place and followed.

It is also important that there be a process in place by which the physician is notified that a patient has requested her own records or has requested that a copy of the records be provided to an attorney. In that case, the physician should acquaint himself or herself with the patient to determine, at least preliminarily, whether this patient suffered an unexpected complication that could reasonably lead to litigation. If there is concern about litigation, it is prudent for the physician to contact his insurance company or attorney and ask for direction.

Teaching Points

- Have a formal, written procedure in place which defines the scope of your medical record for purposes of responding consistently to medical record requests on a day-to-day basis. Speak with your attorney to learn exactly what you are obliged to produce in response before you respond to a medical records request made in the context of active or anticipated litigation.
- Systematically check to confirm that your policy is being followed consistently.
- Be sure that whoever verifies the response knows the office practices for "creating" the medical record and can appropriately verify that the procedures have been followed.

Service of the Summons and Complaint: Initial Meeting with Counsel

The formal civil litigation process starts when the patient files a complaint, has a summons issued, and personally serves the summons and complaint on the physician, giving the physician notice that he has been sued. The procedural requirements relating to how specific the allegations of the complaint must be vary widely depending on the state or federal jurisdiction in which it is filed. Local rules may require that the complaint be specific and detailed and that it be verified (sworn to under penalty of perjury). More often the procedural rules only require that the complaint be specific enough that it identifies who the plaintiff is, who the defendants are, the relationship among the plaintiff and defendants that creates the duty or obligations among them out of which the claim arises, the manner in which the duty was breached or the obligations unsatisfied by the defendant(s), a statement relating to the classification of injuries suffered, and a statement, or prayer, at the conclusion of the complaint outlining the categories of damages sought.

In a medical malpractice case, the plaintiffs named will include the patient and/or affected family members. The defendants will include any one or more of the healthcare providers who attended to the patient's care and typically will include the facilities where the care was provided. The healthcare providers may include the individual physicians, the physicians' corporate or partnership entities or groups, and the physicians' attendant staff, such as nurse practitioners or physician's assistants. In appropriate cases, defendants may include medical instrument manufacturers or suppliers.

The required statement of the relationship among the parties which creates the duty or obligation may be general ("The defendants and each of them undertook to provide the patient's medical care. . . ."), or it may be specific ("On or about January 1, 2015, Dr. A performed a colectomy with anastomosis. . . .").

The statement outlining the breach of that duty may also be general or specific. The statement must, however, provide the defendant with notice of the classification of wrongdoing, which the plaintiff is alleging. The classification of wrongdoing is called a *cause of action*. In most cases, the cause of action stated is medical negligence or medical malpractice.

Extraordinary causes of action may also be alleged, and there may be subtle differences among the causes of action

which are important to recognize. For example, in most jurisdictions, failure by the physician to obtain the patient's "informed" consent prior to surgery is a type or subcategory of negligence. The complaint may set out a separate cause of action for failure to obtain informed consent, but in reality, this is a specification of the allegation of negligence. The elements of the cause of action and recoverable damages mirror those of a medical negligence cause of action.

A claim for failure to obtain "informed" consent must be distinguished from an alleged failure to obtain the patient's consent to perform the surgery which was performed or a claim that the surgery that was performed was substantially different from the surgery to which the patient consented. Performance of a surgery without actual consent is battery, an unconsented-to touching. The allowable damages in a battery cause of action can be substantially different from the damages allowed in a negligence claim. Damages in a battery cause of action may include punitive damages, awarded to punish the defendant rather than to compensate the plaintiff.

In most jurisdictions, battery is considered an intentional tort. The claim of battery in the complaint may create significant insurance coverage issues, as your medical malpractice insurance contract may contain an exclusion for intentional tort claims. The laws of your jurisdiction may not allow an insurance company to indemnify you for damages awarded for battery or for any other cause of action for intentional torts.

Similar concerns arise relating to claims couched in terms of fraud, concealment, or intentional infliction of emotional distress. For example, a patient might allege that the physician fraudulently concealed from her the injury to the adjacent organ which occurred during the surgery. Is the plaintiff alleging mere medical negligence, or is she claiming fraud?

Usually, the caption of the complaint will list the causes of action which are contained within the body of the complaint, but this isn't always true.

The allegations of injury, likewise, may be specific or general, depending on the jurisdictional procedural requirements and the plaintiff's lawyer's preference. The categories of injuries suffered generally include general damages or noneconomic damages for physical or emotional injuries (e.g., pain and suffering) and special damages or economic damages for calculable injuries for past and future medical expenses and/or for past and future loss of earnings, earnings capacity, or financial support. In the appropriate case, future medical expenses may include the cost of medical monitoring, for example, when the claim is based upon a delayed diagnosis of cancer for which monitoring for recurrence is advised. Each of these categories of damages is classified as compensatory damages—damages awarded to compensate the plaintiff for actual loss.

The classification of damages is important, especially as between general/noneconomic damages, such as pain and suffering, and special/economic damages for specific, calculable economic losses (medical expenses and loss of earnings). In several jurisdictions, the classification of damages will determine whether the plaintiff's recovery is "capped" or limited to a specific maximum number as a matter of statutory law. The statutory maximums usually apply only to general, noneconomic losses. Likewise, a defendant's liability for damages may be limited to his or her proportionate fault for general, noneconomic damages, the so-called several liability, whereas each defendant who is held liable at all or in any proportion (even 1%) for the *all* of the damages awarded to the plaintiff for special, economic damages, the so-called joint liability.

When extraordinary causes of action are included in the complaint (e.g., to include claims of willful misconduct such as battery or fraud), the categories of damages requested may be expanded to include punitive damages. Like criminal penalties, punitive damages are awarded to punish the defendant financially, with the secondary effect of deterrence of similar conduct in the future. To punish or deter, the damages must "hurt." Thus, the damages awarded must be in some proportion related to the defendant's wealth. The defendant's income and total financial assets become relevant, and therefore, at some point during the trial, the court may require the defendant to disclose his personal financial information to be used by the jury to calculate just how much must be awarded in punitive damages against that defendant to serve the purposes of punishment and deterrence. Moreover, it is because punitive damages are imposed to punish and deter *the defendant* that public policy precludes an insurance company from indemnifying the defendant from such damages.

The presence of extraordinary causes of action within the complaint creates insurance coverage issues and potential personal financial exposure for the defendant physician. The physician needs to be counseled early on in the litigation about these possible ramifications, so that the issues can be managed effectively.

Once the complaint is filed, a summons is issued. The right of the court to "summon" citizens to answer charges brought against them is rooted in the procedures of English common law. A defendant is deemed "summoned" to respond after proper service of the summons and complaint. The methods of effective service and the time and manner in which the served defendant must respond are established by the state's local procedural laws. The time in which to respond begins to run once the summons and complaint have been served on the defendant.

The complaint will identify each of the defendants who are being sued, but it is the summons which identifies who, among the defendants, is being served and, therefore, who is

obliged to respond. For example, the complaint may name as defendants an individual doctor, the doctor's personal corporation, and the doctor's practice group. That's three different defendants. To effect service on each of the three defendants, the plaintiff will have issued and served three different summonses.

If you practice as an individual doctor, have established a personal corporation (e.g., Dr. Smith, Inc.), and belong as part of a group practice and you are sued in each capacity, you may be served three different times. You will receive three summonses, which may appear identical, except that on one line, which identifies "person served," the wording will be slightly different. A separate copy of the complaint will be attached to each summons. Your attorney will need to obtain copies of all three sets of documents, even though they may appear identical to you. Keep all documents with which you are served and forward each set of documents to your insurance company or attorney as soon as you receive them.

The time allowed for the defendant to file responsive pleadings is short, usually 30 days or fewer from the date of service of the summons and complaint. Before responding to the complaint, the defense attorney must analyze the complaint and the relevant facts and law to determine, among other things:

- Who has been sued?
- Have the defendants been properly identified?
- Was the complaint timely filed, or is it potentially barred by the statute of limitations?
- Has the complaint been timely and properly served, and upon whom?
- Are the causes of action adequately pleaded?
- Does the complaint raise extraordinary causes of action, which require special handling or counseling?

Based on this analysis, the defense attorney will determine whether a routine response, an answer to the complaint, is appropriate or whether a more involved pleading is necessary to challenge the scope or validity of the claims being made. This analysis and the preparation of a formal response by the attorney take time. The time allowed by law is short, so the process must begin as soon as possible. This requires that the physician notifies his attorney or insurance company of the service of the complaint as soon as possible.

Teaching Points

- You and your office need established procedures to handle legal documents and filings.
- When a summons and complaint is received, keep the envelope in which it was served.
- Make a notation of when specifically (date and time) it was received and how it was received (by mail or in person).
- Look on the summons to determine who has been served (the doctor, the doctor's corporation, or the practice).
- Notify your insurance company or attorney immediately, and provide a copy of the summons and of the complaint to them.
- Review the complaint to determine whether any extraordinary causes of action (anything besides medical negligence or wrongful death) are listed on the first page of the complaint.
- Look at the last paragraph of the complaint, the prayer, to determine which categories of damages are being requested.

If you haven't heard from an attorney within 10 days of providing a copy of the complaint to your insurance company, contact the insurance company to identify who has been retained on your behalf. Request that the attorney contact you immediately to discuss any concerns you may have about the timeliness of the complaint and the proposed response:

- Confirm with the attorney that an appropriate and timely response has been or will be made on your behalf.
- Confirm that an appointment with the attorney is made, and ask what you need to have available at that first meeting.
- Create a file separate and apart from your medical chart, and keep a copy of the complaint and any other legal correspondence in that separate file. This is also where you should keep any summaries you may have created in anticipation of litigation.
- Do not speak with anyone (including your partners or office staff) or do any independent research relating to the case, until you have received directions from your attorney.
- Do not alter or supplement your records in any way; *I repeat, do not alter or supplement your records in any way*.

The attorney's first task is to acquire a very basic understanding of the nature of the claim and to respond to the complaint. The procedural rules of the jurisdiction will dictate how specific the response or answer to the complaint must be, just as the rules define how specific the allegations of the complaint must be. The rules may require a point-by-point response admitting or denying each allegation contained in the complaint, or it may require that the defendant merely file a general denial—a summary statement denying each and every allegation of the complaint without specification. Some jurisdictions require that the defendant verify the

pleading by signing the answer under penalty of perjury, confirming that the admissions or denials contained in the answer are true.

A point-by-point response may be a time-intensive process for the attorney and the physician-defendant, as each allegation is considered in light of the then-known information. It may require more than one conference and sifting through medical records. On the other hand, if only a general denial is required, the physician may play no role whatsoever in preparation of the responsive pleadings. The pleading requirements of the jurisdiction should be part of the initial contact between the attorney and the physician, so that the physician will know what is expected of him in this process.

In general, the responsive pleadings will serve to notify the court and opposing counsel that the defendant denies any wrongdoing, that the defendant disputes that anything he has done or failed to do has caused any injury to the plaintiff, and that the nature and extent of any injury alleged to have been suffered are disputed as well. In other circumstances, the responsive pleadings may set forth a legal challenge to the form of the complaint or the adequacy of its allegations to support the cause of action alleged. It may challenge the timeliness of the claim, with a contention that the allegations within the complaint itself establish that it is barred by the statute of limitations. It may challenge the right of the plaintiff to seek extraordinary damages such as attorney's fees or punitive damages, if the complaint contains prayers for these categories of damages.

Successful initial legal challenges to the complaint are rare. The overwhelming public policy is that all factual disputes between the parties are to be decided by a jury, in a trial, after the parties have had an adequate opportunity to conduct discovery in preparation for trial. Judges don't determine what the facts are; juries do. Judges decide what the law is and apply the law to the facts as determined by the jury. Therefore, in deciding whether to sustain or overrule an initial challenge to the complaint, the judge may not adjudicate any factual dispute. The judge must accept as true what is alleged in the complaint. A defendant's legal challenge is sustained only if, "accepting everything alleged in the complaint as true," the defendant's challenge is still valid.

This legal standard is particularly frustrating to defendants when the complaint includes allegations which are patently false. The plaintiff alleges that the physician undertook the subject surgery without his informed consent, without discussing the risks, benefits, or alternatives, and alleges further that if she had been told that there was a risk of injury to an adjacent organ she never would have consented to the surgery. You recall specifically speaking to the patient about the massive adhesions you expected to encounter and the attendant risks of injury to adjacent organs. You recall discussing the relative advantages of laparoscopic versus an open laparotomy approach, specifically as regards potential injury to adjacent structures. Your office medical record for the preoperative encounter includes a detailed note in your own hand outlining your discussion of these very risks and alternatives. Your chart includes a two-page detailed consent form which you and your partners have developed over the last 15 years, outlining the specific risks and alternatives, initialed by the patient in three different places and signed and dated by the patient and an office staff member. There is a similar document signed by the patient in the hospital. Yet, your lawyer tells you, and correctly so, that you have no right to bring this evidence to court at the pleading stage to challenge the complaint. She tells you that despite all existing evidence to the contrary, because the complaint says that you didn't obtain informed consent, the judge (as opposed to the jury) must accept as true that the issue of informed consent is in dispute, and this issue cannot be decided by the judge at the pleadings stage.

Your patience will be similarly tested repeatedly throughout the litigation process. You will repeatedly inquire "What's going on?", "Why is this taking so long?", and "Why hasn't this ridiculous case been dismissed already?" You will be told "These things take time" or "It doesn't work that way" or "There's nothing else we can do for now."

You've read in the complaint that you are being sued for unspecified amounts, based on what you know, or at least perceive, to be unfounded allegations, and now your lawyer is telling you that there is nothing you can do about it "for now." Rather, you must wait until the case or any issue in it is ripe for adjudication, and this may not be until trial. You are overcome by an overwhelming since of frustration, and justifiably so.

The frustration quotient establishes:

$$\text{Frustration} = \text{Responsibility} \ / \ \text{Authority to Act}$$

To avoid frustration in any situation, it is imperative that someone who bears the responsibility for an outcome should also have the authority to act as to effect a *best result*. The king was rarely frustrated. He could simply deny responsibility for anything while maintaining complete authority over the kingdom and his subjects. Surgeons undertake great responsibility for surgical outcomes and patient well-being. Their frustration level is manageable because, generally, the surgeon has the authority to act to effect a positive surgical result. That is the circumstance to which the surgeon has become accustomed. The duty and authority to act to fix the problem is ingrained in the very being of a surgeon and is the only way to avoid intolerable frustration.

On the other hand, surgery and the healing process can be terribly frustrating for the patient, who perceives herself to be helpless and totally dependent on you for her care. To help reduce that frustration, it is incumbent on the surgeon to educate the patient to manage expectations and to maximize her chance for a favorable outcome. The patient must be told in

advance for how long she will be bedridden or unable to return to her activities of daily living and what she can do to accelerate her healing process.

In litigation, the physician-defendant's authority to act is muted by the procedural processes. Initially, the physician-defendant may feel helpless and totally dependent on his attorney. Frustration abounds.

What can you do? Just as you educate your patients so that they can manage their anxiety and frustration, you must seek to educate yourself about the litigation process and manage your expectations and efforts accordingly. This can only be accomplished with an open dialogue between attorney and client. While you may not be able to run to court and protest your innocence, you don't need to sit by idly either. Speak with your attorney. Know what your role is, learn what will be expected of you and when, ask what can you do to best prepare yourself to succeed in your role, and, as importantly, ask what you should avoid doing so as not to inadvertently undermine your case.

There *are* things for you to do to achieve your *best result*. You have the authority to prepare yourself as directed and to manage your own expectations within the parameters of the process. This can and will reduce your anxieties and frustration level.

Teaching Points

- At the initiation of litigation, learn what you can do affirmatively to achieve *your best result*.
- Speak with your attorney early. Ask whether he intends to challenge the legal adequacy of the complaint. Ask what you need to do "now." What information and records need to be assembled? This not only includes medical records but also increasingly includes fax, e-mail, and office telephone or cell phone billing records to establish the existence, date, time, and substance of communications between you and the patient or hospital staff.
- Learn how long the process is expected to take. The estimate you receive may be broad, but it will provide you with some reasonable expectation. Tell your attorney how you would prefer to be contacted: office or personal cell phone. Tell your attorney what mailing address to use: office or home. Tell your attorney whether there is someone in the office other than yourself who can be contacted regarding the case, e.g., an office manager, or if all communication should be with you only.
- Ask when it will it be necessary for you to be personally involved. Are there court hearing dates or deposition dates pending at which you must appear? Is a trial date set? If not, find out how much notice will be given to you when your personal attendance is necessary. Tell your attorney about any plans you have to be out of the area for any significant period of time for vacations or conferences. Update your attorney when new plans are made or when plans change.
- Be patient! This will take time.

The Discovery of the Process

Written Discovery

In most jurisdictions, claims for medical malpractice are resolved in a jury trial. From the time the complaint is served on the defendant until jury selection is commenced, the parties to the lawsuit and their attorneys participate in a formalized accumulation and exchange of information which ultimately will be used at trial to educate the jurors about the relevant facts of the case. This is the discovery process.

To conduct discovery, the attorneys invoke legally sanctioned discovery procedures and the authority of the court to enforce those procedures, including the court's subpoena power. Basically, the law allows a party to subpoena or formally request relevant documents, such as medical records or employment records. The law allows parties to serve written inquiries to opposing parties, usually in the form of written questions called interrogatories. Most importantly, the law allows parties to interview opposing parties or witnesses under oath by way of deposition.

The procedural law of each jurisdiction sets forth in detail the manner in which parties may conduct this discovery. What the physician-defendant needs to know is that the discovery process is to be taken seriously as it has serious consequences.

Any party to a lawsuit may request information from any other party in the form of written interrogatories. The process is controlled by local rules of procedure. Some jurisdictions have created form interrogatories approved by the judicial council of that state. The form interrogatories cover a wide range of topics, which may or may not be relevant to the specific case. The attorney who propounds the interrogatories (i.e., asks the questions) simply checks the boxes on the form relating to the questions to be answered. The rest of the questions on the form can be ignored.

Other jurisdictions do not have judicially approved interrogatories, so that the attorney propounding the interrogatories must formulate the specific questions. Jurisdictions which use judicially approved interrogatories allow the propounding attorney to supplement the judicially approved interrogatories with special interrogatories, specifically drafted by the attorney, but maintain limitations and rules of procedure to do so.

By using judicially approved form interrogatories, the propounding party avoids objections as to the form of the question (e.g., vague, ambiguous, overbroad), which streamlines the process substantially.

The scope of the inquiry allowed by interrogatories is extremely broad. It includes personal and biographical data; insurance information; factual data relating to the underlying occurrence and medical care; information relating to potential witnesses and to legal issues such as contentions of negligence, causation, or damages; or affirmative legal defenses such as the statute of limitations.

Interrogatories are directed from one party to another. Although the interrogatories are directed to a party, the interrogatories are deemed to be directed to the party's attorney as well. The responding party is obliged to include within his response non-privileged information which is known or reasonably obtainable by the party "by inquiry to other natural persons or organizations, except where the information is equally available to the propounding party" [4]. Therefore the response must include information which the responding party may obtain by a reasonable inquiry to his office staff and his attorney. The responding party and his attorney are required to make a good faith search through the medical chart, the physician's personal files, and the attorney's files.

The local rules of procedure dictate the form of the questions and the timing and form of the response. Typically, the responding party must serve the responses within 30 days of his attorney's receipt of the questions. A party may request an extension of time within which to respond. The extension can be obtained by mutual agreement of the parties or, if necessary, by the responding party's going to court and requesting a court order granting additional time by which to respond.

Within the time allotted to respond, much must be accomplished. The good faith inquiry necessary to respond should begin immediately. As the physician-client, you can expect your attorney to have in place office procedures to notify his clients immediately when interrogatories are served. That notification should include a copy of the interrogatories and clear instructions regarding the division of labor: which of the interrogatories the attorney is going to answer and for which of the interrogatories the attorney is requesting assistance from the physician-defendant.

The notification from the attorney should also include a timetable for the response. Generally, the attorney's notification will include a date by which the physician's preliminary responses are due to him. The attorney may also ask the names of key office personnel who may be the source of additional information. There should be an agreement between the attorney and physician-defendant specifying who will be in contact with these additional personnel. In each case, confidentiality must be maintained. Any person contacted must be told not to discuss the conversation or inquiry with anyone outside of the office management staff, the physician, the attorney, or the attorney's staff.

The attorney will organize the information from each of the sources and will draft formal responses to the interrogatories. These responses may include both objections to the interrogatories and answers to the questions. Once the responses are prepared, the responses will be presented to the physician-defendant for verification.

A verification is a signature by the responding party, made under oath or penalty of perjury, which, depending on local rules, may or may not need to be notarized. The signature attests to the accuracy and completeness of the information contained in the response, at least to the best of his or her knowledge.

Once verified, the responses become affirmative statements of the responding party. The other parties to the litigation may justifiably, and legally, rely on the responses as being complete and accurate. The parties may use the responses for any relevant purpose in the litigation, up to and including trial. In some cases, the response to an interrogatory may be used as an admission against that party and can be presented to the jury as such at trial.

One important purpose of interrogatories is for the propounding party to inquire about additional potential sources of information. This could include the names of potential witnesses or other sources of documents and records. The propounding party is entitled to rely on the response to include a complete list of these additional sources, to direct further discovery efforts.

Local rules of procedure provide sanctions and other consequences for a party's failure to provide timely and complete answers. For example, objections contained in the response may be deemed waived as a matter of law if the response was not served timely. Likewise, if the interrogatory has asked for the identity of witnesses (which could include office or operating room staff or assistants) and the responding party has failed to identify a specific potential witness, either out of inadvertence or because of a failure to conduct a good faith inquiry into the records, the responding party may be barred from producing that witness at trial.

It is rarely acceptable to simply respond that the requested information is equally available to the propounding party through alternative means (e.g., looking through the hospital records himself).

As with all aspects of the litigation process the interrogatory process may be time-consuming and burdensome. But it must be taken cautiously. Inadequate or inaccurate responses will be detrimental to your defense.

Teaching Points

- Expect that you will be asked to answer interrogatories.
- Expect that your responses will need to include biographical and personal data from you.
- Expect that you will be asked to include the names of witnesses to the occurrence including relevant office staff,

hospital staff, assistant surgeons, anesthesiologists, and consultants.

- You don't need to wait until you are served with interrogatories, and the time period for responses starts to run, before you begin compiling the necessary information. At your initial meeting, ask your attorney if your jurisdiction has judicially approved form interrogatories which are used by attorneys in that area or if there are other interrogatories which you likely will be asked to answer. Obtain a copy of the anticipated questions, and begin immediately to compile proposed responses. If the opposition will want this information, your attorney should have it as well, and soon.
- Obtain assurance from your attorney that you will be notified as soon as interrogatories are served and that the notification will include the date by when your preliminary responses will be expected. You also have the right to expect that your attorney will anticipate the need to respond to interrogatories and will have begun a search of the relevant data sources in advance of the interrogatories' being served. You also have the right to expect that your attorney will provide you with the proposed formal responses with sufficient time in advance of the deadline to respond so that you can go through the questions and answers with your attorney before you sign the verification.

You can expect that at deposition or trial, your responses to the interrogatories will be presented to you. You will be asked to confirm that the verification includes your signature. You will be asked about the scope of your inquiry before providing the responses and whether you read and considered the responses before verifying their accuracy under penalty of perjury. Therefore, conduct a good faith and thorough search in providing responses, and read and understand your responses before signing the verification.

There are other kinds of written discovery process as well, such as requests for admissions, requests for production of documents (e.g., insurance policies, office protocols, licenses, and certifications), or requests for authentication of documents. In each case, the procedures are similar to responding to interrogatories. Be sure that you understand the time parameters for response and the scope of inquiry which is necessary and that you have reviewed the proposed response before signing the verification.

Your Deposition

Unquestionably, the most important aspect of pretrial discovery for the physician-defendant is the deposition. Giving an effective deposition requires effective preparation, and you have the right to expect that your attorney will aid you in that preparation. It is likely that your attorney attends depositions weekly, if not more frequently. He may have represented physicians at deposition hundreds of times or more. He may be completely comfortable with the process. But this is *your* deposition.

The situation is analogous to taking a patient to surgery. As an experienced surgeon, you have taken part in hundreds, if not thousands, of surgeries before. You have a well-founded expectation concerning what you are about to undertake. However, this may be your patient's first surgery. As a surgeon, you have the responsibility of educating your patient concerning what the patient must do to prepare herself in advance to maximize the likelihood of success at surgery. You must educate the patient regarding what is likely going to occur during surgery, including the risks associated with the process, and you must provide the patient with a spectrum of potential outcomes so that the patient's expectations will be reasonable. You are the surgeon, but this is *the patient's* surgery.

The first step in preparing for a deposition is to know what a deposition is. A deposition is a recorded question and answer session during which the attorneys for all parties to the litigation, including the opposing party and all co-defendants, have the right to ask you questions. The scope of questioning is extremely broad. As a general rule, the witness may be asked questions concerning any topic which might be directly relevant to the case and concerning any topic which might be reasonably calculated to lead to the discovery of relevant evidence. In short, this is the one time that the parties are entitled to conduct a "fishing expedition." Be patient. The deposition may take hours or even days. Your performance in the last 1/2 hour is every bit as important as your testimony in the first 1 hour.

Your deposition may be a videotaped deposition. The party who schedules the deposition will give notice of whether he intends to videotape it. Be sure you know whether it will be videotaped and dress and present yourself accordingly. In your practice, you wear your lab coat, with physician designation. This may or may not be appropriate when presenting yourself for deposition. One issue you will want to discuss with your attorney in advance is what to wear.

The use of videotaped depositions is becoming more prevalent in recent years. I've never thought it necessary for a physician to wear a lab coat in deposition; however, my opinion on this is changing. Jurors are patients. Patients have an expectation of what physicians look like. The videotaping of depositions has two purposes: to intimidate the witness and to present a video record to the jury at trial. You are a doctor. You have the extensive education, experience, and license to justify your use of the title, "Doctor." Wearing your lab coat at deposition provides an ongoing reminder to the audience or jury that you have earned and maintained that status and that your testimony should be considered and

weighed, accordingly. Being a doctor doesn't necessarily make you more believable, but it should add weight to your learned observations and opinions.

It is unlikely that you will be asked to wear your lab coat at trial. The stark difference between your appearance in a lab coat at deposition and in a suit and tie at trial may make your appearance at deposition seem staged. The decision whether to wear your lab coat, or any other questions regarding your presentation and attire, should be discussed with your attorney. In all cases, you should present yourself in business attire.

A deposition is a "legal," "formal" interview. The legality of the process is established by local rules of procedure. Foremost among them is that prior to beginning testimony, the court reporter, who is a designated officer of the court for this purpose, administers the oath. The words may vary, but the upshot is that you are being asked to swear or affirm that the answers you are about to give in deposition "are the truth, the whole truth, and nothing but the truth…." (Notably, the attorneys who are asking the questions aren't under oath. However, as the deposition is in the realm of judicial proceedings, rules of professional conduct oblige attorneys not to make material misrepresentations of fact or law at deposition.)

At the conclusion of the deposition, a transcript of the deposition will be prepared by the court reporter. It will look like a script. The questioner will be identified, and a verbatim transcript of the question will appear. The question will be followed on the page with your answer. You will be provided with a copy of the transcript. Within the parameters of your jurisdiction's procedural rules, you will have the opportunity to review the transcript and to make any changes to your answers which you believe are necessary to accurately reflect your testimony. (You may not make changes to the questions, although you may note typographical or transcription errors.) Your changes may be to form or substance.

The court reporter may have misunderstood or mistranscribed a word or may have left out a word which you believe was spoken and which you believe is necessary for the transcript to accurately reflect your testimony. You may make those kinds of corrections.

You may also make substantive changes to your testimony. For example, you may have been asked at deposition whether, before proceeding to perform surgery, you took the opportunity to review the labs or consult notes. Consistent with your customary practices, you may have answered "Yes" to that question at deposition. Upon further review of the chart or upon further reflection after the deposition, it may become apparent to you that one of the consult notes didn't appear on the chart until after you began your surgery, so that, at least as to that consult note, your appropriate response should have been "No, it wasn't on the chart yet."

You may make that kind of substantive change to the testimony, but you must be cautioned that any substantive changes you make to the transcript can be commented upon by the opposing counsel at trial, and you may be asked why you gave a different answer at deposition. These kinds of changes can adversely affect your credibility at trial and may have an adverse effect on your case. For that reason, it is important that you give your best answers at deposition to minimize the need for changes later.

Because substantive changes can adversely affect your case, it is important that you consult your attorney before marking or making changes on the original transcript. A good practice is to make any proposed changes on a copy of the transcript or a different piece of paper and then to preview the proposed changes with your attorney before they are finalized.

Once you have reviewed the transcript and made any changes you deem appropriate, you are asked to sign the deposition under penalty of perjury. Your signed deposition transcript becomes your testimony, for the trial and for any other subsequent legal proceedings. (In some jurisdictions, there are provisions for use of an uncorrected or unsigned certified copy of the deposition as if it were a signed and corrected original. These provisions may apply if you or your attorney have not notified the court reporter or the parties of any proposed changes within the time limitations provided by law or if the signed original hasn't been returned to the court reporter within the time frame allotted by law.)

Because the deposition is a legal proceeding, you have the right to have counsel present. Whether you are being deposed in a case in which you are a defendant or simply as a witness, it is important that you be represented at the deposition by an attorney. If you are subpoenaed for deposition as a witness in which you are not a party, contact your attorney, risk manager, or insurance company, and ask for representation. Too often, a non-defendant witness is lulled into a false sense of security, appears at deposition without an attorney, and, without proper preparation or representation, provides potentially incriminating testimony which provokes the patient's attorney to name the witness as a new defendant in the case. Depositions are too important to be taken lightly. You need proper representation.

It is your attorney's job to prepare you for the deposition and to represent you at the deposition. Preparation is imperative, but it is important that you be guided by counsel in that preparation. As with many aspects of the case, preparation for the deposition begins with the initial meeting. It is very important that you understand what is expected of you in anticipation of your deposition. Know what your counsel wants you to review in preparation for deposition and what he doesn't want you to review. For example, the case may involve technical aspects of the patient's medical care, such as pulmonary issues or endocrine issues, which you, as a sur-

geon, may not have studied since medical school. You are familiar with the issues and general management, but not with the current state of knowledge regarding ventilation settings or esoteric thyroid stimulation medications. Before beginning a literature search on these or any issues, be sure that the attorney wants you to do so.

Typically, the attorney will want you to be familiar with the documentation which was available to you at the time of your treatment of the patient, as it would be this information which formed the basis of your differential diagnoses, and your treatment alternatives.

As discussed more fully below, the primary liability issue in a medical malpractice trial is whether the physician's care was negligent, i.e., was it below the applicable standard of care? Though language differs by jurisdiction, basically, the standard of care requires the surgeon to act as other duly competent and careful surgeons would act *under the same or similar circumstances.*

Though seemingly tautological, it remains true that *you* acted as you did under the circumstances which then existed. Presuming that you are a reasonable and competent surgeon and accepting that you acted as you did and intended to act, then your conduct under the circumstances that then existed is, by definition, within the standard of care: You, a competent and careful surgeon, acted as you did, under the circumstances as they actually existed at the time.

It is your job at deposition to fill in the facts necessary for your lawyer to make this argument. You must be prepared to testify to your qualifications and experience, as to establish that you are a reasonable, competent, and careful surgeon. You must also be prepared to testify regarding your knowledge of the facts that existed at the time of your treatment of the patient.

The single most effective way to cross-examine a physician-defendant (or an expert) is to establish that the facts which the physician-defendant believed to be true at the time of his surgery, and which formed the basis of his actions or opinions, were not the facts as they truly existed. In that case, the physician was acting under the facts and circumstances as he *thought* them to exist, not as they, in fact, existed. In that case, the physician loses the value of the tautological argument. Knowledge of new or different facts may not have changed the conduct, but it infuses doubt.

The relevant facts would include the patient's recent and distant medical and surgical history; the existence of any peculiar risk factors, comorbidities, or contraindications; recent lab values, imaging studies, or consults; or even something as simple as whether blood had been typed and cross-matched before surgery and was therefore available immediately, if needed.

By the time the deposition takes place, it is probable that you will have forgotten these details. With your attorney's assistance, refresh yourself, so that when questioned at deposition you can recount your knowledge of the relevant facts as they existed at the time, consistently and accurately. Ask your attorney to provide you with copies of the relevant records prior to the deposition so that you have the time and opportunity to refresh your recollection. But don't access additional records unless and until you are instructed to do so by your attorney. There are specific, strategic reasons for this advice.

In most instances, the deposition of the physician-defendant occurs relatively early in the litigation process. The physician-defendant is being deposed as a percipient witness to the occurrences which form the basis of the case. As a percipient witness, the scope of inquiry generally includes exploration of all percipient observations. In the litigation process, perception goes beyond the primary senses. In addition to what the doctor saw, heard, felt, smelled, or tasted, the physician is in the unique position of knowing and, therefore, to testify to *what he was thinking at the time of the events*.

Typically, inquiry into the physician's contemporaneous thoughts is fair game for deposition. Thus, not only he can be questioned regarding what he saw or read before surgery; he can also be questioned regarding his decision-making and thought processes. This would normally include any percipient opinions, opinions *which he came to at the time of his care of the patient* concerning what may have caused or contributed to the patient's adverse outcome.

Opinions which are developed based upon supplemented or retrospective analysis of the facts are expert opinions. They differ from contemporaneous or percipient opinions. While inquiry into *contemporaneously developed* thoughts or opinions is considered appropriate during the physician's deposition as a percipient witness, opinions reached since the litigation ensued, or made retrospectively in reconsideration of the circumstances in anticipation of litigation or in furtherance of the defense, may be handled differently. Again, this is dependent upon procedural differences among the various jurisdictions, but as a general rule, where a physician-defendant processes information in anticipation of litigation, which may include information obtained from the physician's attorney, the conclusions and opinions which are the product of those processes remain the work-product of the attorney, unless and until the physician's status as a witness changes from percipient witness to expert witness. This change in status usually changes in one of the two ways: (1) at the deposition, the attorney for the witness declares his intention to proffer the witness as an expert witness at trial, or (2) during the exchange of expert designations among the parties, the attorney for the physician formally discloses his intention to call his client as an expert. In that case, the plaintiff may have the right to depose the physician-defendant a second time to explore his expert opinions and the bases for those opinions.

Assuming, however, that it is not your attorney's intention to elicit expert testimony from you (or at least he is not in a position to declare his intention to do so on the day of your deposition), then the scope of your deposition will be limited to opinions you came to at the time of your care. In preparing for your deposition, understand the difference between percipient and expert opinions and whether either or both are subject to inquiry at your upcoming deposition.

At deposition, you will be asked questions concerning your recollection of facts and occurrences. The party asking the questions is entitled to your best current recollection of those facts, even if that recollection is cloudy, vague, or nonspecific. In addition, generally, the questioner is entitled to know what documents, if any, you have accessed or reviewed to refresh your recollection. And he is entitled to question you regarding those documents. For example, you may be asked what the estimated blood loss was during the procedure. You may recall that there was nothing significant about the blood loss, but otherwise you can't provide a reasonable answer. Or you may have recently reviewed the operative report in preparation for the deposition and noted that the stated blood loss was actually substantial and estimated to be 500 ml. Reading and being reminded by this note spark a memory, and you now actually recall that there was an estimated blood loss of 500 ml.

Arguably, your present testimony of the facts is dependent upon what the operative note says. You may, therefore, also be asked, "If the note had referenced an estimated blood loss of 800 ml, would that have been your testimony?" In other words, did the entry in the chart actually spark a memory from which you are now testifying, or are you merely accepting as true and accurate what is written in the chart? Are you testifying, or is the chart testifying?

If you are testifying from refreshed memory, you may be asked a series of questions about what it is about this entry that has sparked the memory. If you testify that you are merely accepting what is written in the chart, the follow-up questions may relate to how and when the document was prepared and stored, in an attempt to call into question the accuracy of the document, as opposed to the accuracy of your memory.

For these reasons, the questioner will almost certainly ask you to list all documents reviewed in preparation for the deposition or documents reviewed to help refresh your recollection of the events. Your attorney is going to want to know in advance of the deposition what you are intending to review or have reviewed; he is going to want to control the universe of information to which you have had access in preparing for the deposition. By doing so, he will have some control over the scope of allowable inquiry.

For example, you may want to brush up on your infectious disease medicine before the deposition, out of fear that you will be asked something in that area of medicine. If you do so, you may be questioned about what you reviewed and why. The implication may be that if you *now* believe that this information is important for you to know, why didn't you do your homework before the surgery? Don't conduct independent research before the deposition unless you are directed to do so by your attorney or without first consulting your attorney.

Similarly, it may be that your attorney has provided you with a summary of the records or of the deposition testimony of other witnesses. As a general rule, that information from your attorney is privileged. It was provided to you in furtherance of your defense, not to prepare you for deposition. Know in advance whether you are to review your attorney's correspondence before the deposition, and tell your attorney that you have done so, so that he can be prepared with appropriate legal authorities to support and to invoke the attorney-client privilege in a timely manner.

At deposition, the questioner is entitled to your best estimate of anything that can be quantified. How many surgeries do you do in a year? How long does it typically take you to get to the hospital from your home? How many lap sponges did you use in this case? How long did it take to perform this aspect of the case or that aspect of the case?

The questioner is not entitled to your speculation or to ask you to guess. Often the line between an estimate and a guess is difficult to define. Ultimately, at trial the judge is the arbiter of what information does or does not go to the jury. The first step toward admissibility is for the judge to determine whether the information is reliable. Speculation and guesses typically do not go to the jury because they aren't reliable. Therefore, fundamentally, the difference between an estimate and a guess is whether you have a reasonably reliable basis or evidentiary foundation for your answer. The foundation may include your observations and memory of the case; or it can be based on your customary practices.

To demonstrate the distinction, a lawyer may ask you to estimate the length of the table in front of you. You don't have a tape measure, but based on your ability to observe the table and your presumed fundamental knowledge of units of length, you can give an estimate. Your ability to see the table is the foundation necessary to provide your estimate. If you are then asked to estimate the length of the table in the attorney's private office, where you have never been, you lack the fundamental foundation to provide such an estimate. You may have knowledge about how long office tables usually are, but that is not the question. The question is: "How long is the table in this attorney's office?" You don't even know if there is a table in his office. Any answer you might give to that kind of question is pure speculation, and should not be offered. In that case, your answer should be a direct "I don't know."

This same principle would apply to any question posed to you relating to events or conversations you did not witness.

Likewise, you would rarely have a reliable answer to any question relating to the thought processes of other individuals. You may have knowledge of how nurses usually go about taking a history from a patient in the preop holding area. However, if asked whether a specific nurse asked a specific patient a specific question in this case, and you weren't there, the answer to that question is "I don't know, I wasn't there." It is not "Usually the nurse does ask that question." Let the nurse testify regarding what happened.

Similarly, you may have an understanding as to why a prior surgeon may have decided to do a direct repair of the colon rather than performing a diverting colostomy. Don't guess or presume what he was thinking; let him testify to his rationale. This will minimize the chance of inadvertent conflicts in testimony that could call into question the credibility of both witnesses.

The questions asked at deposition must be fair. To be fair, they must be relatively intelligible and unambiguous. You have the right to understand the question and to ask the questioner to rephrase a question if you don't understand it. Exercise that right. If you don't understand a question, ask for it to be rephrased until you do understand it. If you answer a question, the presumption at deposition and at trial will be that you understood it before answering.

Ambiguous questions are troublesome. The trouble is that certain words are inherently ambiguous, such that they may have different meanings in ordinary speech as opposed to how they are used in medicine. One such word is "emergency." In ordinary parlance, "emergency" is used to describe a potentially dangerous situation for the patient which may require immediate (another word fraught with ambiguity) action. In surgical scheduling parlance, however, an emergency surgery is any surgery not otherwise scheduled as an elective surgery.

You may be asked whether the surgery you performed was an "emergency" surgery. In fact, the surgery was performed in the early evening after all scheduled surgeries were performed that day. It was performed after all appropriate preoperative testing was performed as to confirm the diagnosis and indications for surgery. It was performed by the operating room staff who were regularly on duty at that time. No one was called in. All typical time and care were taken in preparation of the patient for surgery. In anticipation of the potential need for the surgery, the patient was kept NPO since the prior evening. From the standpoint of the surgeon, this was not an emergent situation, and it was not an emergency surgery.

Yet, there on the intraoperative nursing records and on the anesthesia record, the surgery is identified as "emergency surgery." Their designations are based not on patient acuity, but because it was not a scheduled surgery. However, if you answer the question "Was this an emergency surgery?" with an emphatic "No," the plaintiff's attorney will no doubt challenge you at trial with the records prepared by the other practitioners who said it *was* an emergency surgery. This could lead to uncomfortable explanations, contradictions, and perceived back-pedaling.

There are two ways to avoid this kind of situation. In my experience, one is much preferred. The first way to avoid this ambiguity is for the deponent (the person being deposed) to ask the questioner, "What do you mean by 'emergency?'" This kind of response may escalate the situation. The questioner responds, "Doctor, do you know what an emergency is?" To which the physician answers, "I know what an emergency is, but I'm not sure that you do…." This kind of dialogue is rarely productive and may be affirmatively destructive if the jury believes the physician is being obstreperous or evasive.

The second way to handle the situation, and in my opinion the far better way, is for the deponent to answer the question as asked, but to include in that answer his or her definition of the potentially ambiguous word or phrase to clarify his or her answer. This avoids the ambiguity, the dialogue, and any suggestion that the physician is trying to avoid answering the question:

Q. "Doctor, was this an emergency surgery?"
A. "If, by emergency, you mean a surgery which needed to be performed that hour or before thorough preparation could be made, no."

Or

Q. "Doctor, was this an emergency surgery?"
A. "If, by emergency, you mean a surgery which was not a surgery on the operating room's regular schedule, yes."

If the questioner wishes to reconstruct the question to define the word differently, he can do so, and you can answer the new question accordingly.

Adjectives and adverbs used by the questioner must always be considered for their potentially ambiguous usage. The usage may be innocent, but the usage of such words must be tempered with a thoughtful response.

The potential significance of the deposition process cannot be overstated. Once the deposition is completed and signed, it is your testimony. It can be used affirmatively by the opposition at trial to establish facts stated. It can be used by the opposition to contradict the testimony given at trial.

In most jurisdictions, the trial court will actually instruct the jury concerning the effect and significance of deposition testimony. The jury will be instructed in substance, as follows:

> The deposition is the testimony of a person taken before trial. At a deposition the person is sworn to tell the truth and is questioned by the attorneys. You must consider the deposition testimony that was presented to you in the same way as you consider testimony given in court [5].

The opposing party may, therefore, literally begin his case against the physician-defendant by showing a videotape of portions of the deposition. The jury must consider that deposition presentation as if the same testimony was given by you live in court. The most common use of the deposition at trial is to emphasize possible contradictions or inconsistencies in your testimony as impeachment.

In addition, your deposition testimony can be used against you in virtually any future proceedings whether those proceedings relate to the same case or if you are giving potentially conflicting testimony in some future case. For example, if there is an investigation of the occurrence by the state licensing board, they will typically request copies of any depositions taken in the case. Or, in the future, you may be retained as an expert in other cases. It is not uncommon for parties to a case to seek and obtain copies of past depositions given by the experts. Therefore, you could well be cross-examined concerning the testimony you are giving as an expert based upon the deposition testimony you gave in a case 5 years ago.

The deposition process is a "formal" interview. The process proceeds with question, answer, question, answer. The court reporter is obliged to report and transcribe the statements made at a deposition verbatim, in the exact order in which the statements are made. Thus, for example, if, in answering a question, you anticipate the end of the question and begin answering it before the questioner has completed the question, that is exactly how the transcript will read. This leads to broken, and potentially ineffective, testimony.

In addition, your attorney has a job to do at the deposition. That job is to assure that the questions asked are appropriate as to form (relatively clear, unambiguous, and not argumentative). The attorney must also assure that the question does not call for the disclosure of privileged information which would be subject to objection. The attorney cannot do his job if you do not allow some interval after the question is asked before you begin your response.

Wait until the questioner has completed his question. Think before answering. Respond to the question directly and succinctly.

Answer the question which is asked. This would seem to be a simple instruction, easy to follow. In my experience, however, it is the instruction which my clients find most difficult to follow. The deposition process is in the form of an interrogation. It is not a conversation. In conversation, people often answer the question which they assume is being asked rather than literally answering the question which is asked. That is not the process of a deposition.

In conversation, you are asked, "Do you know what time it is?" In response, you look at your watch or your cell phone, note the time, and respond, "About 2:30." A perfectly appropriate course in conversation but a perfectly inappropriate course in deposition. The question was, "*Do you know* what time it is?" The answer to that question is "Yes" or "No." By answering the question in a conversational manner, you have not only not answered the question which was asked; you have potentially provided the questioner with invaluable information to which he was not entitled by asking the question he asked.

You have demonstrated that you use a watch as your timepiece or that you have a smart phone. Demonstrating that you have a smart phone could lead to a series of conversations concerning to what additional sources of information the smart phone is tied. Do you receive texts on the smart phone? Do you receive e-mails otherwise addressed to your office on the smart phone? Do you use the smart phone for your pages? This then could lead to additional discovery concerning your smart phone records, especially if the timing or duration of telephone calls ultimately becomes an issue.

This is not to say that the same information might not otherwise be gleaned if and when the appropriate questions are asked. It is to say that the opposition is not entitled to open that door by simply asking, "Do you know what time it is?" Don't invite him in.

Invariably, when cases go to trial, the physician-defendant reviews his deposition critically. As invariably, when reviewing the deposition, the physician will note several potentially harmful answers which could have been avoided if he or she had simply answered the question asked.

The doctor is asked, "Did you examine the patient's abdomen?" The physician responds "I don't recall, but I usually do, and note my findings in the chart." A quick review of the chart by opposing counsel reflects no examination. Rightfully or wrongfully, the implication based on your expanded answer is that since no examination was recorded, no examination of the abdomen was made—all because the physician failed to restrict his answer to the question asked.

This is not to say that every answer should be "Yes" or "No." In fact, from time to time, it may well be appropriate to provide a more comprehensive response to the question. For example, the question is, "Did you examine the patient's abdomen?" The physician responds, "I don't recall." The next question is: "When you examine the abdomen, do you chart your findings in the records?" The response is, "Sometimes I do; sometimes I don't." The physician would like to expand the answer to indicate that whether or not he charts his examination may be dependent upon his findings. He would chart any abnormal findings but would not necessarily chart the absence of significant findings. The proper way for a witness to expand his answer is not to simply continue to talk. A better way to expand the answer is to remark, "May I explain?" If the questioner responds "Yes," the physician has the opportunity to expand his answer with notice of his intention to do so to his attorney. If the questioner says "No," thus restricting the doctor's opportunity to explain his answer, that can certainly be noted at trial by your attorney.

Finally, thanks to hours of television police shows, we all know the basic Miranda warning, "You have the right to remain silent, anything you say can and will be used *against* you in a court of law." These Miranda rights relate to criminal proceedings. In a civil proceeding, such as a claim for medical malpractice, you don't have a right to remain silent, so you must appear and respond to questions at deposition. It remains appropriate, however, to know that everything you say at deposition can be used *against* you at trial. The deposition is a tool for your opposition; rarely can it be used by your attorney. Every word spoken is potentially an arrow going straight from your mouth to the opponent's quiver, to be loaded in his bow and shot back at you if and when he sees fit to do so.

The foregoing is in no way intended to suggest that you should unduly limit or manipulate your answers. It is important that you answer the question which is asked, and not expand your answers unnecessarily. Yet, in all respects, you must feel free to answer all questions truthfully and, as necessary, to include within your response all information which you believe is required to give a thoughtful, complete, and meaningful response.

Teaching Points

- Always consult with counsel before a deposition, and be represented by an attorney at a deposition, whether you are or you are not a party to the litigation.
- Consult with your attorney sufficiently in advance of your deposition so that if additional record review or preparation is necessary you have the opportunity to do it.
- Know what your attorney wants you to review prior to the deposition and what she doesn't want you to review or access.
- In every case, you should be familiar with the details of your own care, including the substance of all records, consults, or notes which you had available to you at the time of your management of the patient, so that you can reiterate at deposition the basis of your management decisions.
- Understand the difference between giving testimony based upon your memory being refreshed by review of documents and giving testimony based strictly on your acceptance of what the document states. Are you testifying, or is the document testifying?
- Understand in advance whether your attorney intends on your giving expert testimony based on a retrospective analysis or whether you are giving testimony only as a percipient witness, in which case you will testify only regarding thoughts, conclusions, and opinions you actually came to while treating the patient.
- Understand the difference between an estimate and a guess.
- Don't give answers relating to conduct of others which you did not witness or the rationale for the conduct of another, unless that person told you why he did what he did. Knowing *why someone mig*ht do something is not the same *as knowing why this person did* what they did on this occasion.
- Have available at your deposition a list of the documents you reviewed in preparation for the deposition or to refresh your memory, and provide that list to your attorney in advance of the deposition.
- Understand the question before you answer it. If a word used in the question is inherently ambiguous, define the word in your answer to clarify your response.
- Wait until the questioner has completed his question. Think before answering. Respond to the question directly and succinctly.
- Know if your deposition is going to be videotaped, and discuss your attire, accordingly.
- Be prepared to give your best and most complete answers at the deposition so as to avoid the need to make substantive corrections when reviewing the transcript.
- List proposed changes to your deposition on a separate piece of paper, and discuss the proposed changes with your attorney before correcting the original transcript.

The Trial

As the process moves toward trial, your role in many respects changes. Up to the time of your deposition, you have acted primarily as a relatively silent party to the process. After the deposition and as you move toward trial, however, you can become the most valuable and effective asset your team has. It is unlikely that any expert that your attorney retains will have as much knowledge of the situation which you encountered than you do. Often, you will be as well-educated and well-experienced as your expert. Frankly, there will be no one who is more invested in investigating and sorting out the pertinent records and testimony than you are. No one will have more at stake.

While the practices of attorneys vary, I believe that after the deposition and as we proceed toward trial, it is important to provide my physician clients with everything which has been compiled during discovery. This includes the depositions of all of the parties and all of the experts. It includes all of the records and literature.

At trial, the defense has one distinct advantage. Present at counsel table throughout the trial, defense counsel has a built-in expert, knowledgeable of the facts and of the medicine, and fully invested in the defense of the case: you. It is

my opinion that the defense lawyer should leverage the situation to his best advantage, by providing you with all relevant information.

In doing so, the attorney has the right to assume that you will read and analyze the information provided to you. This will be time-consuming. Often, the information fills two or three banker's boxes.

To facilitate this exercise, it is best for the information to be provided to the physician-client as it is accumulated, rather than delivering all the boxes to the doctor's doorstep the night before trial. Communicate with your lawyer. Know what he intends your role to be at trial. Know what he intends to provide to you, and ask that it be sent to you sooner rather than later.

You must make yourself available to meet with your attorney to prepare for trial. This may take as much as a day or two or longer. It will mean time away from your practice and your family. But the work must be done.

It is very important that you be present at trial preferably throughout the trial, but certainly as often as you possibly can be.

The plaintiff will be there. The jury will quickly understand that the plaintiff believes in her case and that she considers the proceedings important enough to her that she has placed all other aspects of her life aside to be present in the courtroom.

The jury is ordered to be in the courtroom. They are told they must arrive on time, they must be present everyday, and they must be attentive throughout the day.

They will expect no less from you. If you are not present, your absence will be noticed. Even if it is assumed that you are literally in surgery saving lives, the jury will nevertheless resent the fact that their lives and the important things that they do have been ordered to be put on hold, while you apparently are free to conduct your personal and professional life. That is not the image the defense wishes to portray. It is far preferred to portray to the jury from the outset that these proceedings, the jury's time and attention, and the outcome of this case are as important to you as it is to the plaintiff.

During the course of the trial day, the jurors will be watching everything which occurs in the courtroom. Do not be disruptive or inattentive. Keep your cell phone turned off or at least on vibrate. Do not answer texts in the courtroom. If it is absolutely necessary, alert your attorney to the situation, excuse yourself from the courtroom (assuming this is permitted by the court), conduct the necessary business, and return to the courtroom.

The trial itself will proceed pursuant to the local rules of the jurisdiction, including any particular courtroom rules of your particular judge. Trial schedules vary significantly. Rarely will a trial judge devote his entire courtroom day or week to a pending trial. There is other business to which the court must attend. Rarely will trials proceed all day, Monday through Friday.

More often, the trial court will not be in session for trial on one or more days during the week. The court's trial schedule will be made known at the outset. Most courts provide attorneys with advance notice of their trial schedules. Ask your attorney on what days the trial will be in session, when you are expected to be present, and on what days there will be no trial (days on which the court is "dark"). This will help you plan your schedule as well.

Alert your attorney as soon as possible to any vacations or schedule conflicts that might impede your ability to be present during the trial. The attorney may be able to have the trial schedule altered to accommodate your schedule, but the likelihood of her being able to do so will be greatly diminished without advance notice.

Although practices vary, trials are typically scheduled to begin on Mondays. Your attorney will appear at trial at the appointed date and time. Often, the court will have scheduled more than one trial to begin on the same day. Most cases don't go to trial; they settle or are otherwise disposed of. Still, the court may have two or more cases ready to begin on the same day, or his courtroom may be occupied with an ongoing trial. Ask your attorney what the likelihood is of your case actually starting on the date assigned, so that you can attempt to accommodate your professional schedule.

Once your case is assigned to a specific courtroom, the attorneys and judge typically proceed with pretrial procedural matters. This may take a small portion of the day, or it may take the entire day. Your attorney should be able to provide you with some preview of whether your personal attendance will be necessary in the morning of the first day of trial, in the afternoon of the first day of trial, or not until the following day.

Once the preliminary matters are completed, the judge will typically call up a panel of jurors who will then be interviewed by the judge and the attorneys to determine their suitability for your trial.

The jury selection process, called *voir dire*, is often time-consuming. Nevertheless, your attendance during jury selection is extremely important.

First, it is within the jury selection process that the prospective jurors make their first impression of the case. You don't want the jury's first impression to be that you are absent from the courtroom.

Likewise, jury selection is the first opportunity you will have to form your first impressions concerning each of the jurors. Observe the jurors. Observe their mannerisms and their willingness to make eye contact. Listen to their comments. Listen to their concerns about their own experiences with the medical profession. Your "gut feeling" about the jurors is important.

In most jurisdictions, your attorney will have the opportunity to excuse jurors without specifying a reason. These peremptory challenges are exercised based as much on *gestalt* as on any science. Your ability to evaluate the perspective jurors' response to the parties, the attorneys, the court, and the process is likely just as valuable as your attorney's. At the appropriate time, share your observations and thoughts. They might be important to the attorney.

Once the jury is selected and this could take an entire day or longer, the attorneys for each party are invited to make an opening statement. The opening statement is not an argument. Rather, it is merely a summation of what the attorney believes the evidence will establish. Some attorneys use a broad approach. Other attorneys provide a detailed analysis of what they believe the evidence will show.

Listen to the opening statements. The plaintiff's attorney may well expose his intentions, which may provide you with additional information concerning what aspects of your testimony need to be better prepared. Do not comment or gesture or react to the statements. To do so is inappropriate and disruptive, and you likely will be admonished by the court.

Your attorney's opening statement will include what she expects the evidence to prove. Implicitly, she is telling the jury what she expects you to tell them when you testify. Listen to what she says. If there have been mistakes made by your attorney about the facts or the medicine, point it out *after* she completes her opening statement so that the errors won't be perpetuated.

The parties then begin presentation of the evidence. The plaintiff has the burden of proof and therefore goes first. The plaintiff's attorney may or may not call you in his case in chief (i.e., the legal term for the initial portion of the trial in which the plaintiff puts on his case).

If you are called to testify by the opposing attorney, he will be questioning you as an adverse witness. This will entitle him to ask you leading questions. Be respectful of the process. Answer the question which is asked. Do not insist on attempting to expand or explain your answers, except, as in deposition, by asking, "May I explain?" Direct your comments to the questioner, not to the judge. By asking the questioner if you can explain, you have once again placed him on the horns of a dilemma. If he answers "Yes," he's inviting a narrative which will no doubt be adverse to his case. If he answers "No," the jury will infer that the lawyer is trying to hide the true facts from them.

The most common derogatory comment made by jurors about any witness is that the witness was evasive, argumentative, and nonresponsive. Don't be.

If your attorney believes that additional testimony from you is necessary on any topic, she will be prepared to ask you those questions herself. Trust her to do so.

During the course of the questioning, the opposing counsel may read from your deposition. Do not try to object to this; it is his right to do so. Do not comment about the passage read by saying that it was taken out of context, etc. Rather, patiently and confidently await your opportunity to explain the answers when asked to do so by your attorney.

During the course of the testimony, always direct your answers to the questioner, unless asked to do otherwise. Unduly directing your comments to the jury may appear patronizing and unduly solicitous. Looking to your own counsel during your answer may appear to be a sign of weakness, as if you are looking for help.

There are other specifics concerning how to present yourself as the best possible witness, which you should discuss with your attorney.

While other witnesses are testifying, be respectful of them as well. Do not gesture as if in disbelief. Do not be dramatic. Present yourself always as the respectful professional that you are. Ultimately, most cases are greatly influenced by the testimony of the physician-defendant. Direct, confident, and responsive answers are always appreciated.

The roles of the judge and jury in a trial are different. It is the jury's duty to determine the facts of the case. The judge determines the law of the case. The jury hears the relevant evidence, deliberates among themselves, and then responds collectively to the questions on the verdict form. Although the questions on the verdict form may have several variations or subparts, there are really three inquiries:

1. Was the defendant negligent in the medical diagnosis or treatment of the plaintiff?
2. If so, was the negligence of the physician a legal cause of injury to the plaintiff?
3. If so, what dollar amount of damages do you award to compensate the plaintiff for the injuries, which you have determined were caused by the defendant's negligence?

Most often, the case turns on question No. 1:

Was the doctor negligent in the diagnosis or treatment of the patient?

The plaintiff has the burden of proof with respect to each of these questions. Generally, this means that in order to prevail, the plaintiff must persuade the jury, by the evidence presented in court, that what he or she is required to prove is "more likely to be true than not true." The jury will also be instructed that "if, after weighing all of the evidence, … you cannot decide that something is more likely to be true than not true, you *must* conclude that the party did not prove it." (Emphasis added.) If the plaintiff has not proven that you were negligent (if, for example, the jury determines that the evidence on this issue is evenly balanced), the jury must decide the issue of negligence in the favor of the defendant [6].

How then can jurors, who are not doctors, decide whether a doctor was or was not negligent?

The jury will be given jury instructions by the judge, which outlines their task and how they are to go about satisfying that task.

The court will instruct the jury on the doctor's duty to conduct himself or herself in accordance with the standard of care and on what evidence the jury should consider in coming to this conclusion.

The basic standard may be expressed as follows:

> A surgeon is negligent if he or she fails to use the level of skill, knowledge, and care in diagnosis and treatment that other reasonably careful surgeons would use in similar circumstances. This . . . is sometimes referred to as "the standard of care" [7].

In directing the jury as to what evidence the jurors may consider when deciding whether the doctor did or did not act as other reasonably careful doctors would act under similar circumstances, a basic instruction is as follows:

> You must determine the level of skill, knowledge, and care that other reasonably careful surgeons would use in the same or similar circumstances, based *only* on the testimony of the expert witnesses [including the defendant] who have testified in this case. (Emphasis added) [7].

In most circumstances, the standard of care is defined as a standard of conduct, not a standard of result. The fact that a patient has suffered an unexpected or unintended adverse consequence is not, in and of itself, evidence of negligence. Again, while the verbiage of any instruction on this issue to the jury may vary depending on the jurisdiction, a basic statement of the applicable standards is as follows:

> A surgeon is not necessarily negligent just because his efforts are unsuccessful or he makes an error that was reasonable under the circumstances. A surgeon is negligent only if he was not as skillful, knowledgeable, or careful as other reasonable surgeons would have been in similar circumstances [8].

The jury typically also will be instructed that simply because the experts on either side differ on what their personal preference is concerning proper management of the situation or that reasonable alternative methods for diagnosis or treatment were available does not necessarily mean that the physician's choice of one approved method over another, even if the defendant's choice, in retrospect, proved to be the wrong choice, was negligent. This tenet of the law can be expressed as follows:

> A surgeon is not necessarily negligent just because he chooses one medically accepted method of treatment or diagnosis and it turns out that another medically accepted method would have been a better choice [9].

"A difference of medical opinion concerning the desirability of one particular medical procedure over another does not… establish that the determination to use one of the procedures was negligent" [10]. Likewise, "[m]edicine is not a field of absolutes. There is not ordinarily one correct route to be followed at any given time. There is always the need for professional judgment as to what course of conduct would be most appropriate with regard to the patient's condition" [11].

It is important for the physician-defendant to understand these various legal propositions and the significance of each of them.

In deciding whether or not the physician-defendant was negligent, the jury is to consider only the testimony of the experts. Ultimately, the jury's decision will come down to which party's experts were more persuasive. The court may also instruct the jury concerning how they might go about weighing the conflicting testimony of the experts. One such instruction is as follows:

> . . . [I]t is up to you to decide whether you believe the experts' testimony and choose to use it as a basis for your decision. You may believe all, part, or none of an expert's testimony. In deciding whether to believe an expert's testimony, you should consider:
>
> (1) the expert's training and experience;
> (2) the facts the expert relied on; and
> (3) the reasons for the expert's opinion [12].

Additionally:

> If the expert witnesses disagreed with one another, you should weigh each opinion against the others. You should examine the reasons given for each opinion and the facts or other matters that each witness relied on. You may also compare the experts' qualifications [13].

In short, the weight to be given an expert's opinion is to be determined not only by the qualification of the experts but also more specifically by considering the reasons given for each opinion and the facts or other matters relied on.

The fundamental question is whether the physician-defendant acted reasonably under the established circumstances. The fundamental method used to invalidate an expert's opinion is to establish that the facts stated as the basis for the opinion are inaccurate or incomplete. An opinion is of no greater value than the facts upon which it is based. An opinion without proper factual foundation must, necessarily, collapse.

In preparation for trial, therefore, as your own advocate in the case, you should be well acquainted with the identities and opinions of the experts on either side. You must likewise be acquainted with the factual basis for each of those opinions. And you should be prepared to guide your attorney to the records which you believe discredits the factual basis of the opinions of your opposing expert and to the records which confirm and support the factual basis of the opinions of your own experts.

In addition, you should be prepared to tailor your own testimony, mindful of the value of testimony you give which

contradicts the factual basis of the opposing expert and supports the basis of your own expert. Knowing the bases of the opinions of the experts on both sides, and tailoring your efforts and testimony to contradict the plaintiff's expert and to support your own expert, is the best way that you can contribute toward a successful defense of your case.

In the proper situation, as noted above, it is not fatal to your case to recognize that alternative methods and diagnosis also existed. In fact, it may be beneficial for you to explain that you were aware of these alternative methods, and considered them, but ultimately selected your method for reasons on which you are prepared to elaborate. By being prepared to discuss (both in deposition and trial) your knowledge of alternative treatments and the rationale for choosing the course you chose after discussing the options with your patient, you are potentially providing your defense with the factual foundation necessary to promote the "alternative methods of treatment" defense.

Familiarize yourselves with the applicable legal standards and instructions used in your local jurisdiction. Doing so immediately before trial, and at trial, is valuable. Doing so at the commencement of the case, as early as your first meeting with your counsel, is far more valuable.

At the conclusion of the evidence, the attorneys will proceed with their summation of the case or final argument. Because the plaintiff bears the burden of proof, traditionally the plaintiff goes first, the defense attorney then makes his argument, and the plaintiff's attorney makes the rebuttal and final comments to the jury. It is within the court's discretion to instruct the jury either before or after final argument.

Once the evidence has been completed and the jury has received the final arguments of counsel and instructions from the court, the jurors will then proceed into the jury deliberation room. The documentary evidence will be delivered to them for their consideration.

During the course of deliberation, the jury may ask questions which will be considered by the court and counsel and responded to. The jury may also request that the testimony of one or more witnesses be read back to them. In that case, depending on the jurisdiction, either the jury will be brought into the courtroom, at which time the court reporter will recite the testimony, or the court reporter will proceed into the jury deliberation room and read the requested passages to them.

Some jurisdictions require that the jury decide the cases unanimously. Other jurisdictions require a so-called super majority; typically 3/4 of the jurors must agree to decide any single question. Once the requisite number of jurors has come to a conclusion, the jury is then returned into the courtroom, and their verdict is announced.

Based on the factual findings, or verdict, by the jury, the judge then will enter judgment in favor of one side or the other. The jury decides the fact of whether or not the physician-defendant was negligent and records that decision on the verdict. With that factual question answered, the judge then decides the legal effect of that answer (decides who wins) and incorporates that decision into his decision in the form of a judgment.

After the jury returns its verdict, either party to the case may ask that the jury be "polled." In that case, each individual juror will be asked his or her response to each of the questions. In this way, it will be confirmed that the requisite number of jurors have responded and agreed on the answer to each question so that it is a competent verdict.

Even if the case is won at trial, it will undoubtedly exact a huge toll on you personally and professionally. Jury trials are extremely expensive in terms of time, effort, and money. The jury system is not perfect, but in my experience, far more often than not, the jury gets it right.

Teaching Points

- At trial, you are your attorney's best technical asset.
- In preparation for trial, obtain copies of all relevant records and depositions, especially your deposition and all expert depositions.
- Analyze the data with a focus on knowing the circumstances as they existed when you treated the patient; point out where the plaintiff's expert is wrong in his assumption of the facts, and be prepared to support the factual basis of your expert's opinion.
- Know the basic legal standards that will be applied to define "medical negligence," so that you can tailor your testimony to meet that standard.
- Understand the significance of "alternative methods" of treatment.
- Alert your attorney to any schedule conflicts as soon as possible.
- Consult your attorney regarding when exactly the trial is set to begin and when your personal presence is necessary.
- Be present at trial, including jury selection.
- Be cognizant of the opening statements of both sides; it will provide you with valuable insights relating to the proposed testimony.
- Do not react to testimony with gestures or speech. Don't be disruptive of the proceedings or of your attorney's efforts.
- When testifying, direct your responses to the questioner, not to the jury, the judge, or your own counsel.
- Do not expand your answers beyond the question asked, unless you have asked to do so, e.g., "May I explain?"
- Recognize that preparation at each stage requires knowledge of the process and the respective roles of attorney

and client and that preparation is the key to achieving your personal *best result*.

Concluding Remarks

It has been the goal of this work to provide a primer for those not acquainted with the litigation process. It is intended as a guide to facilitate timely and effective communication between physician-defendants and their attorneys. It is further hoped that by affording the physician-defendants a better understanding of the process, they can come to a better understanding of what is expected of them as clients, of what they can expect from their attorneys, and of how the attorney and client can work together toward managing expectations, minimizing anxiety and frustration, and formulating a strategy to achieve the *best result* available under the circumstances.

Communication is the key. Meet early. Discuss the case regularly. Know what is expected of you and when. Know when your personal presence is likely to be necessary. Do your homework, and make yourself available.

If you prepare to succeed, the likelihood of achieving your *best result* will improve exponentially.

Quality

71

Elizabeth C. Wick and David A. Etzioni

Key Concepts

- The Donabedian structure/process/outcomes model is a useful paradigm for categorizing and conceptualizing different approaches to measuring quality.
- Process measures are preferable to outcome measures when there is clear evidence supporting a particular clinical activity and when there is a related gap in care delivery.
- Outcome measures are highly valid, but often do not generate a clear path for quality improvement; they are most useful in situations of high complexity where clear standards are not well established.
- Administrative data and registry data can yield very different measurements of quality, and leaders in surgical quality should be familiar with the strengths and weaknesses of these two types of data.
- A broad range of nontraditional measurements of quality are on the horizon, including patient-reported outcomes, patient satisfaction, and return to health.
- Accreditation programs such as the National Accreditation Program for Rectal Cancer (NAPRC) have an important potential role in improving quality of care by improving the structure of care delivery throughout the country.

Introduction: What Is Quality?

The discussion of quality in surgery is pertinent to every aspect the work performed by surgeons, day in and day out, from the clinic to the hospital and beyond. In this chapter we will offer the reader a framework for approaching quality and offer insights about how quality can be measured, analyzed, interpreted, and improved. Toward this goal we will review a broad range of current topics and paradigms that are relevant to the pursuit of quality in colon and rectal surgery.

The National Academy of Medicine has defined quality as the "degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge." The report "Crossing the Quality Chasm" outlined six principle domains of quality [1]:

1. Patient safety: avoidance of harm to the patients during care delivery
2. Patient-centeredness: providing care that respects patient preferences
3. Effectiveness: the use of services that have a basis in evidence
4. Efficiency: healthcare delivery that avoids waste of resources
5. Timeliness: delivery of prompt care to avoid delays that may result in harm
6. Equity: optimizing an optimal level of care for all patients

It is important to consider this definition and the associated domains of quality when reflecting on surgical care and in developing processes for continuous improvement that encompasses all of the areas. For surgeons interested in quality improvement, some of the domains within this definition are more applicable than others.

Measuring Quality

Efforts to improve quality of care in the field of surgery necessarily begin with an organized approach to measuring quality. The measurement of surgical quality is challenging, however. This fact is clear when reviewing the methods used by the wide range of federal and private sector organizations that have sought to analyze and report surgical quality [2–5].

There is no single approach to quality measurement that is best suited to *all* circumstances.

One of the most common approaches to organizing thinking around quality measurement in medicine was described by Avedis Donabedian in 1966 [6]. In his paper he categorizes methods for assessing quality of care into three main domains: outcomes, process, and structure. *Structure* refers to the context in which care is delivered – this includes the facility and services, workforce, and payment structure. Structural measures ask, "Are the appropriate services, equipment, incentives, and people available?" *Process* is the application of these tools, equipment, and policies/procedures to patients (good practices and evidence-based medicine). Process measures ask, "Are the right tools, policies, and equipment being used for all patients?" *Outcome* is the result on patients. Outcome measures ask, "How often do patients achieve the desired result of surgery?" or "How often are patients harmed during the course of their perioperative care?" In the Donabedian model, structure (how care is organized) plus process (what we do) influences patient outcomes (the results achieved).

As one considers the approaches to quality measurement outlined in more detail below, it is important to remember the forums where the metrics can be used – internal quality improvement, informational external reporting (patients and payors), and financial incentives or penalties for hospitals/providers.

Outcomes

For surgeons, the measurement of outcomes as a representation of quality carries important face validity. A broad range of outcomes are commonly used as targets for quality assessment, including complications such as surgical site infection, urinary tract infection or venous thromboembolism, mortality, and readmission. Anything that occurred to a patient in the course of their care that impacts quality of life can be considered an outcome worthy of measurement. Outcomes are therefore a tangible way of assessing the patient's perspective of their treatment and frequently are the most meaningful to surgeons.

Virtually anything significant that happens to a patient as a result of their surgical care is documented in the medical record and translated into a digital format. The wealth of data that arises from the digitization of medical care is widely used as the basis for monitoring quality, through several different surveillance systems. Within the United States, there has been an increasing movement to make these data available to parties interested in using these data for quality reports [7]. This movement has focused largely on postoperative complications, although many other types of outcomes are possible foci of quality improvement (e.g., quality of life, return to work, etc.).

Outcome-oriented approaches to quality measurement are powerful and widely accepted as important metrics. Their appropriate use should encompass a careful evaluation of their underlying accuracy and validity. Also, it is important to note that outcome-oriented approaches to quality of care do not guide interested parties onto a clear path toward quality improvement [8, 9]. These approaches should be viewed as tools to focus and direct other efforts that support quality improvement.

Process

Process-oriented approaches to quality measurement depend on a preexisting body of evidence that informs clinicians regarding what the *right thing* to do for patients is. Armed with this knowledge, it is possible to assess the frequency with which a specified population of patients receives this element of care.

The best example of this in colorectal surgery is the Surgical Care Improvement Project (SCIP) [10, 11]. These measures were developed to guide hospital-based efforts to reduce rates of surgical site infections (SSI). Multiple parties took part in the construction of these measures including the Joint Commission and the Centers for Medicare and Medicaid Services (CMS) with mandatory participation. Ultimately, compliance with the SCP measures was publically reported through CMS' Hospital Compare website and tied to hospital payment. SCIP measures important for the practicing colorectal surgeon were those related to timing, selection, and discontinuation of antibiotics for surgical prophylaxis (surgical site infection [SSI]) prevention, maintenance of normothermia in the operating room (SSI prevention), use of venous thromboembolic event (VTE) chemoprophylaxis, and removal of the Foley catheter by postoperative day.

There is widespread agreement that the SCIP measures were effective in guiding hospitals toward the uptake of evidence-based practice regarding SSI prevention. At the time of the introduction of SCIP measures, less than 60% of patients were receiving antibiotics preoperatively, and many patients were recovering on inpatient units with urinary catheters in place long after they were needed. Despite the clear evidence basis supporting a link between process and outcome, studies linking hospital performance on SCIP measures with complication rates were lacking, however [12, 13]. The SCIP measures were officially retired in December 2014 with a commitment by CMS to move to more outcome-based measures over the next couple of years.

A process-oriented approach to quality measurement can be very effective, especially when there is a clear standard

regarding what should be done for patients with a certain condition. A common example in colorectal surgery is time to initiation of postoperative adjuvant therapy in patients with stage 3 colon cancer. It is established that initiating chemotherapy within 3 months of surgery is associated with improved survival; therefore, it is reasonable to both *measure and improve compliance* with this evidence-based practice. The greatest challenges to a process-oriented approach are faced when the evidence regarding a specific practice is unclear or when the use of evidence-based methods is already near 100%.

Structure

The structure perspective into quality measurement is the vaguest and the most challenging for clinicians to directly impact. According to Donabedian, structure assessment pertains not to the care provided itself, but instead "…the settings in which it takes place and the instrumentalities of which it is the product...." Areas of quality in healthcare that could be described as being related to structure include a wide range of factors, including hospital cleanliness, the availability of CT scanners, and certification/licensure.

The importance of these types of structural factors on quality of care is highly intuitive but challenging to quantify. A significant body of research has focused on several aspects of the relationship between structure and outcomes. Two of the most important domains of research include work demonstrating the importance of nurse staffing ratios and higher patient volumes in determining postoperative outcomes. Not all elements of structure can be easily studied, however. There are no studies examining postoperative mortality in the hands of physicians who are licensed to practice vs. not.

Quality Measurement: Making the Right Choices

A thoughtful approach to quality improvement necessarily includes some strategic decisions regarding the measurement of quality. Each institution, patient population, and clinical practice has factors that need to be considered in order to arrive at a sensible approach. In this section several important "forks in the road" in choosing how to measure quality are presented and discussed.

Process Versus Outcome Measures

The decision to pursue a process-oriented vs an outcome-oriented metric to monitor quality is one of the most important initial aspects of any quality improvement effort. Which types of efforts are best served by one approach over the other? As alluded to earlier, the most important two prerequisites for a process-oriented approach to quality improvement is consensus regarding optimal practice(s) and a significant gap between optimal and current practice. Without meeting these two criteria, a process-oriented approach is infeasible.

In general, situations where rates of undesired outcomes/complications are higher are better suited to an outcome-oriented approach [14]. An outcome-oriented approach assumes that there are multiple processes (known and/or unknown) that play an important role in determining process. The emphasis on quality improvement that arises from an outcome-oriented approach needs to acknowledge this and allow for an approach that is not necessarily grounded in strong evidence for process change. An outcome-oriented approach may form the basis for generating evidence to inform subsequent process-oriented quality improvement.

Registry Versus Administrative Data

The data that are analyzed for quality measurement come from one of the two types of sources. *Administrative* data are those that are captured in the normal course of healthcare delivery. These data are often termed "claims data" as they are the basis for reimbursement to clinicians and hospitals for clinical services. *Registry* data differ from administrative data in that the data are abstracted in a way that is purpose-specific and separate from the financial mechanisms of the hospital. In general, the processes that generate registry date are held to a higher standard for accuracy but engender a significantly higher cost for abstraction.

Administrative Data

Administrative data are derived entirely from the medical record; therefore, only what is documented can be measured. Clinical phenomena are translated into diagnostic and procedure codes most often using the International Classification of Diseases, 10th Clinical Modification (ICD-10 CM). These codes can then be reported through any one of a number of different surveillance systems. The main benefit of administrative data is that they are generated by healthcare facilities as part of the normal way of "doing business." A common criticism of these data, however, is that they are often abstracted by staff with no clinical background and therefore are inaccurate and misleading.

Registry Data

Registry data represent an effort to address the shortcomings of administrative data. In situations where administrative data are either incomplete or inaccurate, a registry becomes a natural solution. Through the use of more highly trained

staff using tightly controlled program definitions, a registry is generally able to abstract data that is of better quality. The American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP) is the registry most relevant to colorectal surgery. Hospitals that participate in the ACS NSQIP receive risk-adjusted outcomes data regarding their performance on a wide range of complications. The data accuracy is considered superior to administrative data, but come at a significant cost.

Which Is Better, Administrative or Registry Data?

The decision to use administrative vs. registry data to monitor quality is critically important to the success of any quality effort, as different systems yield different pictures regarding quality [15, 16]. Why do these systems give such different measurements, even when analyzing the same outcome? Existing research highlights that systems can differ significantly in terms of the definitions that they use, as well as in the accuracy with which their own definitions are applied [17]. In general, the decision to use administrative data or registry data is a question of tradeoff between data quality and cost. With registries, interested parties can exert more control over the mechanisms of data abstraction, but this control comes with a significant additional cost.

Evaluative Versus Transactional Data

Quality data can also be categorized as being *evaluative* or *transactional*. *Evaluative* data refer to those types of data that represent a judgment that was applied. Many complications fit into this category, and an excellent example of this is SSI. The occurrence of a SSI can be determined according to any of a number of different schemes, but each occurrence needs to be identified by a particular person(s) using a particular set of criteria. Each of these occurrences requires an evaluation, and therefore there is an intrinsic possibility of measurement error – false-positive *or* false-negative.

Transactional data refer to those types of data which are generated without any specific judgment. Some examples of outcomes of this type include reoperation, readmission, and length of hospitalization. While different systems may have different definitions for each of these outcomes, the documentation of these types of occurrence happens automatically.

Making the right choice between using evaluative vs transactional data depends on several factors. The US News and World Report methodology is an example of developing a rich outcomes monitoring system without using any evaluative outcomes data [5]. This is a relatively unusual approach and certainly differs from that used by the NSQIP or by CMS in their online reports [2, 18]. There are many more possible outcomes that can be monitored if evaluative data are used. In using evaluative data, however, it needs to be considered that hospitals/institutions may differ in their systems for evaluation and that this may result in biased reports.

Composite Versus Single Outcomes

Fortunately, most postoperative complications are relatively rare. The rarity of complications, however, poses a challenge to parties interested in following outcomes over time. What does it mean if during one measurement period the rate of pressure ulcers increases from 0.1% to 0.3%? Does a tripling of this rate represent a quality gap or statistical noise? An example of this is shown in Fig. 71.1a, with a potentially disturbing increase in the observed/expected (O:E) ratio of central line-associated blood stream infections (CLABSIs).

While the trend in Fig. 71.1a carries some weight because the reported figures are risk-adjusted, there is a serious flaw in how the information is presented. Without knowing the

	7/15-6/16	1/16-12/16	7/16-6/17	1/16-12/17	7/17-7/18	1/18-12/18	7/18-7/19	1/19-12/19
O/E Ratio	0.84	0.41	0.50	0.49	0.49	0.97	1.42	1.88

	7/15-6/16	1/16-12/16	7/16-6/17	1/16-12/17	7/17-7/18	1/18-12/18	7/18-7/19	1/19-12/19
Denominator Cases	5539	6111	5582	5657	5658	5719	5880	5898
Numerator Cases	2	1	1	1	1	2	3	4
Obs Rate/1000	0.36	0.16	0.18	0.18	0.18	0.35	0.51	0.68
Expected Rate/1000	0.43	0.40	0.36	0.36	0.36	0.36	0.36	0.36
O/E Ratio	0.84	0.41	0.50	0.49	0.49	0.97	1.42	1.88

Fig. 71.1 (**a**, **b**) Composite vs. single outcomes. Observed/expected (O:E) ratio; central line-associated blood stream infections (CLABSIs)

actual number of cases at risk (denominators) and actual observed events (numerators), the importance of the noted trend is difficult to understand. A better version of the same graph is shown in Fig. 71.1b, where these important elements of information are included. The problem of limited sample sizes is *almost always* a serious challenge to the accurate interpretation of outcomes. When occurrences are rare, even systems that accurately assess thousands of patients can yield measurements that are plagued by uncertainty.

There are several approaches that can be taken to overcome issues with sample size. Outcomes can be aggregated over a longer period of time. Figure 71.1a, b utilizes this approach but does so informally by placing all the data over a 3.5 year period onto a single visualization. Another valid approach is to aggregate multiple outcomes into a composite outcomes (e.g., death or serious morbidity).

The composite outcome approach is popular with agencies interested in evaluating global quality of care across large numbers of institutions. For example, CMS relies on the Patient Safety Indicator-90 (PSI-90) measure as part of its Value-Based Purchasing Program. The PSI-90 quality measure examines whether a patient had any one of ten different events while hospitalized for any one of a broad range of conditions (Table 71.1) [19].

There are benefits and problems associated with using a composite measure (relative to a single outcome). A composite measure may be more sensitive to detecting *global* issues with quality. For parties interested in improving quality, however, a composite measure will likely not give useful insights regarding specific areas for quality improvement.

Unadjusted Versus Risk-Adjusted Outcomes

Postoperative complications occur at higher rates in patients undergoing more complex operations and especially in those patients with higher degrees of preexisting medical comorbidity. The science of risk adjustment is designed to allow for appropriate comparisons – between institutions – that accounts for the varying levels of risk that are present in patient populations. Risk-adjusted outcomes are widely accepted as a standard for certain types of outcomes reports. Virtually all of the federal and third-party sites that report hospital outcomes use some type of risk adjustment.

If adjustment is not done well, surgeons or hospitals that care for patients with more complex underlying medical comorbidities or surgical diseases may appear worse than surgeons or hospitals that shy away from these cases. The preferability of a risk-adjusted approach over unadjusted outcomes is not always a foregone conclusion. This is particularly true in situations where an outcome is directly/causally linked to an underlying process failure (e.g., specimen labeling errors, iatrogenic pneumothorax). In these situations, the additional burden of data acquisition and analysis may not add any significant additional insight.

Table 71.1 Patient Safety Indicator 90 (PSI-90) conditions

PSI 03 Pressure Ulcer Rate
PSI 06 Iatrogenic Pneumothorax Rate
PSI 08 In-Hospital Fall with Hip Fracture Rate
PSI 09 Perioperative Hemorrhage or Hematoma Rate
PSI 10 Post-Operative Acute Kidney Injury Requiring Dialysis Rate
PSI 11 Postoperative Respiratory Failure Rate
PSI 12 Perioperative Pulmonary Embolism or Deep Vein Thrombosis Rate
PSI 13 Postoperative Sepsis Rate
PSI 14 Postoperative Wound Dehiscence Rate
PSI 15 Unrecognized Accidental Puncture or Laceration Rate

Final Words on Quality Measurement

Surgeons have a good level of comfort with existing/traditional quality metrics (e.g., complication rates, mortality, readmissions, lengths of stay). Looking into the future, there is a broad spectrum of newer quality metrics on the horizon, including patient-reported outcomes, ability to return to health, and patient satisfaction.

There is no perfect metric. Each quality metric has specific strengths and weaknesses in different contexts and may be suitable or unsuitable depending on the situation. In the absence of a perfect metric, leaders in quality have to focus on using/designing quality metrics that best suit their framework. More important than selecting a perfect metric, however, is working to ensure that measurement and data collection are translated into meaningful quality improvement.

Quality Improvement

The ultimate goal of quality, as defined by the National Academy of Medicine is to "increase the likelihood of desired health outcomes and are consistent with current professional knowledge." With this goal in mind, the path to improved quality requires a particular skillset that is not a formal part of standard training in either medical school or surgical residency. Success in quality improvement involves developing an infrastructure that is primed to act on data and drive change.

In the field of surgery, there is an increasing understanding that quality improvement needs to include the entire continuum of care, starting from the decision to operate and not ending until the patient successfully transitions home and recovers fully. This vision of quality naturally requires work-

ing through an effective multidisciplinary team; furthermore, that these teams must be led and resourced for success. Effective leaders in quality find the right ways to align quality improvement efforts with institutional leadership.

Finally, and perhaps most importantly, quality improvement leaders need to employ a scientific approach to design interventions and assess impact. There is no single approach that is useful in all situations. Several resources are specifically designed to help leaders develop an organized, methodical approach to translate concepts into practice. In the final portion of this chapter, we review several important areas of work in the area of surgical quality that are directly relevant to surgeons seeking to lead in quality.

Organizational Culture and Quality and Safety

Culture is to an organization what personality is to an individual – a hidden, yet unifying theme that provides meaning, direction, and mobilization [20]. One way to think about it is that one person's opinion is an attitude while everyone's opinion is a reflection of the culture. Organizations with effective safety cultures share a constant commitment to safety as a top-level priority that permeates the entire organization.

Traditional surgical culture stands have the potential to work in opposition to the values upheld by organizations with effective safety cultures for several reasons. Surgeons have been hesitant to discuss errors as mistakes have been equated to incompetence. Surgeons also tend to minimize the effects of stress on their ability to make decisions. The surgical culture, especially in the operating room, is extremely hierarchical with the surgeon at the leader [21]. Ultimately, while there needs to be clear role clarity, hierarchy can prevent nurses and other OR staff from pointing out potential errors or mistakes made by the team resulting in potentially preventable adverse events.

These cultural barriers to quality are not limited to surgeons or to the operating room. Medicine strongly values professional autonomy, which frequently promotes individualism over cooperation, often to the detriment of patient care [22]. Finally, patient safety, although often viewed as important, is seldom promoted from an organizational priority to an organizational value. Organizations often do not feel the need to devote resources to overhauling their patient safety systems as long as they perceive their existing processes to be adequate.

Alternative Payment Models

Traditionally healthcare providers are reimbursed solely on the basis of services provided. Over the past decade, payers are shifting to a model where payment is linked to high-value care through "value-based payment models." This approach is taking root in both commercial and government contracts. At the federal level, CMS has sent clear messaging that alternative payment models are part of their long-term strategy [23].

Although most of the federal efforts are directed at primary care and population management (accountable care organizations), episode-based alternative payment models (APMs) are being deployed in surgical areas including colorectal surgery. APMs hold both providers and hospitals accountable for both quality of care delivered and the total costs.

An approach that uses APMs to drive quality (and reduce costs) is fundamentally an outcome-oriented strategy. Given that it is easier to evaluate cost than it is to measure quality of care, most of the programs focus on using cost as a proxy for quality. When hospitals and providers engage in APMs, they have the potential to receive additional payments that may arise from cost savings, as well as the risk incurred as a result of excessive costs ("down side risk").

The initial approach of CMS to APMs is through voluntary participation, but over time participation may become mandatory. An example of this evolution is seen in the Bundle Care Program Initiative (BCPI). The BCPI APM looks at 90-day episode costs after select procedures (Fig. 71.2). Within the BCPI program, the greatest experience is seen in total joint arthroplasty, with participation now mandatory in 67 markets around the country [24].

A similar program for patients undergoing major bowel surgery, including colorectal surgery, is in development. Concerns are raised regarding appropriate accounting for the heterogeneity of patient populations and the limited options available to control costs. There is also the possibility that the program could have unintended consequences if the hospital or providers are not adequately supported to transform care to higher quality and value. It is essential that colorectal surgeons partner with their delivery systems to test and evaluate these models so meaningful feedback can be shared with CMS.

National Accreditation Program for Rectal Cancer

Accreditation programs are formal approaches to evaluate and support structural- and process-oriented approaches to improving quality of care. Within the area of surgery, the most mature example of the accreditation process is within the specialty of bariatric surgery. Through a joint venture of the American College of Surgeons and the American Society for Metabolic and Bariatric Surgery, the Metabolic and Bariatric Surgery Accreditation and Quality Improvement Program (MBSAQIP) sets hospital standards. These standards cover a broad range of targets for quality assessment/

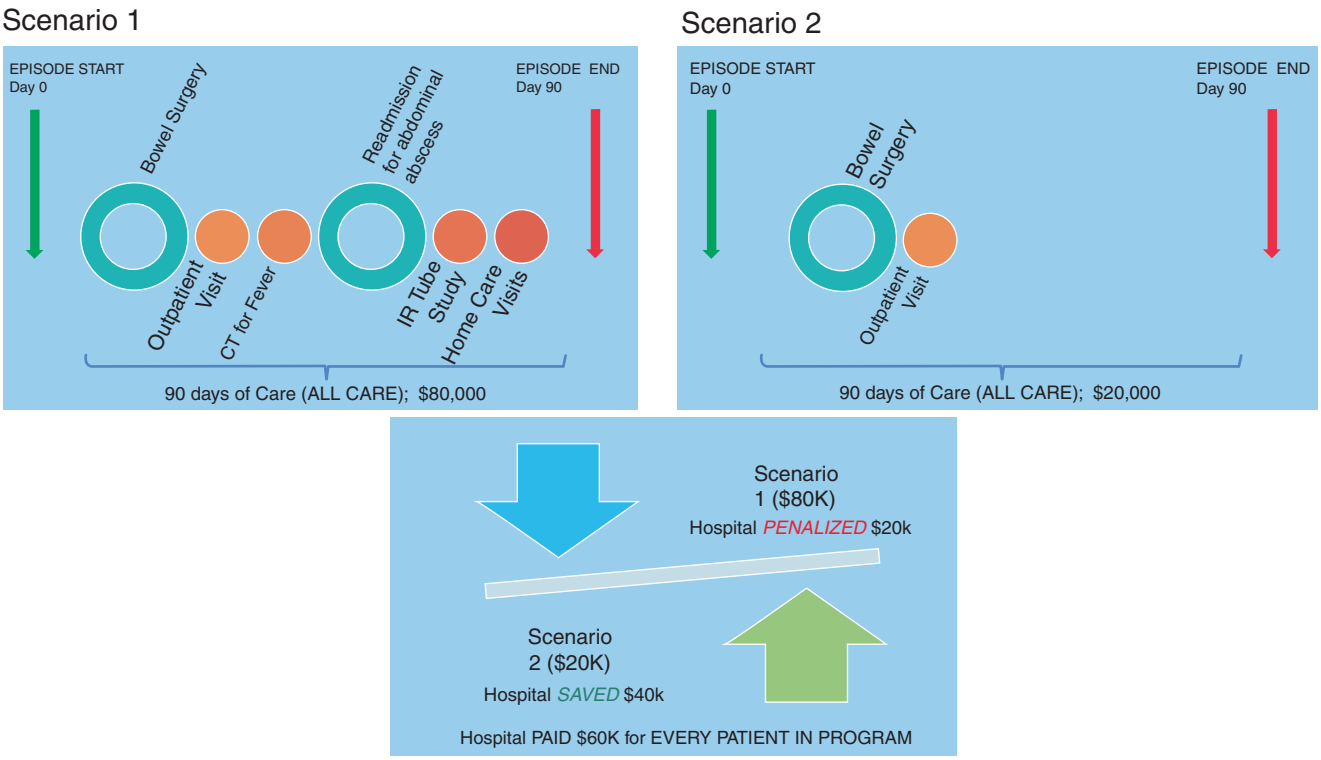

Fig. 71.2 Bundled payments for bowel surgery

improvement, including key physical, and human resources, and practice standards for bariatric surgery. Program compliance is monitored with regular site visits, and all centers are required to monitor and report their surgical outcomes to the MBSAQIP database [25–27].

Despite the intuitive appeal of accreditation, the relationship between accreditation and improved outcomes is unclear. CMS originally endorsed accreditation for bariatric surgery programs and mandated that all Medicare patients undergoing bariatric surgery must be treated in an accredited center [28]. Although procedures done in centers of excellence were associated with superior quality by many measures, this was not reflected in a Medicare analysis, and CMS endorsement of the program was discontinued in 2013 [29].

Within the area of colorectal surgery, the ACS Commission on Cancer (CoC) has worked to develop an accreditation program that is specific to rectal cancer treatment. The structure of this program was initially developed through the Consortium for Optimizing the Treatment of Rectal Cancer (OSTRiCh), a multidisciplinary group including all medical and surgical specialties engaged in rectal cancer treatment. The National Accreditation Program for Rectal Cancer (NAPRC) was developed in 2018 by the ACS-CoC in collaboration with OSTRiCh.

Since its launch, the NAPRC has worked to develop and support standards regarding the optimal care of the patient with rectal cancer. Hospitals review the standards and implement structural changes to ensure that the standards are followed. Effectiveness of the implementation is then verified by site surveyors. Accreditation through the NAPRC is based on the ability of hospitals to comply with 22 standards, covering a broad range of areas related to program quality [30]. To date, 12 hospitals have been verified, and 5 are in the process.

In its current state, the NAPRC accreditation focuses on a broad spectrum of areas regarding the ability of rectal cancer treatment programs to deliver high-quality care [31]. An important focus of the program is a focus on ensuring the presence of dedicated/highly trained surgeons, pathologists, medical oncologists, and radiation oncologists. There is also the requirement for a structured, documented multidisciplinary tumor board where patients with rectal cancer are formally reviewed throughout their care. Additionally, ongoing monitoring of quality metrics and quality improvement activities are requirements for accreditation. Further study will be needed to demonstrate the short- and long-term impact of the NAPRC on rectal cancer care in the United States.

National Surgical Quality Improvement Program

In the field of surgery, the National Surgical Quality Improvement Program (NSQIP) is considered the "best in class" registry for the assessment, analysis, and reporting of

surgical outcomes. The leadership has prioritized data validity, and all data is collected by a trained abstractor, and the data integrity is periodically audited. The program was originally developed in the Veterans Affairs Health System (National Veterans Administration Risk Study) in the 1990s as a means to benchmark 30-day outcomes for VA hospitals. Risk adjustment was a key focus of the program as the Veterans Affairs Hospital population was notably different than other health systems with a preponderance of older, male patients with multiple comorbidities [32].

The VA program became a model for continuous process improvement. In 2001, with support from the Agency for Healthcare Research and Quality (AHRQ), the American College of Surgeons (ACS) began offering the NSQIP to non-VA hospitals [33, 34]. Colorectal surgery has been a key area of focus for the program with special colectomy and proctectomy disease-specific variables developed within the program.

Recognizing that data alone is not sufficient for quality improvement, ACS-NSQIP has worked to develop a community of surgeons who are committed to improvement and provides opportunities to participate in including the Annual American College of Surgeons Quality and Safety Meeting. The meeting has many interactive sessions and draws participants from a broad range of areas including hospital leadership, surgeons, trainees, and data abstractors. Both during and outside of this annual meeting, the ACS-NSQIP provides opportunities to participate in regional collaborative and pilot programs.

Most recently, related to colorectal surgery, the ACS-NSQIP joined forces with the Johns Hopkins Armstrong Institute for Patient Safety to launch the Improving Surgical Care and Recovery Program [35]. This program aims to form a collaborative to accelerate adoption of enhanced recovery programs for colorectal surgery (as well as other surgical areas). To date, over 300 hospitals have participated and benefited from tools, coaching, and shared learnings around enhanced recovery. Early results from participating programs are encouraging, with notable reductions in length of stay, decreased rates of complications, and faster return of bowel function.

Conclusion

The need for surgeons to be actively engaged in quality improvement is increasingly clear. The surgical perspective on quality is critical, and surgeons need to commit to learning how to translate concepts and data into continuous quality improvement. Surgeons finishing training today are far more facile in this type of work than in the past, but ongoing growth in this important area will ask more of future generations of leaders in surgery.

Practice Management

72

Jennifer D. Rea and Jeffrey L. Cohen

Key Concepts

- Building a successful practice starts with providing excellent patient care first and foremost.
- Attempt to achieve the quadruple aim of providing improved patient/customer experience with increased quality and cost efficiency while also focusing on provider health and wellness.
- The basic premise behind salaries is that they should correlate to the work performed by the surgeon and align incentives with the goals of the individual and the practice.
- Developing a practice involves incorporating the four A's of a successful surgeon—availability, affability, ability, and accountability.

Introduction

Being successful in medicine starts with taking excellent care of your patients. Education, training, and board certification launch you into the subspecialty career of your dreams. Establishing a rewarding practice so that you can focus on taking excellent care of your patients does not come with such a clear-cut pathway to success. While there are a lot of resources on these topics in print and in organized web-based or weekend courses, it is often the conversations among physicians in casual settings that offer the most real-world advice about successes and failures in the realm of managing a medical practice. The healthcare environment is rapidly changing, so it would be impossible to predict what policy changes may come about after this publication. It is the authors' goal to provide guidance in maximizing your position to address the opportunities and challenges that will most certainly come your way throughout your practice.

In this chapter, we set out to address some of the most challenging issues facing physicians and practices today outside of patient care in an ever-changing healthcare environment, for instance, understanding the culture in the type of practice model you choose and recognizing the internal and external pressures of each model. When choosing a particular practice setting, you will also be choosing your challenges, as every model will have them. Knowing yourself, how you make decisions and work your best with others should lead you to the right path.

Practice finances bore most physicians. We like anatomy, pathology, and procedures. Profit and loss statements and revenue cycles are for accountants, right? While it is crucial to choose talented, well-vetted advisors, knowing the basics about how your practice finances work are critical. If you are in private practice, these data mean everything to your take-home pay. If you are an employed model, knowledge of the finances of your group means power when negotiating your position.

While some practice models are becoming more popular than others, there are still examples of successful practices in all models. Whether you are employed or private, strategies for building a referral base and running an efficient clinic are similar and are outlined in more detail below. As more healthcare systems form and smaller practices are acquired by larger entities, understanding how that process works will help you to adapt to what is happening in your community, your region, and on a national level. Identifying where your practice fits into this dynamic will help you make decisions about how you are positioned and allow for a well-informed approach to questions such as the following: Should I leave my current health system? Should we merge with another private group? Should we sell our practice to the health system we partner with? Should we consider private equity

investors in our group practice? If you are not thinking about these questions, it is time to ask yourself how serious you are about taking control of your future.

From the perspective of a chief clinical operating officer of a large health system and a full-time clinical surgeon in a multispecialty private group practice, we will outline the highlights of successful practice management applicable to any practice environment.

Practice Models

Independent Practices

Single Specialty

For many decades, the most common type of independent group practice was that of a single specialty. This was true for colorectal surgery as well, with a single specialty group structure being the predominant model until the last decade. A single specialty practice allows for a successful culture to be built on a common focus and interest of the physicians, as well as the staff. There is a singular orientation toward the specialty, with an expert knowledge possessed by all the partners, allowing for the development of a cohesive practice management plan. This also allows for standardization of patient care delivery by the staff and a consistency across multiple sites of service. Furthermore, consensus can be easily achieved with respect to new initiatives, as all the physicians can be involved in both the development and the execution of the emerging opportunity.

Oftentimes, the recruitment of new physicians occurs through the network created either locally or nationally by the specialty society. This furthers the fostering of a cohesive group practice environment and culture, essential to the ultimate success of the independent group practice. Since there are no competing clinical interests from other specialties, a single specialty practice is more easily able to drive a unifying vision. The attractiveness of this model is obvious, not only for newly trained physicians who see a practice like their fellowship training environment but also to well-established physicians who value consistency and clarity within their practice.

While a single specialty practice can enjoy financial security if it is critical to the community it serves, there are risks to this structure should significant competition emerge. Without the diversification of a multispecialty practice (see below), or the support of a health system, the practice may not be able to support the number of clinicians in the practice. This is especially true if the group practice has not been able to develop ancillary services, such as imaging, lab, or surgery centers. In fact, one of the major benefits of single specialty practices is the ability to invest in these ancillary sources of revenue to support the overhead of the practice and allow for an enhanced patient experience commensurate with what large, integrated healthcare systems can deliver. If the single specialty practice is unable to leverage itself with these ancillary revenue streams, then it is likely to face financial pressures to its ultimate viability.

Multispecialty

Over the past two decades, there has been a significant growth in forming multispecialty group practices [1]. This has occurred both as a strategy to deliver integrated care to patients, as well as a response to external pressures on small independent physician practices. From the positive standpoint, coalescing like-minded physicians under a unifying vision can facilitate growth opportunities and initiatives that small group practices and single specialty practices may struggle to achieve. For example, a digestive health division within a multispecialty group practice can bring together gastroenterologists, colorectal surgeons, nutritionists, and therapists to provide an integrated clinical care experience for the patient. This can also be replicated across many service lines, which patients as consumers of healthcare are looking for and coming to expect from their healthcare experience. In addition, having many specialties available to support the development of ancillary services can lead to a higher success rate and ultimate profitability of the endeavor, which is especially true for the ability to support lab and imaging services. As for ambulatory surgery centers, some single-specialty-focused centers, such as orthopedics and ophthalmology, are able to achieve higher returns on investment than multispecialty centers, but having a critical mass of volume from multiple specialties within a group practice can also create a successful investment opportunity. Furthermore, by having the practice own the surgery center, the group's overall practice philosophy can be easily extended to the management of the center.

While there are many positive benefits to the development of a multispecialty group practice as outlined above, there is also a defensive strategy associated with joining a large group practice. With the growth of integrated healthcare systems and the consolidation of commercial payer models across the country, remaining part of an independent practice model has become more challenging. Large systems that are relatively well capitalized can offer an integrated patient care experience comparable to private practices should they orient their care model to achieve that goal. Therefore, creating large multispecialty independent group practices oftentimes is the only way to remain competitive in the rapidly consolidating healthcare environment. Not only is it essential to create a unifying vision that adds value to the patient experience, as well as to the physician partners, but it is just as important to develop cohesive specialties and service lines that cannot be easily replicated by competing organizations. Furthermore, exploring opportunities to partner with either the local

healthcare system or one or more of the payers in the community can create protections from being commoditized, jeopardizing the financial solvency of the group practice.

One of the challenges of multispecialty group practices is that different specialties may have growth imperatives or strategies that are not consistent with the rest of the practice. There can be requirements for capital investment in one service line that requires the rest of the group practice to divert away from other areas and lead to disharmony within the practice. As multispecialty group practices become larger and more diverse, these types of decisions become commonplace and place significant demands on the practice management and culture. It is imperative that a strong governance model be in place that the physician partners are committed to offset the inevitable disagreements that are precipitated by competing interests within the various service lines. Anyone wishing to join a multispecialty group practice should have a clear understanding not only of the practice vision and culture but also of the governance model, the financial strength/challenges of the organization, the pathway to partnership, and the obligations of the shareholders to the organization and their fellow partners.

External Investment (Private Equity, Venture Capitalists)

As healthcare has increased in complexity and with it the requirement for access to capital to remain viable as an independent practice with growth potential, there has been a resurgence in a practice model which proved unsuccessful in the 1990s. Practice management companies, in the form of private equity investment, has returned as a vehicle to support private practices in their goal to remain independent [2]. Given that most states have laws preventing nonphysicians from owning medical practices, private equity companies establish management services organizations (MSO) which take over the business functions of the practice. The practice pays the MSO a management fee, generally either a flat fee or a percentage of the practice's revenue. Care must be taken in the latter arrangement to avoid any structuring which might suggest a fee splitting arrangement. In return for the practice entering into this arrangement, the private equity investor assumes a majority share in the MSO, paying the physician partners a large upfront cash payment. This is generally calculated on the practice's EBITDA (earnings before interest, taxes, depreciation, and amortization) and can range between a 5 and 15 times multiple. In order for this investment to be attractive to private equity, the physician partners agree to accept a reduction in salary for a period of time, as well as contribute their ancillary services to the MSO.

The ultimate payout for the private equity investment comes several years later, when it looks to sell its position in the MSO to another entity, which presents a risk to the practice as it will have a new partner to work with. The majority of the private equity deals over the past decade have taken place in dermatology, as this specialty provides investors with access to a large self-referral base, significant retail options, and other ancillary services, a growing demand for the services supplied by dermatologists, as well as a highly fragmented delivery model. However, over the past several years, this model has expanded to other specialties, in particular, gastroenterology, where some of the same benefits attributed to dermatology also exist. To the degree that a colorectal surgery practice possesses a significant ancillary revenue stream through an ambulatory surgery center and lab services, it can be a desirable target for private equity investment. The cautionary tale is that the ultimate goal for the investment company is to increase profits so as to create a liquidity event and sell their stake at a significant return on investment. This results in the physician group losing control of their destiny at some point in the future even if the initial arrangement was working well.

Employed Models

For the first time since the metric has been tracked, more physicians are working in an employed model than in an independent practice. Last year, the American Medical Association reported that 47.4% of practicing physicians were employed while 45.9% owned their own practices [3]. To further highlight the dramatic trend taking place over the past decade, there has been a 70% increase in the percentage of hospital-based physicians from 2012 to 2018, as well as a concomitant increase in the number of hospital-acquired practices during the same time period. While the trend varies from region to region, every part of the country saw a steady increase in physician employment and practice acquisition during this time frame. And in the Midwest region, fully 55% of physicians are now in an employed arrangement, up from 34% in 2012.

To understand the reasons for the shift from an overwhelming private practice model to one of employment, it is worthwhile to examine the changing healthcare environment, as well as the motivation and goals of those choosing a career in medicine. From a business standpoint, a long-standing trend of flat or declining reimbursement for professional services, while medical inflation has driven up overhead costs, has led to pressure on profits and, therefore, compensation. At the same time, hospitals and healthcare systems are able to recognize the downstream contribution margins of an employed practice model and are willing to increase compensation so as to attract top-flight candidates from residency and fellowship programs. As noted in the previous section, the important offset for this is access to a significant ancillary revenue stream, which is not always available to an independent practice, especially one that does not have a ready source of capital to invest.

Other challenges to the private practice model include the rise of consumerism and retail clinics, insurance and billing changes with the shift to value based care, continual technology investments in an electronic health record and subsequent upgrades to include the integration of big data and artificial intelligence, and, lastly, investments needed to create a full service integrated patient care experience. When added to these factors the diminishing entrepreneurial spirit of those physicians entering practice at the present time, who are oftentimes saddled with a large debt burden, it is not surprising to see the trends in physician employment that have been outlined above.

While traditional employment by hospitals did not tend to address a lot of the issues important to physician engagement and job satisfaction, this is an area that is evolving as well. When physicians were directly employed by hospitals, they were overseen by hospital administrators who generally had little to no experience in practice management. This led to inefficiencies resulting in financial losses and poor patient experience, not to mention diminished staff and clinician satisfaction. Given this scenario, it is somewhat surprising that the trend toward physician employment occurred to the degree that it did, which only serves to emphasize the degree to which the changing healthcare environment played such a central role.

Over the last decade, there has been a recognition by growing healthcare systems that a robust employed clinician enterprise is essential to the ultimate success of the organization and, furthermore, that the business of practice management needs to be separated from that of running hospitals and placed in the hands of experts in this field. When optimized, the governance and operational structure of employed medical groups develop into a dyad model, with healthcare management experts partnering with physician executive leaders, not unlike that seen in successful private group practices. Fortunately, this model has existed for many decades in organizations as diverse as Kaiser Permanente, Mayo, Cleveland Clinics, and Henry Ford Medical Group. They and many others have successfully addressed the issues of perceived loss of autonomy by physicians while preserving clinician and staff engagement. And as physician burnout has become a significant issue facing healthcare, the preservation of some degree of autonomy and governance by physicians, coupled with the robust support mechanisms supplied by large, health-system-employed practices, can be a recipe to offset this disturbing trend [4].

In deciding which type of employed practice model to join, it is important to understand some of the fundamental differences that exist in the varied settings. First and foremost, the underlying mission of the organization should dictate which direction to go in. For example, if research and education are what is most important, then employment by an academic medical center makes the most sense. While other types of organizations may value the contribution that research makes to the enterprise, academic medical centers are constructed to support the mission directly and will supply the resources that are likely to contribute to the individual's success in that environment. Conversely, if the goal is to create the best patient experience while performing cutting edge, innovative surgery, then a large, integrated healthcare system which states those goals as its mission will be a better fit. And in the ultimate, completely vertically integrated healthcare system such as Kaiser Permanente, one can achieve complete clarity of mission and vision with little ambiguity.

A relatively new type of employed physician model has emerged over the past several years that promises to disrupt the existing healthcare ecosystem. Healthcare insurance companies, as well as other nontraditional entities, are entering the physician practice employment model, either for the benefit of their own employees or as an alternative to the perceived lack of consumer responsiveness in the environment today. With the entry of companies such as Amazon, Apple, and Walmart now employing healthcare clinicians, another alternative for physicians interested in employment can be driven by innovation as their mission. And the largest employer of physicians in the United States, OptumHealth, with 50,000 employed or affiliated physicians, is owned by the largest healthcare insurer in the United States, UnitedHealthcare [5]. These resource- and capital-rich organizations provide new opportunities for physician employment and development that for the most part did not exist a decade ago.

Acquisition of an Independent Practice

With the rapidly changing healthcare environment, independent practices need to continually assess not only their continuing viability but also whether they are positioned to effectively deliver on their vision and goals. In particular, if the ability of the practice to experience sustained growth and a differentiating patient experience is limited, then consideration should be given to forging partnerships or becoming acquired by another entity. Should an opportunity materialize whereby there is alignment of the practice's vision and goals with its local healthcare system, the partners may determine that merging into the healthcare system is in their best interests for long-term viability and sustainability.

Independent practices that are considering proceeding through the acquisition process first must build consensus among its partners and, if possible, involve the employed physicians as well. An effective method to achieve this goal is through a series of strategic retreats, which can be facilitated by an outside healthcare consultant. Clarity surrounding the motivation to leave private practice and become acquired is critical to the ultimate success of the merger. In addition, prioritization of objectives to be realized through

the acquisition process should be an outcome of the consensus building process.

As negotiations proceed with the acquiring healthcare entity, the key objectives of each side should be clearly articulated and referenced so as to ensure alignment of goals and reduce the likelihood of post-acquisition disagreements. A prudent investment by the practice is the early engagement of a consultant experienced in the area of healthcare mergers, as well as the ongoing involvement of the practice's accounting and legal teams. At regular intervals during the negotiation phase, the physician leadership team should meet with all of the shareholders to disseminate information and receive feedback. Ultimately, agreement between the parties will have to occur on not just the purchase price for the hard assets of the corporation (an asset purchase agreement) but also on the length of the initial contracts; the compensation model, including salary guarantees and performance as well as productivity incentives; governance within the new entity; staffing models and ratios; stipends for new roles that the physicians may need/want to take on in the employed medical group; and many other details related to decision-making rights within the new entity. The time to reach agreement on all of these issues is before executing the contracts, as all the leverage accrues to the acquiring entity afterward.

It should be noted that there are significant federal statutes and regulations governing the acquisition of independent medical practices by healthcare systems, especially when they are not for profit. The most important concepts relate to fair market value and commercial reasonableness, so as to insure that health systems are not buying referrals as the motivation to acquire a practice. And while physicians tend to think in terms of the downstream revenues that a hospital and health systems enjoy from the work that they perform, compensation cannot be in any way tied to this relationship. Given the risks associated with the acquisition of an independent practice by a healthcare system, it is imperative that each entity be well represented by legal expertise, preferentially with a healthcare background.

Finance

Effective practice management requires a strong understanding of the financial underpinnings of the business. Given the lack of expertise in this area of most physicians not only entering practice, but even those who are well established, generally medical groups will employ a finance team to handle revenue cycle, billing and coding, and compliance. Whether a shareholder in a private practice model or employed by a healthcare entity, it is still recommended that the physician become educated in at least the basics of healthcare practice finance. By partnering with your finance and revenue cycle experts, higher efficiencies and profitability are likely to occur.

Regardless of the practice model, the fundamental principle remains the same. That is, revenue minus expenses determines the ultimate financial success of the practice. While the sources of revenue can be similar for independent practices or an employed model group practice, more opportunities exist for revenue enhancement in the latter structure. Professional fees are either regulated by the federal government through the Center for Medicare and Medicaid Services (CMS) or negotiated with commercial payers, with variation related to the local competitive environment. In general, large organizations such as integrated healthcare systems can command higher reimbursement rates from commercial payers, oftentimes partly related to their obligation to treat all patients regardless of whether they are underinsured or completely uninsured. While all practice models can generate revenue from ancillary services, smaller group practices generally are limited in their ability to do so. Conversely, large healthcare entities are structured to realize significant revenue streams from diverse sources such as ambulatory surgery centers, imaging centers, and lab services and from contracting in value-based models of care.

A key decision for a private practice medical group is whether to outsource revenue cycle functions or develop the expertise internally. While it might be advantageous to fully align incentives by having the revenue cycle team employed by the practice, consideration needs to be given to the size of the group practice and whether it can afford the expertise required to insure best in practice outcomes. For many small- to medium-size practices, it makes more sense to identify a revenue cycle company that is willing to be incentivized by the success they achieve in maximizing the efficiency of the practice's billing and collections processes.

A critical component of revenue cycle is the accurate coding of the provider-patient encounter. Whether the service is outsourced or integrated into the practice, extensive education should take place for all providers. As this knowledge base is not typically acquired during residency or fellowship training, it is essential that billing and coding training takes place as part of the orientation process when entering practice. Furthermore, numerous courses and workshops are available to supplement the training process for colorectal surgeons entering practice and can be quite valuable regardless of in-house expertise. To ensure compliance and reduce the risk of fraudulent billing, in addition to documentation of educational programs, best practice also incorporates routine auditing of the surgeon's billing practices. Certified coders are employed to not only oversee this process but also to partner with the providers in insuring proactively that the correct billing codes are applied for the work that is being done. This includes education and coaching on accurate and complete documentation of the patient encounter, whether in

the ambulatory setting or procedure based. It is incumbent upon the provider to submit timely and complete billing and coding so as to maximize the revenue cycle process and eliminate rework, which not only adds to the cost of the process but can also lead to denials by payers of care and treatment that has been provided.

While an in-depth comprehension of the coding process is beyond the scope of this chapter, the key components can be readily understood. Every encounter requires both a diagnosis code and a procedure code tied to it when one is performed for a medical provider to be reimbursed for services rendered. The catalogue of diagnosis codes is referred to as the International Classification of Diseases (ICD-10), which underwent extensive revision in 2015. It is a medical coding system designed by the World Health Organization (WHO) to catalogue health conditions by categories of similar diseases [6]. The objectives of the system are to measure the safety and efficacy of patient care, determine the health status and risk factors of defined populations, improve and monitor providers' performances, assess healthcare costs, and investigate and prevent coding and billing abuses. Current procedural terminology (CPT) codes reflect the services rendered to the patient and can be in the form of evaluation and management (E/M) codes and/or procedure codes [7]. In the past, the coding would be entered into a paper "superbill," which would be submitted to the payers for reimbursement. With the advent of electronic medical records, all of the billing and coding information can be entered in to the medical chart prior to closing the encounter, which can then facilitate a complete review of the chart for appropriate documentation by the coding department prior to sending out the bill. Ultimately, an explanation of benefits (EOB) will be generated by the insurance company and communicated to the patient and the practice. It will document the allowable contractual reimbursement with adjustments and denials, as well as the patient's responsibility for any portion of the bill.

Compensation

While there are many different compensation formulas, the basic premise is the same. Salaries should correlate to the work performed by the surgeon and align incentives with the goals of the individual and the practice. Needless to say, it also must be competitive relative to the geographic location and the training and degree of specialization of the provider. When evaluating a compensation model, an understanding of the entire benefit package, including expectation of work hours and call responsibilities, is essential to avoid surprises and misunderstanding later.

Since the underpinning of a medical practice is its profitability, the most straightforward calculation relates to a revenue minus expense model. When appropriately applied to an individual surgeon, it has clarity with respect to the financial contribution of the clinical effort. However, there is tremendous variation in how the expenses are applied to an individual contributor, since there are both fixed and variable components involved. Furthermore, startup costs for the new surgeon can be considerable if related to an expansion of services or minimal in the case of a replacement for a retirement. A straight calculation of profitability to determine salary can undermine the value of non-remunerative contributions of the individual to the group practice culture, as well as foster a culture of an "eat what you treat" mentality which discourages the synergy of a group culture. Some of these issues can be overcome by designing a compensation model that pools excess revenue over expenses at the specialty or group level and then distributes it in a predetermined sharing formula that attempts to align the distribution with the practice's goals.

Implementation of a relative value unit (RVU)-based model of compensation allows for more flexibility and is almost essential in multispecialty group practices that employs a variety of specialties. An RVU represents an attempt to standardize physician work into numerical units [8]. They account for the time it takes to perform a specific service, the skill needed to complete the service, the judgement and experience required of the provider, and the liability risk associated with the service being performed. There are three individual components to the RVU calculation which determine the clinical activity of the service: the work effort, the practice expense, and the malpractice expense, and this can be adjusted for geographical differences. The Center for Medicare and Medicaid Services determines the value for RVUs related to CPT codes, and there are committees that incorporate physician and medical society feedback to recommend adjustments to the assigned values as new procedures are developed and implemented.

It is the ability to value a provider's services across specialties that enhances the value of the RVU methodology in a multispecialty group practice when creating a compensation model. Furthermore, the RVU is "payer blind," as the value does not vary according to insurance, an important consideration in not-for-profit care models whose mission may be to treat all patients regardless of their ability to pay for the care they receive. In addition, compensation is decoupled from the revenue cycle, with the exception of the accurate tracking of RVUs. This creates an environment where the surgeon is not beholden to the performance of the revenue cycle team, although care must be taken to engage and create accountability for the timely and accurate submission of bills by the provider.

When creating a compensation model based on RVU productivity, consideration should be given to nonclinical activity and how that is incorporated into overall income that the

surgeon receives. Examples of nonclinical activity might be serving or chairing committees in the practice or larger organization, development of new service lines, mentoring or peer support, or community-based activities. These valuable contributions to the practice can be recognized through stipends or reduced thresholds to earn productivity incentives. Alternatively, the individual who is valued to perform these services may be allowed to earn a full-time salary yet have protected time to attend to these activities.

In fact, this is now the preferred methodology for academic medical practices, who generally have the dual mission of clinical activities while focusing on education and research. A determination is made as to the percentage of time that the surgeon devotes to each area, and the research/education component is protected by time and guaranteed salary. The clinical responsibilities can be rewarded by a compensation model that is RVU based, so as to align income with clinical effort.

Separate from compensation based upon productivity or nonclinical activities is the potential for earning additional income through the generation of ancillary revenues. As discussed earlier, the opportunity to invest in and realize income from ancillary sources is generally proportional to the size of the practice and its ability to access capital for the initial investment. While seen most commonly in large, independent medical practices, some employed models also allow its providers to invest in activities such as ambulatory surgery centers or real estate investments. Regardless of the employment arrangement, the one guardrail is that it is illegal to tie income of any type to the volume of referrals to that healthcare entity.

Distribution of ancillary revenues within the practice is most commonly through equal distribution to all shareholders if in private practice or to all employed physicians that contribute to the activity. This is also the methodology for distributing revenue from value-based contracts, although incentives can be aligned for an individual's successful achievement of the metrics specified in the value contract. Segregating these activities and utilizing a sharing model fosters the goal of aligning a group practice culture, which is important to achieving the benefits of driving patient-centered care through teamwork and care coordination.

Developing a Referral Base

We have all been taught the three A's of a successful surgeon—availability, affability, and ability. More recently accountability has been added as a fourth value of utmost importance to the successful surgeon. Certainly, these hold true regardless of practice type. Saying yes to consults and helping other physicians when called upon is not just essential for new surgeons, it is vital to maintain an outstanding reputation throughout your career. You want referring doctors to say that everyone in your group takes care of their patients, answers phone calls promptly, and makes it easy for them to take care of patients with you and your partners. This is especially relevant in markets with competing colorectal specialty groups. Furthermore, taking advantage of the wealth of knowledge and experience of senior members of the practice should not be overlooked. Seeking out their opinions and advice can be invaluable. A culture of mentorship is prevalent among colorectal practices. Oftentimes, a senior surgeon will pass his or her practice on to a younger partner. This group of patients will feel most comfortable knowing that their new designated physician has been oriented to their long-time provider's practice philosophy and methods. While passing the baton is an important part of transitioning retiring surgeons out of the practice, retiring surgeons should maintain standard of care in their practice if they continue to participate in clinical activities, especially surgery, as the group's reputation can be as powerful as the individual reputation.

According to an American Osteopathic Association survey, the top five resources adults utilize when selecting a physician for themselves or a loved one are [9]:

- Word of mouth, i.e., family, friends, and coworkers (65.9%)
- Insurance provider directory (51.9%)
- Physician rating websites, i.e., Vitals, Healthgrades (22.8%)
- Hospital website (10.8%)
- Consumer review websites, i.e., Yelp (10.5%)

The first take-home message from these statistics—be kind, be affable. If you are kind, you will rapidly engender respect in the community, and your practice will grow. It is easy to become frustrated with a slow schedule at the beginning of your career. After all, you just finished residency or fellowship where every day brought new experiences and a wealth of opportunities to care for patients. It can feel like an abrupt slamming of the breaks on a career that has been defined by clinical volume and intense activity. Instead of focusing on the slow schedule, use this time to develop relationships. Relationships aren't important—they're everything, whether in our business, in our homes, or among friends. They are the threads that weave through the fabric of our entire being [10]. This is a gift of time. In order to have patients find you by "word of mouth," other patients have to have something nice to say. Spend extra time in consultation and get to know your patients. If you are in a new city, have them show you where they are from on a map. Take extra time with family members in the waiting room after surgery. The patient and family interactions are invaluable to your success, but do not underestimate your interactions with

everyone else from the unit clerk to the janitor to the CEO of the hospital. Every time someone mentions your name, you want people to say, "Dr. New is so nice." Of course, this behavior should be delivered in a genuine way. And remember, even when you are tired and frustrated, be kind. There's never a good time to be unkind.

You may be employed in a system where there is a well-defined referral network and there is less energy to be spent on securing referral sources to fill the schedule. However, in these models, the relationships you form with your employed colleagues will not only bring satisfaction to you personally but also help drive the culture of the organization. Furthermore, in many organizations you will likely be evaluated on collegiality, and your contract renewal may factor in these considerations.

Spending time meeting referring providers in person at the beginning of your career will be time well spent. Now that hospitalists have taken over inpatient care of the medical wards, the days of meeting primary care providers in the doctor's lounge is over. However, these settings are still fruitful for networking. You will invariably encounter oncologists, radiologists, and other specialists that create your multidisciplinary shortlist of go-to providers of inpatient services. In addition, you are likely to encounter representatives from hospital administration. This is a good time to talk with them about new projects, as well as inquire how you can help achieve their goals and that of the health system. Phone calls can be a way to facilitate relationships in the absence of face-to-face time. If you have a patient in your office with a particularly difficult situation or a new cancer, a quick call to introduce yourself and discuss the case shows dedication to quality care. There are more and more concierge medical practices opening, and these providers are paid fees by their patients for personalized care coordination. Reaching out by phone to these providers is not only appreciated, but often expected to be part of their referral network.

When you can schedule face-to-face time with referring providers, be mindful of their busy schedules. Be prepared to have a very brief period of their time. Scheduling breakfast or lunch in their office can make your meeting easier on their schedule. As a rule, bring food for the whole office and inquire about dietary restrictions/preference. This is a good time to highlight services you provide and also letting them know about new techniques you might be adding to the practice such as transanal minimally invasive surgery, robotics, fecal transplant, etc.

Highlighting new services your practice is offering gives a reason to reach out to new referring providers, as well as remind regular referring providers why you are the colorectal surgeon of choice. You might put together a short video of an operation and the cosmetic outcome for patient. It is always important to understand established referral patterns of your partners prior to determining your strategy. It is unlikely to sit well with your partner and likely to confuse the referring provider if you schedule a visit with someone who is committed to sending patients to one of your partners. These types of meetings should be supported by the entire practice, and communication about the strategy should be determined by the group.

When meeting with referring providers, try to figure out how you can make their lives easier. If the provider says everything is going well and they are getting your notes and letters and patients are happy, talk to the office staff/scheduling coordinators. They may prefer fax referral forms to free up their staff from the telephone. A laminated original may help them to be able to make copies easier (Fig. 72.1). Offering same-day appointments for diagnoses such as acute rectal pain, abscesses, and fissures can help their patients avoid ER visits. Practices participating in accountable care organizations are motivated to keep their overall cost of care down, so this may be very attractive to them. Being able to offer same-day or next-day diagnostic colonoscopy for patients that might have otherwise gone to the hospital is a valuable option, and referring providers need to know this is possible and available. Given that there are so many challenges in healthcare today, when meeting with referring groups, ask about their biggest challenges. Maybe you can share a practice problem and can work on a solution together which can create loyalty through collaboration. This could cover anything from IT support to health insurance to staffing. These visits are also a good time to inquire how they are marketing their practice and what they have had success with while learning what has failed.

One strategy for identifying potential referring providers is to find providers that are like you in some way, such as race, ethnicity, or gender. As a female, gynecologists and urogynecologists may be an untapped source of referrals, especially if you are joining an all-male group. As a minority, networking with other minority providers can be powerful as minority patients tend to choose providers of their own race [11]. If you speak a language other than English, network with other providers in your area that do as well as you are able to offer a unique resource to inpatients whose primary language may not be English.

One way to help strengthen a relationship is to change the environment [10]. Setting up a fun community event for referring providers and even their families can create an atmosphere of collegiality that is not possible in the office or hospital settings. A sports arena dinner with a famous guest speaker and an exclusive tour of a thoroughbred farm or distillery could be venues to consider. Not only referring providers but their staff as well can be advocates for your practice. Doing special things for referral coordinators, the people who often have a lot of power over where the referrals get sent, can be money well spent. This could range from

flowers at Valentine's day, Starbucks cards, or even a night out at a local pub. In these clerical positions, they may not be receiving the type of positive feedback that the clinical providers do in the practice and a little appreciation can go a long way with this group.

Getting involved in the community, outside of the healthcare setting, can be an effective way to meet people and increase your visibility. Local medical societies, hospital committees, coaching youth sports, parent-teacher organizations, and church groups are just a few of the opportunities for not only networking, but learning more about unmet needs in your area. If you have a significant other, they can also get involved and tastefully get the word out about you and your practice to others. For several reasons outside of building your practice, community service and involvement can be very rewarding.

Although you might be achieving the three A's and offering the best that colorectal surgery has to offer, there might be external forces affecting referral patterns that you are not able to control. Hopefully, you were aware of these prior to taking the job. With changes in the healthcare environment, new challenges with referral pattern challenges may come up, even after you have been in practice for some time. You may experience your established referring doctors leaving independent practice to go to work for a health system or switching systems. There is often considerable pressure on providers to keep patients within a health system. Some clinic models are organized such that there are financial

incentives for referring providers to keep patients within the system. While there can be incentives for in-network utilization as long as there is evidence that there is value being provided by the coordination of care, contracts for employed physicians must include a provision specifying that patient choice will be respected.

Although patients may be restricted in their choice of provider if they have enrolled in a narrow network health insurance plan, it is still possible that they may choose someone outside of the integrated healthcare system if there is some flexibility.

Healthcare systems have focused on "leakage" of patients. The electronic medical record which tracks every referral a physician makes provides this data to physicians as well as practice managers. Relationships with healthcare systems are more important than ever for independent groups. Demonstrating quality and the value that you provide for their organization is crucial. If you are only viewed as leakage and an outsider, there could be significant challenges to practice viability. For example, a local healthcare system that competes with our group for outpatient endoscopy services implemented a new EMR that linked their outpatient and inpatient sites of service. Our independent practice, even though affiliated with this system with all of our physicians having full credentials, was left off of the EMR dropdown list of providers for 6 months until we were able with a tremendous amount of time and effort to get back on the list. The workflow remains set up so that those providers must make extra effort and clicks to get patients to us versus their hired physicians. If you are in private practice, tracking practice volume and referrals is essential to analyze the stability and future of the practice in an environment of mergers and acquisitions of practices by health systems.

Although these systems have tremendous resources and creating fully integrated care models with more narrow networks, the future of well-run independent practices remains bright in our current healthcare climate focused on quality and value. By partnering with your healthcare system in meaningful ways that create synergies for enhancing care delivery models, not only can independent practices remain viable, they can actually thrive. For instance, you could probably easily list several obvious areas of waste in the operating room at the hospital. Independent physician run groups and facilities are typically a tight run ship when it comes to expenses and have the discipline to focus on areas of inefficiency to improve the hospital environment. There is demand for high-quality, low-cost sites of service whether or not the health system is also the insurer. Often cost-efficient physician-owned practices and facilities have advantages when negotiating with insurers especially where and when they can deliver similar medical services at a lower price point. Payers are likely to have access to this information, and it is important to leverage this to your practice's advantage while making sure that you collect and monitor your own data to ensure its accuracy.

For employed physicians, even though there might be an established network of referring providers, understanding the stability of the referral base is equally as important. There may be quite a few gastroenterologists in the system, but are they happy? Are they planning on leaving because of dissatisfaction with the "system"? If they leave, what does that mean for your practice? Investing in creating and enhancing referral relationships, as well as working to support and grow the organization's culture, can not only mitigate a perception of loss of control of your practice but can actually replicate the physician-led group practice governance and management seen in independent practices.

Marketing

If your group's reputation is excellent and in network with the most common insurers in your area, then patients will choose you if they know you exist.

As internet marketing has dominated current strategies for most practices, the cost has come down on some of the most effective ways to reach patients with your message. You may choose to hire someone full time or part time with a marketing background and hire consultants from time to time to do project work such as getting your website up and running or cleaning up social media profiles. You may also hire a firm to have continual management of the marketing side of the practice. No matter what the strategy, metrics on effectiveness of marketing projects are key to determine what is working and what is not.

Digital marketing has largely replaced traditional marketing strategies such as print and billboards. Billboards, mailers, putting up signs at the baseball field, pin ups at the gym, etc. can certainly reach a small audience and enhance brand recognition, but these strategies should not be the center of the marketing plan. Digital platforms are not just for millennials. Adults ages 50–64, who spend the most overall time across all platforms of any age group, spend 51% of their time watching TV and TV-connected devices and 31% on digital platforms (Fig. 72.2) [12]. Facebook Ads has become the digital billboard. In addition to a broad reach to consumers, this platform also allows the ability to target a specific audience by a variety of parameters such as age, location, gender, education, and interests. By creating a custom audience, marketers can target the exact population their services are aimed toward without wasting money on persons outside of their target audience. Facebook Ads allows you to see the reach, engagement, and impressions of each ad and post so that you can know what type of content works and does not work for your audience such as in Fig. 72.3. A call-to-action on most posts is needed to drive your audience from just

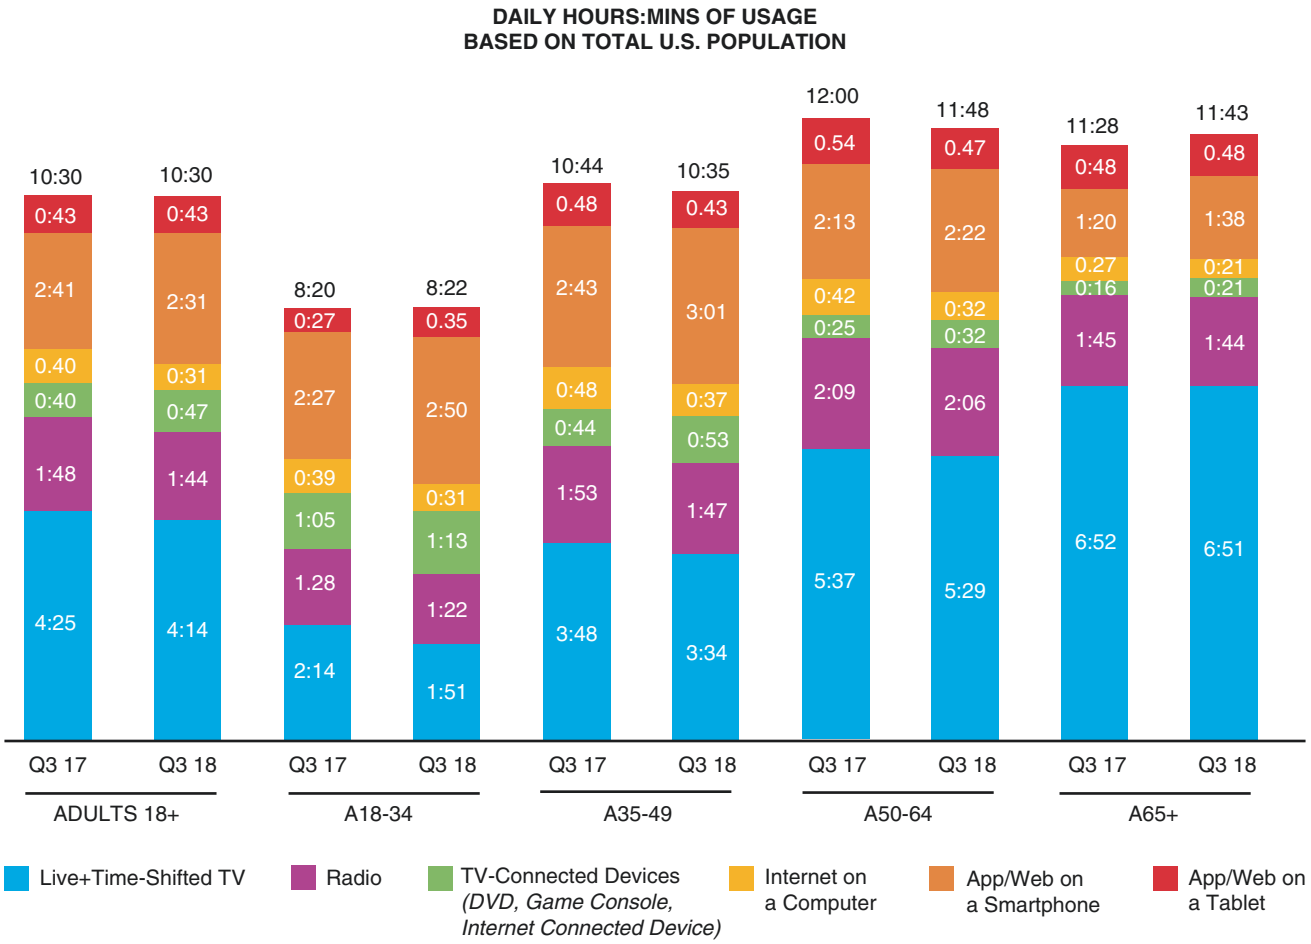

Fig. 72.2 Media time by demographic. Adults 50–64 spend more time on media than any other group

looking at your content to acting, such as scheduling an appointment.

The key to marketing a medical practice is to gain the trust of your audience. Unlike marketing tactics for a retailer or other service, marketing for a medical practice involves a higher degree of connection with your audience. Since the person's health is involved, their choice of which doctor or facility to select for their care is taken more seriously, and additional research is involved. Potential patients need to feel a sense of trust in the doctor and practice before they schedule an appointment. Healthgrades.com and Vitals.com are the first step for most patients when researching a doctor. With roughly 100 million people searching Healthgrades.com per year, keeping track of the reviews of the doctors in your practice is crucial. The same is true of Vitals.com. One major difference in these two websites is that Vitals.com allows ads on their website so practices can market directly to those patients who are using Vitals. Managing the reputation of the providers and the practice on social media should be done regularly. Reviews on Healthgrades and Vitals cannot be deleted, but they are listed in order of the date the review was written. One strategy to decrease the visibility of negative reviews is to encourage satisfied patients to leave good reviews. Another strategy is to leave a reply to negative reviews, which may demonstrate to others that you care and/or there might be other details relevant to the complaints. This could also be an opportunity for others to see that you are making efforts to remedy perceived wrongfulness and that you care. Responding to positive reviews with gratitude is also encouraged.

Content that engages your audience such as videos on healthcare-related topics or getting to know the physician and photos usually perform the best in terms of reach and engagement. A medical practice's social media accounts should always be professional, but at the same time, social media accounts should be inviting and personal. For example, your Facebook page should have a personality that matches the brand, tone, and voice of the practice. Facebook Insights allows administrators to see how each post performs and follower behavior which relates to the best time and day to post.

Aside from social media marketing, other forms of digital include over-the-top marketing (OTT) which is ads shown to a target audience through streaming services and most cable

Fig. 72.3 Example of feedback from Facebook ads regarding the results of online marketing efforts

providers and search engine marketing (SEO) which adds tags so that Google and other search engines show your page in the results of internet searches and an up-to-date website with easy to find information. YouTube channels and the era of "celebrity surgeons" is upon us. Now is the time when a patient can scan a QR code and watch a video of their surgeon performing the operation that they are about to undergo. These channels can be used for operative videos but also perioperative instructions, information about the physicians, topical discussions, etc.

As you can see, the social network environment has become extremely complicated and requires a high level of expertise to succeed in. While a physician well versed in social media can help guide a group practice's digital footprint, it is advised if at all possible for a professional to be hired either internally or as a consultant to continually manage the process. As health systems get larger and reap the benefits of scale, this has become a true focus and area of expertise for employed physicians within the network. Oftentimes, there is an entire marketing and planning department that supports this enterprise. While there are laws governing how a health system can market an independent individual or group practice in its community, there are opportunities for co-branding that can benefit each entity and the patients they care for.

Community involvement is also a good way for practices to brand themselves. Health fairs, festivals, and sponsorships of local community events such as youth sports and concerts are all high visibility opportunities to showcase the practice's logo as well as create a casual atmosphere for the public to get to know the providers and staff of the practice. There are other creative ways to market, including by reaching out to local service clubs, such as Kiwanis, the Lion's Club, or the Rotary Club to see if you can come and give a brief talk. Take business cards and handouts about the services in the practice. You may also bring a staff member who can schedule appointments right at the event. Becoming engaged with your local AORN and other nursing groups will have a far

reach. They have regular dinner meetings and conferences and need speakers. Local news stations may also have opportunities for exposure, such as a colon cancer awareness month piece on the morning show during March [13].

It should not be overlooked that some insurers will reach out to their customers with incentives to patients for utilizing certain facilities for their healthcare needs. It is essential that you know where your practice falls on these lists with the insurance company you hold contracts with. For instance, a patient may receive $100 check directly from the insurance company if they schedule their colonoscopy with a different facility which might change their decision to come see you. You want to be able to influence the variables that are in your control. Some insurers even engage in narrow network contracts where the policy covers certain healthcare services with only one provider. These are uncommon but exist and might be an option for your practice.

Setting Up Your Office

Most often you will be joining a practice that already has a system in place for seeing patients in the office setting. The office is most efficient and profitable with attention to having staff practice at the top of their license. Data entry can be done by medical assistants which are the least expensive staff to employ. Whether it be medical students, residents, or medical assistants, data entry into the EMR for medical histories, allergies and medication lists, etc., by other staff will free you up to focus on HPI, exam, assessment, and plan. At the beginning of your career, you will need less help. However, eventually, this type of staff support will be essential for you to accomplish the clinical work you have. Attention to this in your contract is imperative. Stories of surgeons being let go for poor productivity performance exist when, in reality, the employer did not provide the staffing in the office to achieve sustainable revenues or its surrogate, RVU's, for the surgeon. For example, on a day when there are 30 patients in clinic for one surgeon, a successful strategy might be having one person checking patients in and another person checking patients out. With three medical assistants in the clinic, one person chaperones in the room and two others are rooming patients and entering data into EMR. Two-three exam rooms to work in can facilitate the patient flow, while having a separate procedure room can be ideal.

Office-Based Procedures

As colorectal surgeons, the office serves as not only our primary location for consultation but also an ideal location for many simple procedures. Office-based procedures, when executed effectively, help facilitate efficient care of our patients. They also can contribute significantly to the revenue stream from the office. Anoscopy, rigid proctoscopy, flexible sigmoidoscopy, incision, and drainage of perirectal abscess among others are well-suited for the office setting. A list of common office procedures with their respective CPT code, global period if applicable, and Medicare allowable can be found in Table 72.1. The reimbursement for these procedures with private insurers will be specific to individual physician contracts. Office procedures can be done with the patient in either the prone jackknife position or left lateral position depending on the type of table available and surgeon preference. An assistant is essential. A general list of necessary supplies for the clinic is listed in Table 72.2. While not exhaustive, this should cover the majority of what you would need to perform in most office-based procedures in our specialty. There are several vendors on the national and local levels that can be used to obtain the necessary supplies and equipment for the office. A couple of the equipment vendors for items such as anoscopes, proctoscopes, and fistula probes typically visit the annual ASCRS meeting. This is a great

Table 72.1 Common colorectal office procedures with associated CPT code, global period, and Medicare reimbursement

CPT	Procedure	Global period	Medicare reimbursement
45330	Flexible Sigmoidoscopy	0	$160.70
45331	Flexible sigmoidoscopy with biopsy	0	$251.92
45338	Flexible sigmoidoscopy with snare polypectomy	0	$263.39
45300	Rigid sigmoidoscopy	0	$114.46
45305	Rigid sigmoidoscopy with biopsy	0	$150.92
45309	Rigid sigmoidoscopy with polypectomy	0	$177.02
46600	Anoscopy	0	$95.07
46606	Anoscopy with biopsy	0	$235.68
46614	Anoscopy with control of bleeding	0	$137.06
46900	Acid treatment-warts	10	$221.73
46930	Infrared coagulation	90	$199.96
46221	Internal hemorrhoid banding	10	$257.43
46230	Excision anal skin tags or papillae	10	$276.97
46320	Excision of thrombosed hemorrhoid	10	$185.16
46050	Incision and drainage of perirectal abscess	10	$202.95
10080	Incision and drainage of pilonidal abscess	10	$194.14
44385	Pouchoscopy	0	$185.29
44386	Pouchoscopy with biopsy	0	$275.86
57452	Vaginoscopy (not payable when combined with any other scope under Medicare)	0	$115.20

Table 72.2 Supplies for the colorectal clinic

Supplies		Medications
Disposable	*Reusable*	
Abdominal pads	Anoscope	Local anesthetic with and without epinephrine
Adhesive gauze roll	Autoclave	Local anesthetic cream or ointment
Alcohol swabs	Banders with forceps	Monsel solution
Band-Aid	Biopsy forceps	Depo-Medrol
Betadine	Blade holder	Gentian Violet 5%
Bleach	Fistula probe	Podophyllum Resin Salicylic Acid
Cotton swabs	Flexible sigmoidoscope	Silver Nitrate 20% Solution
Culture swabs	Forceps	Dichloroacetic Acid
Foley catheters	Hagar dilators	
Gauze	Hemostat	
Gloves	Hyfrecator	
Iodoform packing strip	IRC machine	
IRC sheaths	Light cord	
Lubricating jelly	Light source	
Mushroom catheters	Needle driver	
Needles	Oxygen tank	
Bands for ligatiors	Scissors	
Paper tape	Staple remover	
Peroxide	Suction pump	
Proctoscopes	Suction wand	
Rubbing alcohol		
Sani-Cloths		
Silver nitrate sticks		
Sterilization pouches		
Suction tubing		
Surgical blades 10, 11, 15		
Suture		
Syringes		
Table paper		
Tape		
Tissues		
Underwear/pads		

opportunity to talk with them as well as have them demonstrate their available options.

While sterilization of anoscopes and proctoscopes in the office can be easily managed with simple processes, the processing and maintenance of flexible scopes adds a layer of complexity you may or may not want to entertain. A description of this can be found at https://www.cdc.gov/hicpac/flexible-endoscope-reprocessing.html. A small autoclave and Cidex solution can be used for essentially all equipment. These processes should not take up too much space, as seen Fig. 72.4. Having enough staff in the clinic must be a consideration when setting up your clinic design. There are several vendors that now offer disposable anoscopes and proctoscopes if the staff time for processing instruments is unavailable.

Ancillary Services

Ancillary services in healthcare include a range of services that support physicians, such as laboratory tests, medical equipment, and rehabilitation programs. Ancillary services are typically classified into three categories: diagnostic (radiology, diagnostic imaging, etc.), therapeutic (physical and occupational therapy, massage, nutritional counseling, etc.), and custodial (hospice care, nursing facilities, and urgent care). Offering ancillary services as part of the practice meets several needs for patients and physicians. Services such as a pelvic floor center with anorectal manometry, physical therapy, ambulatory surgery center, and a pathology lab may be well-suited for a colorectal practice. A practice that is diversified in their revenue streams is more likely to adapt to further decline in physician compensation and rising costs of running a practice. However, embarking on projects to solely increase revenues should be avoided. Declining or delayed reimbursements, insurance claim hassles, increasing costs, growing regulatory pressures, patient demand, and patient satisfaction are good reasons to diversify the revenue stream. By adding ancillary services, physicians may be able to provide more convenient care, improve clinical outcomes, control the operation and quality of services, increase access to care, provide efficient and effective care, and offer additional services within their practice. Improved outcomes result in increased patient, physician, and payer satisfaction and decreased viability [14]. What's more, providing in-house services makes it more likely for patients to comply with physician instructions [15].

There are risks in adding ancillary services to your practice which include losing money, violating Stark laws, damaging relationships with referring physician practices or hospitals, causing harm, losing the trust of your patients, damaging one's reputation, and performing more tests/procedures than medically indicated and lawsuits [14]. Ancillary services cannot violate Stark, federal self-referral and anti-kickback laws, anti-markup rules, location oversight requirements, federal/state statutes, license and certification, OSHA, clinical laboratory improvement amendments (CLIA) certification, and insurance liability. The best advice before you make an investment or participate in ancillary income is to contact a healthcare attorney who is knowledgeable about the nuances of the Stark and other laws [14]. CMS.gov-Section 1877 of the Social Security Act (the Act) (42 U.S.C. 1395nn), also known as the physician self-referral law and commonly referred to as the "Stark Law" [16]:

Fig. 72.4 Colorectal clinic sterilization space and equipment

1. Prohibits a physician from making referrals for certain designated health services (DHS) payable by Medicare to an entity with which he or she (or an immediate family member) has a financial relationship (ownership, investment, or compensation), unless an exception applies
2. Prohibits the entity from presenting or causing to be presented claims to Medicare (or billing another individual, entity, or third-party payer) for those referred services
3. Establishes a number of specific exceptions and grants the Secretary the authority to create regulatory exceptions for financial relationships that do not pose a risk of program or patient abuse

The following items or services are DHS:

1. Clinical laboratory services
2. Physical therapy services
3. Occupational therapy services
4. Outpatient speech-language pathology services
5. Radiology and certain other imaging services
6. Radiation therapy services and supplies
7. Durable medical equipment and supplies
8. Parenteral and enteral nutrients, equipment, and supplies
9. Prosthetics, orthotics, and prosthetic devices and supplies
10. Home health services
11. Outpatient prescription drugs
12. Inpatient and outpatient hospital services

By law, physicians cannot be compensated according to the value or volume of their referrals or by the income they generate. The regulations do eliminate certain forms of self-referral, but do not ban self-referrals to specialty hospitals, ASCs, or office-based surgical or imaging procedures [17]. Ancillary services development requires a dynamic interpretation of multiple elements including cost, changing regulations, and altered reimbursement that will impact income projections and often extend the time to a positive cash flow. This is especially true for projects that require a high upfront

capitalization. Physician financial commitment to ancillary service development needs to be carefully assessed and measured in a healthcare environment that is placing increased emphasis on cost containment and value.

Ambulatory Surgery Centers

For the outpatient procedures requiring more time, equipment, and personnel than the clinic can handle, the ambulatory surgery center (ASC) is an ideal location. Most successful ambulatory surgery centers pride themselves on efficiency and decreased cost compared to inpatient operating rooms. Often, there will be restrictions on the types of patients that can be scheduled there based on factors such as BMI and ASA class. However, all but the sickest, largest patients are typically well-suited for colorectal procedures in an ASC.

Credentialing at an ambulatory surgery center should be a straightforward process. Typically, independent ambulatory surgery centers are more than happy to accommodate block time for a new surgeon to increase the procedure volume of the facility. The ambulatory surgery center generates revenue predominantly based upon facility fees that are charged on a per procedure basis. In the ASC, volume is the critical driver for profitability. Ambulatory surgery centers go through JCHO accreditation similar to hospital facilities [18]. State licensure often requires JCHO accreditation. Often, insurance companies will require state licensure for the surgery center to charge facility fees for outpatient surgical procedures. There are certain states where a certificate of need (CON) is required to open and operate an ambulatory surgery center. In those states, an option to contract with insurance companies for office-based procedures can be accomplished and may be an option for practices that have not acquired a CON. While Medicare and Medicaid require state licensure to bill facility fees for procedures, commercial insurers may be more flexible and provide contracts with similar reimbursement to the facility as if it were state licensed. In-depth understanding of your state's laws regarding ambulatory surgery centers is essential if you are considering becoming an owner or shareholder of an ASC. Counsel with specific experience in CON laws in the state is essential to the process. Currently, 36 states and Washington, D.C., operate a CON program with wide variation state-to-state [19].

Owning and operating an ASC can be extremely rewarding in many ways. Not only will it increase revenue streams to the practice if properly managed, but it gives the surgeons and patients control over cost and scheduling. With high deductible plans, patient have the potential to save money on their healthcare procedures when done in the outpatient setting. We have seen differences in patient's bills from an inpatient facility and an ASC of thousands of dollars for the same procedure. For the surgeon, control over scheduling, personnel, workflow, and equipment can be a welcome change of pace from the often slower more cumbersome inpatient care facilities. The win-win for the patient and the surgeon makes the ASC an ideal part of the colorectal practice.

Other Ancillary Services

To decide on ancillary services to add to your practice, start by doing a thorough economic analysis of the services you're currently sending out. You may also look at your community to see if there is an unmet need for the type of service you are thinking of adding. A practice's patient panel can be an important consideration in choosing an ancillary service that has the most potential to improve care [13, 15]. Some of the data required to evaluate the potential of a new ancillary service might include how often the practice currently refers out the service; total investment costs, including staff and training; and the amount of reimbursement expected. Practices should also know in advance what qualifications their payer contracts specify, such as Clinical Laboratory Improvement Amendments certification, which may be required for lab services. Upfront costs for equipment can range from just a few hundred dollars to tens of thousands. However, practices might size up the return on investment in terms of patient volume. Anorectal manometry equipment used to be a physically large machine and very expensive. Now, technology has much improved and the equipment is small, portable, easier to use, and more affordable. This is a test that most colorectal surgeons use to make clinical decisions. It is also a test that does not take that very long to complete but often requires an additional appointment at another healthcare institution for a patient who is already in your office. Therefore, adding anorectal manometry as an ancillary service to your colorectal practice would be an ideal type of service to consider. A manometry machine, for example, might cost $20,000, while the reimbursement for the procedure is $700. Disposable equipment costs $115 per procedure, which results in collected revenue to $585. It does not take long before the practice will see a return on investment. Other providers, such as gastroenterologists, may also be interested in referring these exams to you and would also provide an opportunity for networking if they are not already offering this service as part of their practice. It could also serve as an opportunity to let the gastroenterologist know what types of treatment options that you are providing to patients with chronic constipation. Consideration for additional physician and staff training must also be part of the business plan, the creation of which is an essential part of the process for this ancillary service or any other that you are contemplating.

Billing and coding for ancillary services cannot be an afterthought. Covered diagnosis codes for the services you provide are important to understand so that when the test is

submitted to insurance for billing, reliable reimbursement is expected. This includes some wariness about the Medicare Access and CHIP reauthorization Act's (MACRA) impact on ancillary services as payment moves from fee-for-service to quality-based reimbursement. Physicians should review the specific requirements of modifier −25 as they relate to each payer in a practice's mix. Some payers may deny a modifier −25 code (separately identifiable evaluation and management service by the same physician on the same day of a procedure or other service), potentially resulting in nonpayment for ancillary services [20]. Many payers, including Medicaid, do not recognize the modifier. It is also vital to market and promote the ancillary services that your practice provides. If patients are not aware of the services you are providing, they will not use them. Put posters in the waiting and exam rooms. Include details on the practice's website. Include information about these services when the practice holds community events and visits referring provider's offices.

Leadership Roles

While we all share the common goal of taking excellent care of the colorectal surgical patient, other career goals among us vary greatly. Some aspire to lead international surgical societies, while some focus on their clinical work with their patients, and others dive deep into research pursuits or cutting edge minimally invasive techniques. When done well, involvement in local, regional, and national leadership activities are the path to bigger and more important roles. If these are your goals and the path to success is not clear to you, seek out mentorship. There are now formal mentorship programs developed in surgical societies, including the ASCRS. Committee work at the local level might not seem like it should matter very much to the career of a researcher or busy robotic surgeon. However, participation is a great way to build relationships for collaborators and referring providers. If unfortunate events such as credentialing issues come about for you or one of your partners, it is crucial to have representation on medical executive committees and peer review, so you or your group have influence in making decisions about privileges. Local medical society offices can lead to state medical society appointments and even national appointments. These roles help build your personal CV but can also help your practice stay in the know on legislation affecting surgical practices such as tort reform, changes in fee schedules, certificate of need, Medicaid expansions, etc.

There may be a time in your career when you would like to transition out of direct patient care. If your nonclinical activities and interests are robust, you will likely have more opportunities for jobs and projects as this stage presents itself. An advantage of being part of a large healthcare system is that there are a myriad of career paths available to consider. This can be tied to clinical activities, such as managing a service line or leadership of the employed group practice. This is especially important if the goal of the health system is to create a physician-led culture, at least for the clinical activities. With the trend toward physician leadership of the entire healthcare system enterprise, nontraditional physician roles including operational leadership all the way to the C-suite have now become commonplace.

Sometimes, these transitions may be a conscious choice, or unfortunately it may be out of the surgeon's control. At times, due to medical illness, advanced age, or loss of privileges, a surgeon may have to give up clinical activities, including operating. Obtaining professional advice, including counseling if the transition is particularly challenging, is highly recommended as part of the process. Ultimately, a diversified approach to your skill set, just like diversification in a retirement plan, can offer a safety net in these circumstances.

Conclusions

Healthcare is rapidly changing and can be overwhelming at times. Given the magnitude of growth of the industry and its impact not only on the patients we treat but also the US economy, it is no surprise that disruption is taking place on a daily basis. Rather than resist the inevitable changes taking place, it is far more productive and healthy to both adapt, as well as lead the journey to achieve the quadruple aim (improved patient/customer experience with increased quality and cost efficiency, while also focusing on provider health and wellness). The ASCRS recognizes its role in supporting the journey for its members and there are resources available to the practicing colorectal surgeon as presented in this chapter and through the ASCRS to navigate these challenges. Topics relevant to practice management are now highlighted in a formal symposium at the ASCRS national meeting. The Healthcare Economics Committee remains dedicated to representing the needs of colorectal surgeons to lawmakers. In addition, there is now a formal mentoring program through the ASCRS. More information can be found at https://fascrs.org/my-ascrs/career-center/mentoring-program.
