### Abstract

Residual pulmonary vascular obstruction (RPVO) and chronic thromboembolic pulmonary hypertension (CTEPH) are both long-term complications of acute pulmonary embolism (PE), but it is unknown whether RPVO can be predicted by variants of fibrinogen associated with CTEPH.

We use Akaike Information Criterion to select the best predictive models for RPVO in two prospectively followed cohorts of acute PE patients, using as candidate variables the extent of the initial obstruction, clinical characteristics and fibrinogen-related data. We measured the selected models' goodness of fit by analysis of deviance and compared models by  $\chi^2$  test.

BP recruited patients, performed experiments and helped write manuscript; OS, JE, GM helped design study and contributed to manuscript; JM, PC, RM, GG performed laboratory experiments and contributed to manuscript; GL planned analysis and contributed to manuscript; TW, AG performed statistical analyses and contributed to manuscript. TM is the study PI, planned study, performed experiments and contributed to manuscript.

RPVO occurred in 29/102 (28.4%) subjects in the first cohort and 46/182 (25.3%) subjects in the second. The best-fit predictive model derived in the first cohort (p = 0.0002) and validated in the second cohort (p = 0.0005) implicated fibrinogen B $\beta$ -chain monosialylation in the development of RPVO. When the derivation procedure excluded clinical characteristics, fibrinogen B $\beta$ -chain monosialylation remained a predictor of RPVO in the best-fit predictive model (p = 0.0003). Excluding fibrinogen characteristics worsened the predictive model (p = 0.03).

Fibrinogen Bβ-chain monosialylation, a common structural attribute of fibrin, helped predict RPVO after acute PE. Fibrin structure may contribute to the risk of developing RPVO.

### Keywords

pulmonary embolism; residual vascular obstruction; fibrinogen; V/Q lung scan

### Introduction

After acute pulmonary embolism (PE), thrombotic material in the pulmonary arteries typically disintegrates, although in some cases it transforms into permanent obstructing scars.[1] Residual pulmonary vascular obstruction of 10% or more (RPVO) is common after PE and can diminish physical activity, reduce quality of life and worsen overall prognosis. [2–7] RPVO is associated with dyspnea,[8] hypoxemia,[9] gas exchange deficits, [9] exercise intolerance[2] and other serious clinical impairments.[9–11] RPVO incurs the risk of recurrence[12] and of chronic thromboembolic pulmonary hypertension (CTEPH),[2, 13] an uncommon[14, 15] but severe complication of PE[16, 17] in which obstruction is extensive and pulmonary arterial pressure rises.[18]

The mechanisms by which fibrin-rich thromboemboli transform into permanent obstructions characteristic of RPVO and of CTEPH are incompletely understood. RPVO is not associated with "thrombophilia" or with impaired fibrinolytic enzymes.[2] We observed that fibrin itself derived from some patients with CTEPH forms clots resistant to lysis[19, 20] with aberrations in molecular configuration[21] and clot structure[22] that reflect otherwise rare fibrinogen gene mutations.[20] CTEPH-associated dysfibrinogenemia may be a model for more common fibrin characteristics that might tip the balance from clot resolution towards RPVO.

To gain insights into the development of RPVO, the Prediction of Residual Obstruction Manifested after Pulmonary Embolism Treatment (PROMPT) study followed two cohorts of patients after acute PE to determine the best predictors of RPVO. We investigated whether fibrinogen post-translational modifications and other common fibrin structural attributes might help predict the development of RPVO after acute PE. If fibrin properties are consistently associated with RPVO, then they might be implicated as a mechanism of its development.

### Methods

### Study design and study population

We used clinical data and biological material from two single-center, prospective, observational cohort studies conducted on separate groups of acute PE patients in an academic teaching hospital (Hôpital Européen Georges Pompidou, Paris, France). The two studies were approved by the local ethics committee. All patients provided written informed consent before enrollment.

For cohort 1, we enrolled consecutive patients with PE from our center who had been included in the FARIVE study, a multicentre case-control study that evaluated the interactions of environmental, genetic and biological risk factors on the risk of a first venous thromboembolism (VTE). The study included consecutive subjects who were above 18 years and had their first symptomatic occurrence of pulmonary embolism. Patients were excluded if they had active cancer unless they had been treated successfully and had no evidence of recurrence for the previous 5 years. Patients were also excluded if they had short life expectancies secondary to other associated pathologies, anticipated impossibility of follow up or a previously diagnosed thrombophilia.

For cohort 2, we enrolled consecutive patients with PE followed-up at our center between February 1999 and May 2006 who had not been enrolled in the FARIVE study.[2] This study was designed to assess the clinical significance of residual pulmonary vascular obstruction after an episode of acute PE. Patients were included if they were above 18 years of age and had completed at least 3 months of oral anticoagulant therapy without having recurrent PE.

In both cohorts, the diagnosis of PE was established through high-probability lung scintigraphy, thoracic CT scan, pulmonary angiography, sonography showing the existence of a proximal venous thrombosis in the absence of a differential diagnosis for the reported pulmonary symptoms, or nondiagnostic pulmonary scintigraphy associated with lower extremity ultrasound disclosing proximal DVT. The type and duration of long-term therapy was left to the discretion of physician in charge of the patients. The standard practice was to treat provoked PE for at least 3 months and unprovoked PE for at least 6 months.

### **Residual Pulmonary Vascular Obstruction**

All patients underwent a standardized ventilation/perfusion (V/Q) lung scan at least six months after the acute PE.[23] A trained investigator (BP) blinded to all other study data identified and scored mismatched perfusion defects according to a pre-specified protocol.[24] We defined RPVO as a residual vascular obstruction of 10% or more, which corresponds to an amputation of at least two pulmonary segments (the minimal obstruction defining a high-probability result on diagnostic V/Q lung scans[25]) and is associated with dyspnea and exercise intolerance after acute PE.[2]

### Demographic and clinical data

A standardized tool was used upon study enrollment to record clinical data (including the type of acute therapy and the duration of long-term therapy) and conduct a structured interview. Except for the fibrinogen-related laboratory data described in the following section, all laboratory values were measured in the clinical laboratory of Hôpital Européen Georges Pompidou. Physicians blinded to the other data of each patient used a validated score to calculate the initial pulmonary vascular obstruction on the original diagnostic CT scan[26] or V/Q scan.[24] None of the subjects had pulmonary angiography as the initial diagnostic test.

### Fibrin structural attributes

Upon enrollment, blood samples were collected by venipuncture into anticoagulantcontaining tubes. Plasma was separated by two consecutive centrifugations and stored at  $-70^{\circ}$ C for analysis. Plasma fibrinogen levels were measured in a clinical laboratory at the time of blood collection.

Research assays were performed on fibrinogen that had been purified from citrated plasma by ethanol precipitation and exposure to Gelatin Sepharose (GE Healthcare) to remove residual fibronectin, followed by dilution to 4mg/mL.[20] Appendix 1 includes the detailed assay methodologies, which have been previously reported.[19, 20, 22] They are briefly described below.

Fibrinogen, thrombin, and calcium chloride were combined to form fibrin clots in the amounts appropriate for each structural assay. We determined the turbidity of the fibrin clots, which corresponds to fibrin network fibril dispersal and branching as validated by microscopy.[20, 22] We measured fibrin clot susceptibility to lysis through the rates of turbidity decrease, measured consecutively after clots were exposed to a mixture of plasminogen and tPA.[20] We measured fibrin clot permeability, which reflects the organization with which fibrin polymers are formed,[22] by the rate of passage of permeability buffer through fibrin clots. More organized fibrin networks with large pores have higher flow compared to disorganized fibrin networks with small pores. We measured by SDS-PAGE the degree that fibrin crosslinks its  $\alpha$ -chains as a reflection of the potential to form stabilized clots during thrombosis.[19] We used I<sup>125</sup>-labeled antibodies specific for the  $\beta_{15-42}$  peptide sequence chain (anti- $\beta_{15-42}$ ) to measure the accessibility within the fibrin clots of the fibrin  $\beta$  -chain amino termini (residues 15–42), which are implicated in a variety of physiological events that affect thrombus remodeling into intravascular scars.[27–29]

We measured precise fibrinogen masses with liquid chromatography, followed by mass spectrometry (LC/MS) to identify post-translational modifications.[20] We analyzed the LC/MS spectra representing the fibrinogen A $\alpha$ -chains, B $\beta$ -chains, and  $\gamma$ -chains and measured the proportional heights of mass peaks corresponding to variants we had observed in CTEPH-associated dysfibrinogenemias and any other mass peaks that represented 10% or more of the associated fibrinogen chains.

### Statistical analysis

Categorical variables are presented as numbers and percentages, and continuous variables are presented as means  $\pm$  SD. All available demographic, clinical and fibrinogen data were compared between the two cohorts, using t-tests, Wilcoxon-Mann-Whitney tests, Fisher's exact tests or Chi-square tests, as appropriate. Univariate assessment of predictors of RPVO was performed for each cohort, using the same tests, as appropriate.

Because the interaction of lysis, inflammation and cellular remodeling that leads to RPVO likely develops through a complex interaction among clinical factors and biological factors, the careful selection of a predictive model was critical to our goal. A joint predictive effect would be obscured if simplistic univariate analyses are used.[30] For this reason, we used a step-wise multivariate logistic regression procedure based on Akaike Information Criterion (AIC)[30, 31] to select the most parsimonious and accurate multivariable prediction model for RPVO in each cohort, using as candidate predictors both clinical risk factors and fibrin structural properties. If the best predictive models selected in this fashion depended on fibrin structural attributes, then the analysis would support the role of fibrin properties in the development of RPVO after acute PE. The AIC-based approach avoids selecting models solely on the basis of apparent significance of the individual terms or global fit, both of which are likely to be over-stated; overfitting is penalized.[31] We used deviance-based goodness of fit, a standard logistic regression metric, to assess the quality of the selected models in each cohort.

Multivariable modeling was performed on information from subjects who had complete data (without missing values), to enable model comparisons. For cohort 1, AIC-based stepwise logistic regression was used to identify the best clinical and demographic predictors of RPVO. Then, AIC-based stepwise logistic regression was used to select the best model to predict RPVO, using as candidate predictors each patient's previously identified relevant demographic and clinical measures, as well as the results of the fibrinogen experiments we described. We used the Receiver Operating Characteristic (ROC) curve [32] to find the best probability cutoff for predicting RPVO and assessed the model's sensitivity and specificity. We then validated the model derived in cohort 1 by using it to predict RPVO in cohort 2.

To confirm the role of specific fibrin structural attributes in RPVO, we performed the prediction model selection process again in cohort 1 and included in the candidate predictor pool only the fibrinogen properties and the initial degree of obstruction (excluding the clinical data). The initial degree of obstruction is such a strong predictor of residual obstruction[2] that all predictive models would include it. We were interested in finding additional, independently predictive measures. Finally, to further verify the role of fibrinogen, we used a  $\chi^2$  test of residual deviances to determine whether the model that included the initial obstruction as well as fibrinogen properties were significantly better predictors of RPVO than the model that excluded fibrinogen properties.

To confirm the generalizability of individual RPVO predictors identified in cohort 1, we repeated the multivariate modeling process in cohort 2, but limited the candidate variables to those that were disclosed by the cohort 1 analysis. We reasoned that variables predictive of RPVO in both cohorts might be implicated in RPVO development in the general population

of patients with acute PE. If a variable derived from cohort 1 was not included in the optimal prediction equation generated for cohort 2, or if its coefficient was in the opposite direction, we reasoned that it would be less likely to be predictive of RPVO in other PE populations.

### Results

### Subject populations

From January 2003 to January 2009, 137 patients were recruited into cohort 1 (Figure 1A). Two patients (1.4%) were not assessed for RPVO because they were lost to follow up, in six (4.4%), the follow-up V/Q lung scans were missing. Plasma samples for fibrin(ogen) laboratory analysis were unavailable from 27 subjects (20.9%). There were no significant differences between the 35 patients excluded from cohort 1 and the included patients from cohort 1 on age, sex, time from symptoms to diagnosis or residual obstruction. Among the 102 subjects included in the analysis, 29 (28.4%) had RPVO greater than or equal to 10% (Table 1). The mean ( $\pm$  SD) time from PE diagnosis to V/Q Lung scan was 8.3 ( $\pm$  2.5) months and mean degree of persistent perfusion defect was 8.1% ( $\pm$  11.7%).

From February 1999 to May 2006, 185 patients were recruited into cohort 2 (Figure 1B). Two patients (1.0%) were lost to follow up. Plasma samples for fibrin(ogen) laboratory analysis were unavailable from one subject (0.5%). The excluded patients were not outliers on any of the studied characteristics. Among the remaining 182 subjects, 46 (25.3%) had RPVO greater than 10%. The mean ( $\pm$  SD) time from PE diagnosis to V/Q Lung scan was 10.9 ( $\pm$  3.7) months and mean RPVO was 6.8 % ( $\pm$  12.7 %).

The subject characteristics are compared between the two cohorts in Table 1 (a comprehensive list is included in appendix 2). Cohort 1 was significantly younger than Cohort 2 ( $52.2 \pm 19.6$  years vs  $61.3 \pm 18.5$  years, p = 0.0002). Cohort 1 had a lower prevalence of cancer (2.0 % vs 12.1 %, p = 0.003), a lower prevalence of bed rest (8.8 % vs 20.3 %, p = 0.01), a lower use of thrombolytics (0 % vs 5.5 %, p = 0.02) and a lower use of IVC filters (0 % vs 4.5 %, p = 0.03) than Cohort 2. However, family histories of VTE were more common in Cohort 1 than in Cohort 2 (31.4 % vs 18.0 %, p = 0.01). PE was diagnosed somewhat earlier after the onset of symptoms in Cohort 1 than in Cohort 2 ( $11.2 \pm 17.1$  days vs  $14.3 \pm 28.6$  days, p = 0.04).

A univariate analysis of the factors associated with RPVO is displayed in Table 2. In both cohorts, the initial pulmonary vascular obstructions were smaller among those who recovered without RPVO, than in those with RPVO. Notably, a CTEPH-associated mutation (fibrinogen<sub>San Diego III</sub>)[20] was found in one subject from Cohort 1, who had RPVO of 29.5 %.

### Derivation of RPVO predictive model in cohort 1

Prediction model creation and selection was performed on 94 subjects in cohort 1 who had complete clinical and fibrin-related data sets. When all candidate variables were considered, the optimal model to predict the probability of RPVO included the initial extent of vascular obstruction, fibrinogen B $\beta$ -chain monosialylation, the days between symptoms and diagnosis and fibrinogen $\gamma$ '(Table 3). The goodness of fit of the model was highly

significant (difference between null and residual deviances = 21.8,  $\chi^2 p = 0.0002$ ). The area under the receiver operator characteristic (ROC) curve was 0.762 (p = 0.0001). The sensitivity was 0.679 (95% CI 0.476 0.841) and the specificity was 0.727 (95% CI 0.604, 0.830).

### Validation of RPVO predictive model in cohort 2

The optimal predictive model derived from all candidate variables in cohort 1 was applied to the 141 subjects in cohort 2 who had complete data sets. The area under the receiver operator characteristic (ROC) curve was 0.693 (p = 0.0005). The sensitivity was 0.622 (95% CI 0.448, 0.775) and the specificity was 0.692 (95% CI 0.595, 0.777).

### Derivation of RPVO predictive model in cohort 1 using fibrinogen properties

When the candidate predictor pool excluded the clinical and demographic data, and encompassed only the initial extent of obstruction and fibrinogen data, the best prediction model's goodness of fit remained highly significant (difference between null and residual deviances = 26.2,  $\chi^2 p = 0.00003$ ). Initial obstruction and fibrinogen B $\beta$ -chain monosialylation remained as predictors of RPVO in that model, which also included fibrinogen  $\gamma$ 'and the fibrin lysis rate (Table 4). The area under the receiver operator characteristic (ROC) curve was 0.802. However, when the candidate predictor pool also excluded the fibrinogen data,  $\chi^2$  tests of residual deviances disclosed that the best-fit models did not predict RPVO as well as when fibrinogen data were included (difference between the two models' deviances = 9.0,  $\chi^2 p = 0.03$ ).

### Derivation of RPVO predictive model in cohort 2 using predictor pool from cohort 1

A prediction model was created for cohort 2, with the pool of candidate predictors restricted to only the four predictors identified by the model creation and predictor selection process performed for cohort 1. When only those candidate variables were considered, the optimal model to predict the probability of RPVO included the initial extent of vascular obstruction, fibrinogen B $\beta$ -chain monosialylation and the days between symptoms and diagnosis. Fibrinogen $\gamma$ 'was no longer included as a significant predictor. The goodness of fit of the model remained highly significant (difference between null and residual deviances = 18.8,  $\chi^2 p = 0.0009$ ). The area under the receiver operator characteristic (ROC) curve was 0.702.

In a post-hoc analysis, the median extent of B $\beta$ -chain monosialylation among the entire (two cohort) group was 59.2%. Among the half of patients with B $\beta$ -chain monosialylation below the median level, 19.4% had RPVO, whereas 31.9% of those with higher levels of B $\beta$ -chain monosialylation had RPVO (p = 0.0169).

### Discussion

We followed two cohorts of patients after acute PE to determine the factors that were most predictive of RPVO. High proportions of monosialylation of the fibrinogen B $\beta$ -chain were consistently predictive of RPVO across the two cohorts. Among the other candidate variables, only the initial degree of vascular obstruction was more predictive of RPVO, which is in agreement with our previous observations.[2]

We defined RPVO as persistent lung perfusion defects in 10% or more of the lungs (i.e. in at least two lung segments). Although we did not objectively measure quality of life or other symptomatic outcomes in the current study, we previously reported that our definition of RPVO, which occurred in 29% of acute PE patients, was significantly associated with dyspnea, elevated pulmonary artery pressures and exercise intolerance.[2] Among PE patients with this degree of RPVO, 16% were subsequently diagnosed with chronic thromboembolic pulmonary hypertension (CTEPH).[2]

The predictors selected by the model were highly associated with the subsequent development of RPVO (p = 0.0001 in the derivation cohort and p = 0.0005 in the validation cohort). The diagnostic accuracies of the model were not sufficiently high to exclude of predict RPVO for clinical purposes (AUC 0.762 and 0.693 in the derivation and validation cohorts, respectively). However, the association between RPVO and fibrinogen properties provides insights into the mechanism whereby some patients develop RPVO or even CTEPH after acute PE. No association with genetic thrombophilia has been identified,[2] which raises the possibility that impairments in the process of fibrinolysis are responsible.[33] We focused our investigation on fibrin itself, since the resistance of purified fibrin clots to lysis has been observed in some patients with CTEPH[19, 20] and, to a lesser extent, in some PE patients.[33, 34] We used as our model the properties of fibrin[21, 22] that we had observed in CTEPH-associated dysfibrinogenemias.[20] We reasoned that variations in post-translational modification patterns might influence fibrin formation and lysis[35, 36] less severely, but more commonly, than CTEPH-associated dysfibrinogenemias and that they may have a role in persistence of thromboemboli after acute PE.

Our results support the hypothesis that attenuation of the body's normal mechanisms for resolution of fibrin-rich thrombi is an important pathophysiological step in the etiology of chronic syndromes after venous thromboembolism.[5, 18] One possible mechanism is that properties of the fibrin clot would delay or limit plasmin-mediated fibrinolysis or modify other clot resolution mechanisms such as angiogenic and inflammation responses.[18] Our observations suggest that fibrin structural attributes may influence fibrin clot structure sufficiently to contribute to poor clot resolution and chronic disease after acute PE.

High proportions of monosialiated B $\beta$ -chains were predictive of RPVO in both PE cohorts that we studied. Sialylation occurs during fibrinogen formation and has various effects on fibrin polymer organization and resolution due to the electrostatic effect of the negatively charged sialic acid. Experimental sialic acid removal results in disordered fibrin clot formation,[35, 37, 38] while excessive sialylation of B $\beta$ -chains and  $\gamma$ -chains also results in abnormal clots.[22, 36] Monosialylation is increased when clotting might be beneficial, such as during pregnancy[39] and acute infection.[40]

The results for the two cohorts we studied differed somewhat in the predictive power of low fibrinogen  $\gamma$ ', which has been implicated in the regulation of fibrin crosslinking. The differences might be due to chance. Alternatively, they might reflect subtle differences between the two cohorts or even different implications of fibrin(ogen) characteristics at the time of the acute PE (when blood samples were collected from the first cohort) and several months later (when the second cohort was sampled).

Our study is limited by the fact that we did not independently confirm the clinical significance of RPVO in our patients by objective measurements of dyspnea, hemodynamics or subsequent clinical outcomes after completion of the study protocol. We have, however, validated the association between RPVO and those findings in a previous series of similar PE patients.[2] We also acknowledge that 20% of patients in the first cohort were excluded because they did not have adequate plasma samples for fibrinogen analysis, which could have introduced a potential for bias in that cohort's analysis. While we did not disclose an association between the type of acute or long-term anticoagulation therapy and RPVO, the study was performed prior to the widespread use of direct oral anticoagulants, so we cannot comment on the influence of those therapies. Finally, despite the consistency of our findings in both cohorts who had similar rates of RPVO, they should be confirmed in subsequent prospective studies.

### Conclusion

The extent of pulmonary vascular obstruction at the onset of PE, as well as fibrinogen  $B\beta$ -chain monosialylation, were predictive of RPVO after acute PE in the two cohorts we studied. Our results confirm our previous observations and support the role of fibrin properties in the resolution or persistence of thrombi after acute PE, which is similar to the role played in the development of CTEPH. It is possible that abnormal fibrin properties could help identify acute PE patients at high risk for RPVO for whom adjuvant therapy to modify disease progression might be evaluated. For example, since fibrinogen properties such as fibrinogen B $\beta$ sialylation may be influenced pharmacologically,[39] the effect on RPVO of such interventions to alter fibrinogen or the body's response to fibrin may have clinical implications.

### Bullet point:

Fibrinogen helps predict RPVO after PE: results from the PROMPT study

A

В

### Figure 1. Study outline for both cohorts.

A. In cohort 1, of 137 subjects recruited at the time of acute PE diagnosis, 102 subjects could be evaluated, 29 (28.4%) of whom had RPVO of at least 10%. B. In cohort 2, of the 185 subjects recruited after long-term treatment for acute PE, 182 subjects could be evaluated, 46 (25.3%) of whom developed RPVO of at least 10%.

### Table 1.

### Comparison of characteristics between cohort 1 and cohort 2.

Wilcoxon-Mann-Whitney was used to calculate p-values for continuous variables. Fisher's exact test was used for binary variables.

# Table 2. Univariate comparison of characteristics between patients with RPVO and without.

Wilcoxon-Mann-Whitney was used to calculate p-values for continuous variables. Fisher's exact test was used for binary variables.

### Table 3.

### **Predictors of RPVO in Cohort 1.**

Candidate predictors with p values listed in the table were incorporated in the corresponding models that had been selected by the Akaike Information Criterion to be the optimally predictive of RPVO after acute pulmonary embolism for the cohort.

Candidate predictive variables	(95% CI)	*a
Presentation and treatment		
Initial obstruction	1.041 (1.018, 1.064)	0.000369
Interval symptoms to diagnosis	1.026 (0.997, 1.056)	0.078758
Fibrin property		
Bβ-chain mono sialylation	1.074 (0.986, 1.168)	0.100657
Fibrinogen $\gamma'$	$0.641\ (0.419,\ 0.980)$	0.040079
Model goodness of fit **	0.00022	

p value from multivariate analysis.

 $^{**}$  Deviance-based goodness of fit, comparing the fit of each model with the fit of the null model.

Author Manuscript

### Table 4.

## Predictors of RPVO in Cohort 1, considering only the initial obstruction and fibrin properties.

Candidate predictors with p values listed in the table were incorporated in the corresponding models that had been selected by the Akaike Information Criterion to be the optimally predictive of RPVO after acute pulmonary embolism for the cohort.

Candidate predictive variables	OR (95% CI)	*d
Presentation and treatment		
Initial obstruction	$1.054\ (1.028,\ 1.080)$	0.00003
Fibrin property		
Bβ-chain mono sialylation	1.095 (0.994, 1.206)	0.0655
Fibrin clot lysis rate	10.872 (0.349, 338)	0.1737
Fibrinogen $\gamma'$	$0.614\ (0.386,\ 0.975)$	0.0388
Model goodness of fit **	0.00003	

p value from multivariate analysis.

\*\* Deviance-based goodness of fit, comparing the fit of each model with the fit of the null model.
