ABSTRACT

Ultra-high gradient radio frequency linacs require efficient and reliable power sources. The induction linac has proven to be a reliable source of low energy, high current and high brightness electron beams. The low energy beam is bunched, transported through resonant transfer cavities in which it radiates microwave energy that is coupled to an adjacent high energy accelerator. The low energy beam is maintained at a constant energy by periodic induction accelerator cells. This paper describes the engineering aspects of the induction accelerator based relativistic klystron. The physics issues are covered in another paper at this conference.

INTRODUCTION

During the past decade, several rf power sources using relativistic Klystrons have been tested for driving high gradient accelerators. In order for these power sources to be competitive with the conventional Klystrons, they must be capable of producing equivalent peak power levels, reliably, economically and efficiently. At first glance, it would seem that building low gradient, high current accelerator in order to drive another would be a more complex and costly proposition. Experiments in generating a relativistic electron beams and extracting the energy by passing it through cavities have shown that very high peak RF levels can be efficiently generated. The practicality of such a method is determined in part by the system which generates and drives the relativistic electron beam. The paper addresses the engineering issues associated with building an efficient and reliable electron accelerator where the energy is extracted periodically after re-acceleration. The physics design and the beam dynamics are covered elsewhere at this conference.

INDUCTION ACCELERATOR

The induction accelerator has provided a reliable and efficient way to accelerate high current beams. Currents from hundreds of amperes to many kiloamperes have been accelerated to many tens of MeV's. They are capable of producing beam pulses from tens of nanoseconds to microseconds in duration at kilohertz repetition rates. Fig.

1 shows the equivalent circuit of an induction accelerator cell. I_C is the magnetizing current required to drive the core, I_B is the beam current, and I_N is any compensating network current.

Fig. 1

The efficiency of an induction accelerator can approach 100% if the beam current is much greater than the current required to magnetize the transmission line transformer (or autotransformer) which forms the induction cell. For example, the advanced test accelerator (ATA) induction cell required less than 1 kA of magnetizing current while it accelerated a 10 kA beam for 70 ns.

The efficiency of the TBA accelerator will depend on a number of factors. Beam transport dynamics will determine the size of the beam pipe and the accelerating gradient. The output power requirement will determine the pulse duration, beam current and repetition rate. Once these factors are established, then the induction cell outer diameter and drive will be determined once the optimum magnetic material has been selected. For accelerators with pulse duration less than 100 ns, Ni-Zn ferrites have been used as the magnetic material for the induction cell. For pulse duration in the several hundred nanoseconds to several microseconds, magnetic materials such as Ni-Fe and Metglas¹ have been used. The optimum choice of material for the TBA, which requires a pulse of 300 ns duration, is established by the material's losses and the economics for achieving the desired pulse. From Fig. 2, one can see that the saturation losses for the ferrites are about one fifth the losses of nickel-iron or Metglas. However, the ferrites have a flux swing which is about one fifth that of the Metglas. This, of

¹Metglas is a trade name of Allied-Signal

In this case, we have chosen to drive each of the five cores with 20 kV inducing a total voltage across the cell of 100 kV. Driving at this voltage level avoids any step-up

transformers and can be generated directly by a thyatron with 40 kV charging voltage on the pulse forming network (PFN). As shown in Fig. 3, the current drive to the cores is somewhat nonlinear, but a constant amplitude pulse can be generated, within bounds, simply by tapering the impedance of the PFN stages. The PFN will consist of many coupled L-C stages each with impedance which temporally matches the impedance of the induction core. This tapered impedance PFN is resonantly charged to twice the output voltage required. From Fig. 7, one can see that the PFN charging current flows through the induction core, thus resetting the core to $-B_r$ ready for the next acceleration cycle.

COOLING OF INDUCTION CORES

Each 100 kV induction module will dissipate about 1500 watts at 120 Hertz. Each magnetic core will be supported by a mandrel with voltage feeds on each side of the core which allow for cooling channels. Each core

dissipates 300 watts and this heat is removed by circulating oil which also acts as a high voltage insulator at the acceleration gap. Further studies are required, but it

may be feasible to use sulfur hexafluoride under pressure to insulate and remove the 1500 watts dissipated in the cores.

CONCLUSION

A simple power conditioning system has been conceptualized for driving induction cells at a relatively high efficiency. The power conditioning system is based on previous experience which incorporates conservative thyatron line modulators without nonlinear magnetic pulse compression or step-up transformers. It is expected that at 120 Hz, the thyatron will offer acceptable reliability which is comparable to the life of a Klystron driven system. This conceptual design will be prototyped over the next several months to confirm our studies.
