Abstract—Hardware accelerators, in particular accelerators for tensor processing, have many potential application domains. However, they currently lack the software infrastructure to support the majority of domains outside of deep learning. Furthermore, a compiler that can easily be updated to reflect changes at both application and hardware levels would enable more agile development and design space exploration of accelerators, allowing hardware designers to realize closer-to-optimal performance. In this work, we discuss how large language models (LLMs) could be leveraged to build such a compiler. Specifically, we demonstrate the ability of GPT-4 to achieve high pass rates in translating code to the Gemmini accelerator, and prototype a technique for decomposing translation into smaller, more LLM-friendly steps. Additionally, we propose a 2-phase workflow for utilizing LLMs to generate hardware-optimized code.

I. INTRODUCTION

Hardware accelerators [1], [2], [3] have become a critical driving force for the recent breakthroughs [4], [5], [6], [7], [8] in artificial intelligence and machine learning. They provide hundred-fold improvements in performance and energy efficiency in running deep neural networks (DNNs). With the proliferation of new TA designs, the number of compilers and domain-specific languages (DSLs) has also exploded. For deep learning applications, compilers like XLA and TVM provide end-to-end support for the popular deep learning frameworks PyTorch, JAX, and TensorFlow frameworks which are used to implement most DNN software [9], [10].

However, these accelerators are not only useful for processing DNNs. For example, the systolic array architecture at the heart of many of these accelerators has long been known to be useful for a wide range of tensor-related computations, such as tensor decomposition [11]. Furthermore, recent work suggests that these accelerators, which we call tensor accelerators (TAs), have promise in accelerating a range of applications ranging from graph algorithms like PageRank to partial differential equations for financial modeling [12], [13].

As shown by these works, in order to leverage the performance benefits of TAs, applications must be compiled to primitive operations in the domain-specific language (DSL) supported by one specific TA, and in order for this to occur the TA must first support the key operators of the application. The development of both applications and accelerators is limited by this cyclical dependency. Adapting existing code to DSLs requires developers to manually translate the code or even build custom compilers, which must be modified each time the hardware backend changes.

An ideal compiler framework can adapt to changes both above it (application-level) and below it (architecture- or microarchitecture-level). Recent work demonstrates the impressive performance of large language models (LLMs) in various code-related tasks [14], [15], [16], [17], as well as general reasoning ability and instruction-following [18], [19]. However, it is unclear how LLMs perform in code analysis and generation for DSLs with little to no presence in their training corpora. In this work, we investigate how LLMs can be used in an agile compiler framework for hardware accelerators, and propose that optimizing compilers could be implemented in a two-phase flow. The first phase involves translating the given source program to a functionally correct implementation in the DSL, ensuring functional correctness. The second phase focuses on optimizing the DSL code using a cost model-driven search approach to maximize performance on the target hardware accelerator.

II. RELATED WORK

Code translation is essential for keeping software workflows updated with recent DSLs and optimizations. Existing approaches include pattern matching-based compilers [20], search-based techniques [21], and neural methods [22]. However, these approaches require significant human effort to develop and maintain, and often struggle to scale to complex domains. In this work, we leverage LLMs success in code generation [23] and optimization [24] to explore their potential for generating optimized code for TAs.

There has been a significant amount of work in exploring the performance spaces of hardware and software implementations for TAs. However, while significant performance improvements are possible, such design space exploration techniques are often limited to finding an optimal point within a given search space [25], [26], or use abstractions from which bridging the gap to real systems is difficult [27]. Automatic compilers robust to application and hardware changes will allow designers to quickly modify search spaces without significant compiler update efforts.

Existing systems for tensor computation make use of abstractions like the BLAS library or, as in the case of Halide, use DSLs to represent computations in a portable and scheduling-friendly manner [28]. In this work, we focus on enabling TA developers to compile code to accelerators as

quickly and easily as possible, so we elide the addition of heavy infrastructure that would add burden to the developer workflow. However, we are not opposed to the use of intermediate representations or other abstractions when building LLM-aided compilers, and believe that development in such a direction will enable LLM-aided compilation and optimization to be carried out in a more systematic and verifiable manner.

III. PROPOSED METHODOLOGY

A. Overview

In this section we provide an overview of our two phase approach. In Figure 1 shows our proposed workflow which integrates the search-based translation and hardware cost models. Our workflow involves a code synthesizer generating potential translations for a general-purpose code, which are then verified for functional equivalence with the source program using testcases. Subsequently, the verified code is passed to the cost model, which offers concrete feedback indicating changes the synthesizer should apply to the generated code.

B. Code Template Generation with LLMs

There are two general approaches to building code translators: symbolic and neural. Symbolic approaches include building pattern-matching compilers, for which rules can be painstaking to manually specify and maintain. To address this, verified lifting [21] uses search followed by verification to find a functionally equivalent implementation of the source program in the target language. However, most lifting-based approaches rely on symbolic solvers that use strategies like enumerative or constraint-based search to perform the translation. Scaling symbolic search requires significant effort and domain knowledge, as users must explore heuristics such as type-based filtering, template enumeration, and multi-phase synthesis to shrink the search space.

LLMs have emerged as a promising alternative to symbolic approaches. These models have been trained on massive amounts of code data from sources such as documentation and code repositories, which potentially allows them to learn about the syntax and semantics of various programming languages. TAs and other DSAs present a unique challenge because their low-level programming languages have little to no presence in LLMs' training corpora. We propose that LLMs can nonetheless be leveraged to simplify the process of generating optimized code for TAs by exploiting their contextual reasoning capabilities [18] and decomposing the problem into multiple semi-structured steps.

To guide the LLM in generating the desired target code, we provide a structured prompt that consists of three main components: instructions, target language specification, and the source program. The instruction section contains a high-level description of the task, specifying the goal of translating the source program to the target language. The target language specification section enumerates the available operators and constructs in the target language, and optionally provides example programs in the target language, providing the LLM with the necessary context about the TA. Finally, the source

program section includes the high-level code that needs to be translated. Appendix A shows an instantiation of this prompt structure demonstrating how the components are populated with specific details, and Section IV-A discusses how well these prompts work.

C. Cost Model-Driven Code Translation

In addition to being correct, compiler-generated code should be performant, especially when the target is hardware accelerators meant to improve application latency and efficiency. For performance optimization, we propose a search-based technique for code translation that integrates feedback from a TA cost model. Previous work, such as Ansor [29], has successfully implemented cost model-based approaches for scheduling tensor operations in the TVM compiler framework. While these approaches are effective, they rely on manually designed search spaces and require extensive training for each new hardware target. In contrast, we seek to leverage LLMs' knowledge about programs to optimize a less structured space.

In particular, we suggest an iterative and hierarchical approach. First, we prompt the model with a set of possible optimizations, such as combining instructions or changing data movement patterns. The model is then asked to optimize each block of computation based on the available optimizations and any latent knowledge about program optimization. We experiment with two approaches: 1) having the LLM directly generate the optimized code, and 2) having the LLM generate Halide-style scheduling operations [28]. Next, we prompt the model to generate the optimal ordering of these blocks in the final program. If the LLM understands dependencies and program performance, it can propose an efficient arrangement of the blocks, taking into account factors such as data locality and parallelism. Program performance (and potentially other indicators, like hardware counters), generated from a cost model or by running the code, can be used as feedback, providing domain-specific information for the model to iteratively refine its optimization decisions.

IV. EXPERIMENTS

In this section, we discuss a number of experiments that explore the feasibility of utilizing LLMs for various parts of the accelerator compilation flow. Based on these experiments, we discuss the most effective strategies we observed and suggest directions for future exploration.

A. Translating Robotics Kernels to Gemmini's ISA

Robotics is a driving application with rising interest, both across the scientific community and in relation to hardware acceleration. Prior work has investigated the potential for custom hardware accelerators to speed up key robotics kernels [30], [31]. These kernels are a target for acceleration via systolic array accelerators on the edge, due to their latency sensitivity and heavy use of matrix operations. However, implementing performant code for such applications on custom hardware is difficult due to the lack of compilers, and building general-purpose libraries can actually result in control flow-heavy
Fig. 1. An overview of our proposed framework.

code with worse performance than an assembly implementation. In this section we demonstrate translation of general-purpose matrix code from these kernels to the instruction-set architecture (ISA) for Gemmini [32], an academic systolic array accelerator. The prompt describing the set of functions available to the LLM, which effectively represent Gemmini's ISA, is given in Appendix A.

We use a simple test to determine whether a correct result has been generated. However, these results do not provide the model with access to the test cases, nor is there yet a feedback loop of test results to code generation. So, it is highly unlikely that model outputs are overfit to our current set of test cases.

1) Model-Predictive Control (Matrix-Vector Operations): We begin by translating a kernel from the TinyMPC model-predictive control implementation [33]. Specifically, we focus on the backward pass, which contains four matrix-vector multiplications of different sizes. The sizes reflect those for a quadrotor drone; the largest operation comprises a 12×12 matrix multiplied by a 12×1 vector. We use a configuration of Gemmini with a 4×4 systolic array, meaning that such a computation requires at least 9 compute instructions, plus instructions to configure the accelerator and move data into and out of local memory. For this kernel, we translate one matrix-vector multiplication at a time, following the strategy from Section III-B.

We ablate a number of prompting techniques. This is to 1) evaluate the importance of each component of our prompt, and 2) evaluate the effectiveness of the LLM's (specifically, `gpt-4-turbo`'s instruction following and in-context learning (ICL) [18] in the context of accelerator DSLs with little information available in pre-training data.

Specifically, we explore the following options:

- **Zero-shot**: We try generating Gemmini code with only ISA descriptions and no implementation example, to evaluate the LLM's ability to generate code based solely on pre-training and its ability to reason about the functions in the specification.
- **One-shot**: We provide a single Gemmini code example for a matrix-vector multiplication. This boosts code correctness significantly, and qualitatively reduces the variance in generated code hugely. Because generated code follows the style of the provided examples, syntax and other compilation errors also decrease significantly. Note that for all cases, we evaluate pass rate on problems other than the one used for this example.
- **NL annotation**: We annotate the one-shot example with inline natural language (NL) comments explaining each

function call and its arguments. We find that this technique improves the ability of the LLM to reason about the provided functions, and extrapolate implementations that are different from the provided example while following its style.
- **No ISA**: We remove the ISA (target language) specification from the prompt. The results establish that it is an essential part of the translation flow.

	pass@k		
	k=1	k=10	k=50
Zero-shot	0.33%	3.33%	16.7%
One-shot ICL	44.67%	84.42%	99.79%
One-shot ICL (NL-annotated)	46.0%	88.81%	99.98%
No ISA, One-shot ICL (NL-annotated)	1%	9.12%	29.29%

TABLE I
`gpt-4-turbo` TRANSLATED CODE CORRECTNESS FOR MATRIX-VECTOR MULTIPLICATIONS, WITH NATURAL LANGUAGE DESCRIPTIONS FOR FUNCTIONS IN THE INPUT CODE.

We additionally explore whether it is more useful to provide NL descriptions, or full implementations of functions in the input (general-purpose) code. We implement matrix-vector multiplication as the more general matrix-matrix multiplication. Even though this is a very common operation, translation correctness improves in both zero-shot and one-shot scenarios with code implementations. This is consistent with previous results, as we suspect that like our one-shot example, a general-purpose implementation provides structure for the LLM to follow in its response.

As shown in Table II, providing both NL and code hurts correctness of generated code in both zero-shot and one-shot cases, showing that increasing prompt size without providing new information may degrade code generation performance.

	pass@k		
	k=1	k=10	k=50
NL only	46.0%	88.81%	99.98%
Semantics only	50.67%	92.23%	100%
Semantics and NL	46.33%	87.48%	99.96%

TABLE II
`gpt-4-turbo` TRANSLATED CODE CORRECTNESS FOR MATRIX-VECTOR MULTIPLICATIONS, WITH DIFFERENT PRESENTATIONS OF SOURCE CODE FUNCTIONS.

2) Riccati Recursion (Matrix-Matrix Operations): Next we translate C++ code for Riccati recursion, a well-known method for solving the finite-horizon discrete time linear quadratic regulator (LQR) problem [34]. Specifically, we focus on implementing seven matrix-matrix multiplications of various sizes

and types, one of which is used for our prompting example. In some cases, matrices are multiplied; in some cases, a bias matrix is added or subtracted from the result. The largest is a 36×36 and 36×12 matrix-matrix multiplication, with state and action space sizes based on a quadrotor drone (assuming an action space size of 4) and a quadruped [30].

Due to cost constraints, we replicate only the best-performing of experiment from Section IV-A1, that with reference implementations for input code, as well as an NL-annotated in-context example. We next compare the case of providing a matrix-vector example with the case of providing two matrix-matrix examples, one with a transposed matrix and a bias, and one without. Providing both examples does not boost pass rate, but we note that the LLM performs better when examples are provided *before* other instructions in the prompt. Table III shows `gpt-4-turbo`'s pass rate for these 6 functions. Ultimately, we are able to generate correct code for 5 out of 6 test functions.

| | pass@k | | |
	k=1	k=10	k=50
One-shot ICL (Matrix-vector example, NL-annotated)	2.33%	20.55%	64.51%
One-shot ICL (Matrix-matrix example, NL-annotated)	1.67%	15.21%	51.21%
One-shot ICL (Matrix-matrix example w/ transpose and bias, NL-annotated)	50.05%	72.89%	89.65%
Two-shot ICL (Both examples after instructions)	15.55%	57.39%	81.26%
Two-shot ICL (Both examples before instructions)	32.41%	75.68%	83.29%

TABLE III
`gpt-4-turbo` TRANSLATED CODE CORRECTNESS FOR MATRIX-MATRIX MULTIPLICATIONS.

B. Repairing Translated Code

In the previous section, we successfully translated 8 out of 9 total kernels with the prompting techniques listed. However, there was one kernel which could not be translated - this kernel multiplies a 12x4 matrix, transposed, with 4x12 matrix, not transposed, and subtracts from the result a 12x12 bias matrix. Manual inspection of generated candidates demonstrated that there were several cases of near-correct translations, where errors often occur due to incorrect addressing, strides, or constants in instruction arguments. This corresponds with prior observations that even the most powerful LLMs can struggle with arithmetic-related tasks [35].

Prior work has addressed such challenges by fixing LLM errors such as syntactic search [36]. For this case, we were able to produce a working result by breaking down error correct into multiple steps, i.e. by taking a close-but-incorrect candidate, prompting the LLM to locate areas of uncertainty and replace such holes with its own variable names, then produce candidates for programs with these holes filled using a set of possible constants. In this case study, this sequence of prompts was able to produce a correct result, unlike a simple prompt asking the LLM to fix the constants in its response. The specific prompts used can be found in Appendix A.

C. Code Optimization

In this section, we describe our preliminary results with different strategies for optimizing the translated code.

1) Structured LLM-Driven Code Rewrites: We evaluate our hierarchical optimization process by optimizing the translated matrix-vector multiplication code described in section IV-A1. First, we prompt Figure 4 the LLM to generate optimized versions for each block of computation in the translated code. Next, we prompt Figure 5 the LLM to reorder the optimized blocks generated in the previous phase. Upon comparing the LLM-optimized code with hand-tuned code, we observed that the generated code was similar in structure and performance. LLM was able to correctly identify the optimal ordering of the blocks resulting in minimizing the data movement.

2) LLM-driven Autoscheduling: Instead of directly generating optimized code, we are also experimenting with using LLMs as code schedulers. In this approach, the LLM selects schedule operations (loop reordering, etc.) to apply to the code. In our preliminary experiments, we use Exo [37] as the scheduling library. Every successful Exo rewrite is guaranteed to be semantics preserving, thus eliminating correctness issues due to hallucination. Appendix B shows `gpt-4-turbo` scheduling the `doitgen` kernel from PolyBench [38], a multiresolution analysis kernel from MADNESS [39], on x86.

V. CONCLUSION: TOWARDS AGILE, AUTOMATED HARDWARE AND COMPILER CO-DESIGN

In this work, we demonstrate how careful prompting and breaking down compilation problems into smaller, more LLM-friendly steps can help make accelerator code translation tractable for LLMs. Specifically, we use a combination of such techniques to fully translate a set of robotics kernels to the Gemmini accelerator's ISA. Automated code translation will speed up the accelerator design process and reduce engineering effort, by reducing the need to build and maintain compilers early on and allowing for faster evaluations of hardware. Furthermore, we believe that future work integrating LLMs into the existing extensive corpus of tensor code optimizations will help make it easier to apply new DSLs and optimization techniques that can improve accelerator performance. By automating software compilation problems that are today solved ad hoc, hardware-aware, cost model-guided code translation will serve as a key component for more agile and automated accelerator design.

'''
Gemmini's private memory is "row-addressed", where each row is DIM elements wide, where DIM is the number of PEs across the width of the systolic array. These elements will be of type
    inputType in the scratchpad, and of type accType in the accumulator.

Every private Gemmini memory address is 32 bits long. The three most signficant bits are reserved, and have special meanings:

    Bit 31 (the MSB) is 0 if we are addressing the scratchpad, and 1 if we are addressing the accumulator.
    Bit 30 is ignored if we are addressing the scratchpad, or if we are reading from the accumulator. If, instead, we are writing to the accumulator, then bit 30 is 0 if we want to overwrite
        the data at that address, and 1 if we want to accumulate on top of the data already at that address.
    Bit 29 is ignored if we are addressing the scratchpad, or if we are writing to the accumulator. If, instead, we are reading from the accumulator, then bit 29 is 0 if we want to read
        scaled-down inputType data from the accumulator, and 1 if we want to read accType data from the accumulator.
        If bit 29 is 1 for an accumulator read address, then we do not apply activation functions or scaling to the output of the accumulator.
'''
```

Fig. 2. Gemmini ISA specification from Section IV-A.

```
Gemmini is a systolic array accelerator with a scratchpad, a DIM by DIM systolic array, an accumualator, and a backing DRAM.
The set of available functions for the Gemmini accelerator are as follows.

<insert ISA prompt here>

Your task is to rewrite the given 'test' C++ Function. You need to use only the set of provided functions and constants to achieve this.
    The rewritten program should be semantically equivalent to the 'test' function.
Please make sure that the generated code fully computes the desired operation and that the output is correct. It is essential and
    important that function arguments such as rows and columns should not violate constraints such as "less_than_or_equal_to".
Recall that systolic array size is 4 by 4 (DIM equal to 4) and each element is 4 bytes.
Example 1 is a simple example which should only be used for style inspiration. Write the low level code for Example 2.
```

Fig. 3. Code translation task description, as described in Sections III-B and IV-A.

```
Your task is to optimize the given program. The program can be optimized by reducing the number of instructions. Instructions can be
    reduced by minimizing the data movement, reordering computations, and merging instructions. The rewritten program should be
    semantically equivalent to the original program. Do not use any loops. Systolic array size is 4x4 (DIM=4) and each element is 4
    bytes.
// heuristics:
1. moving data ahead of time helps
2. do not remove any compute instruction unless it can merged or replaced by another instruction
3. do not remove any preload instruction unless B_spad_addr and C_spad_addr are the same as the previous preload instruction
4. number of mvin rows <= 4

<insert ISA prompt here>

<insert unoptimized block here>
```

Fig. 4. Task description for optimizing blocks of code.

```
Your task is to optimize the given program. Generate only a plan to optimize the given program. The rewritten program should be
    semantically equivalent to the original program. Do not use any loops. Systolic array size is 4x4 (DIM=4) and each element is 4
    bytes.
// Instructions:
1. The exeuction order of the blocks can be changed. Generate the block ordering as a plan. Do not optimize the instructions within
    block. Return the plan as a list of blocks.

<insert ISA prompt here>

<insert unoptimized code here>
```

Fig. 5. Task description for reordering the blocks of unoptimized code for generating optimized code.

```
Below we describe the functions present in the input code.

```
SYSTEM: You are an expert performance engineer with experience in optimizing numerical linear algebra kernels.

USER:
I need help with optimizing a numerical kernel. It is written in a Python DSL
for code optimization called Exo, which is similar to Halide.

Here are my relevant hardware details:

- The target hardware is an x86 CPU with AVX2 support.
- We will be targeting single-core execution, so you can ignore parallelism.
- L1 instruction cache size: 32 KB
- L1 data cache size: 48 KB
- L2 cache size: 2 MB
- L3 cache size: 36 MB

Here is the kernel I need help with, written in Exo:

def doitgen(A: f32[64, 64, 64] @ DRAM, C4: f32[64, 64] @ DRAM,
            sum: f32[64] @ DRAM):
    for r in seq(0, 64):
        for q in seq(0, 64):
            for p in seq(0, 64):
                sum[p] = 0.0
                for s in seq(0, 64):
                    sum[p] += A[r, q, s] * C4[s, p]
            for p in seq(0, 64):
                A[r, q, p] = sum[p]

Currently I get 5.64 GFLOPS.

Please provide a step-by-step plan for optimizing the kernel.
Once you have a plan, begin optimizing the kernel by giving me a series of
commands, each of which are described below. I will apply the command one at a
time, and provide you with the new kernel code and its performance.

You can use the following commands:
'''json
{"optimization": "tile", "description": "tile the loop at 'line' with 'tile_size'", "arguments": {"line": "source code of line to apply
    tiling", "tile_size": "size of the tile", "outer_name": "name of the new outer loop variable", "inner_name": "name of the new inner
     loop variable"}}
{"optimization": "fuse", "description": "fuse the loops at 'line1' and 'line2'", "arguments": {"line1": "source code of first line to
    fuse", "line2": "source code of second line to fuse"}}
{"optimization": "reorder", "description": "reorder the outer loop at 'line' to be the inner loop", "arguments": {"line": "source code
    of outer loop to reorder"}}
{"optimization": "fission", "description": "fission the loop containing 'line' into two consecutive loops, splitting at 'line'", "
    arguments": {"line": "source code of line to fission at", "location": "split (before | after) 'line'"}}
{"optimization": "unroll", "description": "fully unroll the loop at 'line'", "arguments": {"line": "source code of loop to unroll"}}
'''

When you are ready to give the optimization, end your message with JSON as follows:
'''
APPLY: {"optimization": "optimization name", "arguments": {"arg1": "value1", ...}}
'''
Only give a single command at a time. Do not give multiple commands in a single
message.

Important Notes:
- Consider reordering loops before applying tiling or vectorization.
- Reorder loops to maximize data reuse and minimize cache misses.
- Assume matrices are stored in row-major order.
- If the same source line appears multiple times in the code, end the line
  with ' #N' where 'N' is the occurrence number (0-indexed). For example,
  'for i in seq(0, 32): #0'.
```

Fig. 12. Task description for scheduling the doitgen kernel.

```
ASSISTANT: To optimize the given kernel, we should focus on improving data locality and reducing cache misses. Here's a step-by-step
    plan:

1. **Loop Reordering**: We'll start by reordering the loops to maximize data reuse. The innermost loop should iterate over the dimension
    that allows us to access continuous memory locations, which is beneficial for a row-major storage format.

2. **Loop Tiling**: This technique will help in fitting the data accessed by the loops into the L1 or L2 cache, reducing the number of
    cache misses.

3. **Loop Unrolling**: This can help to increase the instruction level parallelism by executing multiple iterations of a loop
    simultaneously. It can also reduce the loop overhead.

4. **Loop Fusion**: If applicable, we can combine loops that iterate over the same range to reduce loop overhead and improve cache
    locality.

5. **Vectorization**: Since the target hardware supports AVX2, we should ensure that the innermost loops are conducive to vectorization
    by the compiler, which can significantly speed up the computations.

Starting with loop reordering, we aim to access 'A' and 'C4' in a more cache-friendly manner. Currently, the access pattern to 'A' and '
    C4' in the innermost loop ('sum[p] += A[r, q, s] * C4[s, p]') suggests that reordering the loops to bring 's' loop outside could be
    beneficial. This would align the access to 'C4' continuously in memory.

Let's start by reordering the loops to bring the 's' loop outside of the 'p' loop:

APPLY: {"optimization": "reorder", "arguments": {"line": "for p in seq(0, 64): #1"}}
=====================================================================================================

USER:
An error occurred while applying the optimization:
argument 1, 'nested_loops' to reorder_loops: expected the body of the outer loop to be a single loop, but it was a def doitgen(A: f32
    [64, 64, 64] @ DRAM, C4: f32[64, 64] @ DRAM,
        sum: f32[64] @ DRAM):
    for r in seq(0, 64):
        for q in seq(0, 64):
            ...
            for p in seq(0, 64):
                A[r, q, p] = sum[p]  # <-- NODE
Please fix the error and try again.

[a few more errors follow...]

ASSISTANT: It appears that my previous attempts to specify the fission location were incorrect. Let's try a different approach to
    optimize the kernel without relying on fission at this point.

Given the structure of the loops and the constraints we're facing with the fission command, let's attempt to optimize the kernel by
    tiling the loops instead. Tiling can help improve cache locality and potentially expose more opportunities for optimization.

We'll start by tiling the 'p' and 's' loops, which are involved in the computation 'sum[p] += A[r, q, s] * C4[s, p]'. This should help
    keep the accessed data in cache, reducing cache misses. We'll choose a tile size that is likely to fit well within the L1 cache.

Let's tile the 'p' loop with a size of 16, which is a common choice for small tiles that fit well in cache lines:

APPLY: {"optimization": "tile", "arguments": {"line": "for p in seq(0, 64): #1", "tile_size": "16", "outer_name": "p_outer", "inner_name
    ": "p_inner"}}
=====================================================================================================

USER:
I have applied the optimization. The new kernel code is as follows:

def doitgen(A: f32[64, 64, 64] @ DRAM, C4: f32[64, 64] @ DRAM,
        sum: f32[64] @ DRAM):
    for r in seq(0, 64):
        for q in seq(0, 64):
            for p in seq(0, 64):
                sum[p] = 0.0
                for s in seq(0, 64):
                    sum[p] += A[r, q, s] * C4[s, p]
            for p_outer in seq(0, 4):
                for p_inner in seq(0, 16):
                    A[r, q,
                        p_inner + 16 * p_outer] = sum[p_inner + 16 * p_outer]

The new code achieves 6.06 GFLOPS. Please give me another optimization to
apply, using the same format as before.
```

Fig. 13. LLM autoscheduling excerpt for `doitgen`, showing erroneous schedule commands and eventual recovery.

```
ASSISTANT: It seems that directly fusing the 'r' and 'q' loops is not feasible due to their structural positions or other constraints in
    the code. Let's consider another optimization strategy that might be more straightforward to apply given the current loop
    structure.

Since we've seen some benefits from tiling and unrolling, let's try to further optimize by unrolling another loop. The 's_outer' loop,
    which controls the outer part of the tiled 's' loop, is a candidate for unrolling. This could potentially reduce loop overhead and
    increase the efficiency of the computations inside.

Here's the command to fully unroll the 's_outer' loop:

APPLY: {"optimization": "unroll", "arguments": {"line": "for s_outer in seq(0, 4):"}}
================================================================================================

USER:
I have applied the optimization. The new kernel code is as follows:

def doitgen(A: f32[64, 64, 64] @ DRAM, C4: f32[64, 64] @ DRAM,
            sum: f32[64] @ DRAM):
    for r in seq(0, 64):
        for q in seq(0, 64):
            for p in seq(0, 64):
                sum[p] = 0.0
                sum[p] += A[r, q, 0] * C4[0, p]
                sum[p] += A[r, q, 1] * C4[1, p]
                ...
                sum[p] += A[r, q, 62] * C4[62, p]
                sum[p] += A[r, q, 63] * C4[63, p]
            for p_outer in seq(0, 4):
                A[r, q, 16 * p_outer] = sum[16 * p_outer]
                A[r, q, 1 + 16 * p_outer] = sum[1 + 16 * p_outer]
                ...
                A[r, q, 14 + 16 * p_outer] = sum[14 + 16 * p_outer]
                A[r, q, 15 + 16 * p_outer] = sum[15 + 16 * p_outer]

The new code achieves 43.33 GFLOPS. Please give me another optimization to
apply, using the same format as before.
```
