Abstract

Inorganic polysulfur compounds (polysulfides, S_x^{2-} ; polysulfur radical ions, $S_x^{\cdot-}$; thiosulfate, $S_2O_3^{2-}$; polythionate, $S_xO_6^{2-}$; elemental sulfur, e.g. S_8) participate in numerous geochemical processes related to the sulfur cycle. These include authigenic pyrite formation in sediments undergoing early stages of diagenesis, reactions associated with magmatic-hydrothermal processes, and numerous other aquatic sulfur redox processes (e.g., pyrite and sulfide oxidation). Sulfur isotope fractionations among many of these and associated compounds (e.g., H_2S , HSO_4^-) are either unknown or unconstrained over wide ranges of temperatures. We present theoretical estimates of equilibrium sulfur isotope fractionation factors among aqueous polysulfur compounds (including select polysulfides, polysulfur radical anions, and polythionates) and select aqueous sulfide and sulfate compounds that correspond to all three stable isotope ratios of sulfur ($^{33}S/^{32}S$, $^{34}S/^{32}S$, $^{36}S/^{32}S$). Our estimates are based on electronic structure calculations

performed at the B3LYP/6-31+G(d,p) level of theory and basis set implemented in concert with an explicit solvation model whereby molecules are encapsulated in water clusters of varying size (30-52 H₂O) to simulate the aqueous solvation environment. These calculations yield relatively small magnitude fractionation factors between aqueous polysulfides, polysulfur radicals, and reduced sulfur moieties in polythionates relative to the aqueous sulfide compounds but reveal numerous crossovers that result in non-intuitive temperature dependencies. Our predictions of ³⁴S/³²S-based fractionation factors among aqueous sulfur compounds generally agree with previous experimental constraints where available within estimated uncertainties (e.g., HSO₄⁻/H₂S_(aq), H₂S_(aq)/HS⁻, HSO₄⁻/S⁰, H₂S_(aq)/S⁰). We use our calculations to explore equilibrium isotope fractionations among polysulfur and sulfide compounds that are precursors to authigenic pyrite in the framework of established mechanisms (e.g., the polysulfide mechanism). We examine possible explanations for why pyrite formation may be associated with relatively small isotope fractionation with respect to precursor aqueous sulfur compounds. We additionally use our theoretical calculations to constrain multiple sulfur isotope (³³S/³²S, ³⁴S/³²S, ³⁶S/³²S) mass balance models associated with the abiotic hydrolytic disproportionation of intermediate sulfur compounds (SO₂, S₈, S₃⁻) relevant to hydrothermal-magmatic-volcanic systems in order to illustrate the potential for subtle but potentially resolvable effects expressed in values of Δ³³S and Δ³⁶S associated with these processes. We apply a SO₂ disproportionation mass balance model based on previous work but newly constrained by our theoretical calculations to (hyper-)acid crater lakes associated with active volcanoes, and newly highlight the potential for the utility of multiple sulfur isotope analyses in volcanic gas monitoring and constraining sulfur cycling processes in such systems.

Keywords: sulfur isotopes, polysulfides, pyrite formation, disproportionation, acid crater lakes, hydrothermal

1. Introduction

Inorganic polysulfur compounds contain more than one sulfur atom and typically contain one or more sulfur-sulfur bonds. They commonly occur as anions dissolved in aqueous solutions. These include the aqueous polysulfides (S_x^{2-} and their protonated counterparts) and polysulfur radical anions ($S_x^{\cdot-}$) that contain relatively reduced sulfur (low oxidation state), and polythionates ($S_xO_6^{2-}$) and thiosulfate ($S_2O_3^{2-}$) that contain mixed-valence sulfur (low and high oxidation states).

The aqueous polysulfides can play a direct role in the formation of authigenic pyrite (FeS_2 ; e.g., Luther, 1991; Rickard & Luther, 2007). Authigenic pyrite is a ubiquitous component of marine sediments and sedimentary rocks that can begin forming in the water column and during the earliest stages of sediment diagenesis. Much of the reduced sulfur that is incorporated into pyrite is ultimately derived from dissimilatory sulfate reduction that produces H_2S/HS^- via anaerobic respiration. Pyrite preserved in sedimentary rocks is thus broadly viewed as a primary archive of the environmental sulfur and related elemental cycles, capturing a record that preserves isotopic signals of sulfur cycling processes at the time of their formation (e.g., Canfield, 2004; Johnston, 2011; Rickard, 2014). However, little is known about the potential isotope fractionations that may accompany pyrite formation processes from more primary sulfur sources in sedimentary environments. This may in part be due to the complexity of the aqueous sulfur speciation of compounds that are thought to directly participate in pyrite formation.

The molecular forms of sulfur and iron that participate in the process of pyrite precipitation and growth can vary depending on the environment and conditions, but a handful of relevant reactions have been identified based on experimental studies (Luther, 1991; Rickard, 1997; Rickard & Luther, 1997; Butler et al., 2004; Rickard & Luther, 2007):

29 The S_x^{2-} represent the polysulfides of various chain-length (' x '; $x = 2 - 8$;
 30 [Kamyshny et al., 2004, 2007](#)) and their protonated forms HS_x^- and H_2S_x ([Schwarzen-](#)
 31 [bach & Fischer, 1960](#); [Meyer et al., 1977](#)), the S^0 generically refers to a form of
 32 zero valent sulfur (e.g., orthorhombic α -S, monoclinic β -S and γ -S, dissolved S_8
 33 rings, etc.; [Meyer, 1976](#); [Boulegue, 1978](#)), and $FeS_{(aq)}$ can refer to the molec-
 34 ular ferrous sulfide monomers in solution (e.g., the $FeS_{(aq)}^0$ monomer species
 35 that may exist in a pH-dependent equilibrium with $FeSH^+$) and/or dissolved
 36 nano-particulate forms that have poorly constrained compositions and struc-
 37 tures ([Rickard & Morse, 2005](#); [Rickard, 2006](#); [Rickard & Luther, 2007](#)). The
 38 reactions represented in equations [3](#) and [4](#) (the 'polysulfide' and 'hydrogen sul-
 39 fide' mechanisms, respectively) are regarded as overall representations of the
 40 two experimentally documented mechanisms for pyrite nucleation/precipitation
 41 ([Luther, 1991](#); [Rickard, 1997](#)), which combined with pyrite crystal growth mech-
 42 anisms ([Harmandas et al., 1998](#)) represent the primary reactions thought to be
 43 responsible for 'pyrite formation' under conditions relevant to marine sedimen-
 44 tary environments ([Rickard & Luther, 2007](#)).

45 The isotopic composition of freshly precipitated/nucleated pyrite can be
 46 influenced not only by the isotopic composition of ambient $\sum H_2S_{(aq)}$ (e.g.,
 47 sourced from dissimilatory sulfate reduction), but also the mass balance of ex-
 48 change between aqueous sulfide and ambient elemental sulfur (potentially pre-
 49 dominately sourced from the oxidative cycling of aqueous sulfide) that is facili-
 50 tated by the polysulfides (Eq. [2](#)). Aqueous sulfide and polysulfide compounds
 51 appear to achieve relatively rapid isotopic equilibrium at low temperatures ([Fos-](#)
 52 [sing & Jørgensen, 1990](#)). Thus, if the 'polysulfide mechanism' is in operation

the equilibrium isotope partitioning between aqueous polysulfide and sulfide may place first order controls on the isotopic composition of pyrite relative to ambient aqueous sulfide depending on the additional isotope fractionations that accompany the precipitation of pyrite. Although it is presently understood that the isotope fractionations associated with pyrite formation (e.g., relative to ambient $\sum H_2S_{(aq)}$) resulting from the mechanisms above must be relatively small (Wilkin & Barnes, 1996; Butler et al., 2004), there has been no attempt to quantify the fractionation factors associated with either pyrite formation processes or those among the precursor aqueous sulfur compounds that participate in pyrite precipitation and growth.

The role of analogous polysulfur radical anions ($S_x^{\cdot-}$) in natural sulfur cycling is actively being elucidated. Radical polysulfur anions have long been recognized to be responsible for the deep blue coloration of some sodalite group minerals (e.g., McLaughlan & Marshall, 1970) and some sulfur-rich aqueous fluids at elevated temperature (e.g., Giggensbach, 1971; Chivers & Elder, 2013, and references therein). Recent experimental work of sulfur-rich hydrothermal fluids has reinvigorated the study of the trisulfur radical anion ($S_3^{\cdot-}$; Pokrovski & Dubrovinsky, 2011; Jacquemet et al., 2014; Pokrovski & Dubessy, 2015; Schmidt & Seward, 2017). In particular, the trisulfur radical ion has been recently recognized as a potentially important ligand in the hydrothermal mobilization and transport of precious metals such as gold under certain redox/pH conditions (Pokrovski et al., 2015) and as having an intermediary role in thermochemical sulfate reduction (Truche et al., 2014). Additionally, the trisulfur radical anion has been observed to be a component of naturally-occurring aqueous fluid inclusions in minerals (quartz, fluorite, anhydrite) associated with thermally processed evaporites upon their re-heating in the laboratory (Barré et al., 2017). Polysulfur radical anions could play a role in facilitating isotope exchange between oxidized (i.e., sulfate) and reduced sulfur (i.e., sulfide) at elevated temperatures in hydrothermal fluids under some conditions (e.g., Pokrovski & Dubessy, 2015; Kokh et al., 2020) but such processes are not yet understood in detail. Few studies have directly constrained the isotopic fractionations among the polysul-

fur radicals and coexisting sulfur compounds such as aqueous sulfide and sulfate (i.e., limited to the theoretical calculations of Tossell, 2012). Such constraints are required to lay the groundwork for understanding the possible role these compounds may play in sulfur isotopic variability among naturally occurring phases that result from transformations related to these compounds.

In the present study, we use *Gaussian09* software (Frisch et al., 2013) and a ‘supermolecular’ explicit solvation water cluster model (encapsulation of solute in clusters containing 30-52 water molecules) to estimate equilibrium sulfur isotope fractionation factors for all three isotope ratios of sulfur ($^{33}\text{S}/^{32}\text{S}$, $^{34}\text{S}/^{32}\text{S}$, $^{36}\text{S}/^{32}\text{S}$) among numerous aqueous sulfur compounds. These include: (a) select polysulfides (S_x^{2-} , HS_x^-) and aqueous sulfide compounds (H_2S , HS^- , $\text{FeS}_{(aq)}^0$, FeSH^+) that are relevant to authigenic pyrite formation mechanisms, (b) aqueous polysulfur radical anions ($\text{S}_2^{\cdot-}$, $\text{S}_3^{\cdot-}$) and some of the coexisting sulfide and sulfate compounds/ion-pairs (e.g., H_2S , HS^- , $(\text{Na}^+\text{HS}^-)^0$, HSO_4^- , SO_4^{2-} , $(\text{Na}^+\text{SO}_4^{2-})^-$) relevant to some natural and experimental hydrothermal systems (Ohmoto & Lasaga, 1982; Pokrovski & Dubessy, 2015; Schmidt & Seward, 2017), and (c) select polythionates (trithionate, $\text{S}_3\text{O}_6^{2-}$; tetrathionate, $\text{S}_4\text{O}_6^{2-}$) that are also relevant to biological, aquatic, sedimentary and hydrothermal-magmatic systems (e.g., Takano, 1987; Zopfi et al., 2004; Leavitt et al., 2015; Findlay & Kamyshny, 2017). We additionally model a molecular S_8 ring in a 50 H_2O cluster to obtain estimates of the sulfur isotope partitioning behavior of dissolved elemental sulfur relevant to hydrothermal systems. S_8 is only sparingly soluble in water at 25°C (e.g., 19 ± 6 nM; Boulegue, 1978) but its solubility increases substantially with increasing temperature (e.g., Kamyshny, 2009). Most naturally-occurring and relevant forms of crystalline sulfur are also comprised of molecular S_8 (Meyer, 1976). The purpose of this study is to examine equilibrium sulfur isotope fractionations among predominately reduced sulfur compounds/moieties, and to provide constraints that may be useful to elucidating isotope partitioning in aqueous systems that exhibit complex molecular compositions.

2. Methods

2.1. Reduced Partition Function Ratio

Theoretical equilibrium isotope fractionation factors among molecular substances of interest can be computed utilizing computations of the reduced partition function ratios (RPFR) of their component isotopologues (Urey, 1947; Bigeleisen & Mayer, 1947):

$$RPFR = \prod_i^l \frac{u_i^* \times e^{-u_i^*/2} \times (1 - e^{-u_i})}{u_i \times e^{-u_i/2} \times (1 - e^{-u_i^*})} \quad (5)$$

where * denotes terms related to the isotopically substituted molecule and $u_i = \frac{hc\omega_i}{k_bT}$, where: k_b is the Boltzmann constant, h is the Planck constant, c is the speed of light, T is temperature, and ω_i is the wave number for harmonic vibrational mode i (note vibrational frequency $\nu_i = c\omega_i$) and the product is over all harmonic vibrational modes (number of modes equal to $l = 3a - 6$ for a non-linear molecule and $l = 3a - 5$ for a linear molecule, where a is the number of atoms in the molecule). This approach has been extensively reviewed elsewhere (Urey, 1947; Richet et al., 1977; Chacko et al., 2001; Liu et al., 2010). The primary variables needed to estimate RPFRs and, thus, fractionation factors are the harmonic vibrational frequencies (ν_i) of relevant isotopologues that can be readily obtained using modern quantum mechanics-based computational chemistry software packages.

2.2. Quantum Mechanical Software: Gaussian 09

We use *Gaussian09* software (Revision E.01; Frisch et al., 2013) for our electronic structure calculations. We implement the B3LYP/6-31+G(d,p) level of theory and basis set size to generate harmonic vibrational frequencies (unscaled) for computing RPFRs following our previous sulfur isotope study (Eldridge et al., 2016). As described in Eldridge et al. (2016), the B3LYP method is a hybrid HF/B-LYP theoretical approach that employs the Becke and Lee, Yang, Parr 3-parameter gradient-corrected correlational functional (Lee et al.,

140 [1988; Becke, 1993; Foresman & Frisch, 1996] that includes electron correlation.
 141 The basis set is the double-zeta Pople basis set (6-31G) with diffuse functions
 142 added (+) to the non-hydrogen atoms that is often required for modeling an-
 143 ions, and polarization functions (p functions for all atoms, d functions for all
 144 non-hydrogen atoms) for additional flexibility in the computation of molecular
 145 orbitals. This approach is of relatively low/moderate computational complexity
 146 and accuracy that has been chosen for reasons of practicality given the relatively
 147 large molecular clusters modeled in this study. We use this same computational
 148 approach for calculations of the polysulfur radical ion species for the purpose of
 149 computing RPFRs following directly after Tossell (2012) (note: time-dependent
 150 methods for treating excited states such as TD-B3LYP and CIS have also been
 151 previously implemented for these species but only for the purpose of calculating
 152 UV-Visible spectra, which is beyond the scope of the present study; cf. Tos-
 153 sell, 2012). In conjunction with an explicit solvation model, this approach has
 154 been shown to be reasonably accurate for predicting equilibrium sulfur isotope
 155 effects among a number of aqueous sulfur compounds based on a comparison to
 156 available experimental constraints (Eldridge et al., 2016, 2018).

157 2.3. Explicit Solvation Model

158 Modeled sulfur compounds are encapsulated in clusters of water molecules
 159 (ranging 30-52 H₂O) to approximate the effect of aqueous solvation on molecu-
 160 lar vibrations and RPFRs (e.g., Liu & Tossell, 2005; Rustad & Bylaska, 2007;
 161 Rustad et al., 2008; Zeebe, 2009; Li et al., 2009; Zeebe, 2010; Rustad et al.,
 162 2010; Li & Liu, 2011; Hill et al., 2014; Eldridge et al., 2016). The largest aque-
 163 ous clusters for a given solute were constructed following an analogous ‘manual’
 164 cluster building technique to our previous study (Eldridge et al., 2016). The
 165 manual aqueous cluster building technique differs from another common cluster
 166 generating technique that utilizes molecular dynamics simulations of solutes in
 167 water clusters to generate “snap shot” geometries to use as a starting point
 168 for optimization and frequency calculations for similar purposes (Rustad & By-
 169 laska, 2007; Rustad et al., 2008, 2010; Hill et al., 2014). In short, our approach

involves the manual coordination of the sulfur solute with water molecules in a step-wise optimization procedure (typically 3-5 water molecules per step) until a maximum cluster size is achieved (ca. 45-52 H₂O in the present study). In general, the small cluster sizes generated during this step-wise procedure were not used for frequency calculations due in part to some instances of incomplete solvation coverage of the solute.

Several different clusters (up to 8 depending on the solute) of varying size (30 to 52 H₂O) were typically computed for each sulfur compound in order to assess the variability in RPFRs associated with water cluster size. Aqueous clusters of smaller size were primarily generated by the procedure of removing water molecules from the largest clusters generated for a given solute (ca. 45-52 H₂O) and subjecting the resulting clusters of smaller size to optimization and frequency calculations. This ‘whittling-down’ approach allows for much greater control on the solvation coverage of the solute in smaller clusters by selective water removal in order to avoid errant situations of incomplete solvation (i.e., migration of solute to the edge of a cluster), and also allows for the tracking of the same atomic sites of the solutes through different cluster sizes and optimizations. As we will demonstrate below, this approach led to different solvation environment around solutes based on observed differences in the number of water molecules that appear to be directly coordinated with atomic sites of the solute. A list of the computed sulfur solutes (polysulfide, polysulfur radical, polythionate, sulfide, elemental sulfur, and sulfate compounds) embedded in water clusters of various size is provided in Table I for reference.

2.4. Approach to Modeling the Polysulfides and their Structures

Thermodynamic data presently exists for polysulfides (S_x²⁻) containing up to eight sulfur atoms (Kamyshny et al., 2004, 2007) but polysulfides with up to nine sulfur atoms have been observed experimentally (Gun et al., 2004). The pK_{a1} of polysulfides (H₂S_x = HS_x⁻ + H⁺) decreases with increasing chain length from 5.0 for disulfide to 2.9 for octasulfide, and the pK_{a2} (HS_x⁻ = S_x²⁻ + H⁺) decreases from 9.7 to 4.4 for the same species (Schwarzenbach & Fischer, 1960).

200 [Meyer et al., 1977](#)). Thus, under circum-neutral pH conditions the polysulfides
 201 with $x > 3$ predominantly exist in the form of S_x^{2-} and disulfide and trisulfide
 202 exist in the form of HS_x^- . For the purposes of the present study, the polysulfides
 203 of primary interest will be S_x^{2-} ($x = 2 - 8$) and HS_x^- ($x = 2 - 3$).

204 Multiple stereoisomers are possible for S_x^{2-} when $x \geq 4$ ([Steudel, 2003](#);
 205 [Rickard & Luther, 2007](#)). For simplicity, the longer chain-length polysulfides
 206 ($x = 5 - 8$) have each been modeled solely as helical structures that closely
 207 resemble all-trans stereoisomers ([Steudel, 2003](#); [Rickard & Luther, 2007](#)). Addi-
 208 tionally, we have not attempted to distinguish between the d - and l -isomers of
 209 polysulfides ranging from $x = 4 - 8$ ([Rickard & Luther, 2007](#)), and similarly we
 210 do not make any attempt to distinguish between the stereoisomers of the proto-
 211 nated polysulfide, HS_3^- . These different stereoisomers result in different relative
 212 orientations of the component atoms but do not result in changes in bonding
 213 order with respect to a given sulfur atom. For simplicity, we also consider
 214 the aqueous ferrous sulfide species ($FeS_{(aq)}$) as the monomeric neutral diatomic
 215 $FeS_{(aq)}^0$ and its protonated counterpart $FeSH^+$ because the precise structures
 216 and compositions of $FeS_{(aq)}$ relevant to natural systems are complex and per-
 217 haps not well understood ([Rickard & Morse, 2005](#); [Rickard, 2006](#); [Rickard &](#)
 218 [Luther, 2007](#); [Haider et al., 2013](#)).

219 2.5. Fractionation Factors

220 RPFs corresponding to the isotopologues of a particular molecular sub-
 221 stance can be conveniently related to isotope fractionation factors via β -values
 222 ([Richet et al., 1977](#)), represented in simplified and approximate form as:

$$\beta \approx \prod_{i=1}^x RPF_i^{\frac{1}{x}} \quad (6)$$

223 Where x is the number of elemental sites in the molecule, and the product is
 224 over all singly-substituted isotopologues. In principle, the β -value represents
 225 a fractionation factor between a molecular substance of interest and an ideal
 226 monoatomic gaseous reference atom under the condition of equilibrium ([Richet](#)

et al., 1977). The exact β takes into account all isotopologues corresponding to a particular isotope substitution (i.e., ^{33}S or ^{34}S or ^{36}S) and their relative abundances including multiply substituted isotopologues to comprise a bulk isotopic composition of the molecular substance with respect to a particular isotope ratio. Eq. 6 approximates β by ignoring additional terms that relate to multiply substituted molecules that in practice have negligible influence on bulk isotopic compositions (e.g., Richet et al., 1977).

When elemental sites are not equivalent, more careful treatment may have to be taken in order to ensure accuracy. For the polysulfides and polysulfur radical anions in this study, we approximate β by assuming that the β -factor for the given S_x^{2-} (or HS_x^-) or $\text{S}_x^{\cdot-}$ is equivalent to the product of the RPFRs of x -number of individual singly substituted isotopologues raised to the power of x^{-1} (i.e., Eq. 6). This approximation includes the assumption that the singly substituted isotopologues of a given polysulfide chain (e.g., for S_3^{2-} or $\text{S}_3^{\cdot-}$: $^{34}\text{S}\text{-}^{32}\text{S}\text{-}^{32}\text{S}$, $^{32}\text{S}\text{-}^{34}\text{S}\text{-}^{32}\text{S}$, and $^{32}\text{S}\text{-}^{32}\text{S}\text{-}^{34}\text{S}$) contribute in an equally proportional manner to the overall bulk isotopic composition of the polysulfide (i.e., are present in equal abundance), which is reasonable given what we will show to be the relatively small differences in RPFR between individual isotopologues of polysulfides and polysulfur radicals. We will illustrate in Section 3.3 the likely negligible impact of this approximation on our computations of β -factors for the polysulfides and polysulfur radical anions. For aqueous sulfur molecules containing only one sulfur atom (i.e., aqueous sulfide and sulfate compounds), $\beta \approx \text{RPFR}$ to a very good approximation that ignores only the contributions from multiply substituted isotopologues.

This treatment allows for straightforward computation of equilibrium fractionation factors (α) among compounds by taking the ratios of their β -factors (e.g., between compound A and compound B):

$$^{33}\alpha_{A-B} = \frac{^{33}R_A}{^{33}R_B} = \frac{^{33}\beta_A}{^{33}\beta_B} \quad (7)$$

$$^{34}\alpha_{A-B} = \frac{^{34}R_A}{^{34}R_B} = \frac{^{34}\beta_A}{^{34}\beta_B} \quad (8)$$

$$^{36}\alpha_{A-B} = \frac{^{36}R_A}{^{36}R_B} = \frac{^{36}\beta_A}{^{36}\beta_B} \quad (9)$$

Mass-dependent relationships can be computed from fractionation factors
via the following relations:

$$^{33/34}\theta_{A-B} = \frac{\ln(^{33}\alpha_{A-B})}{\ln(^{34}\alpha_{A-B})} \quad (10)$$

$$^{36/34}\theta_{A-B} = \frac{\ln(^{36}\alpha_{A-B})}{\ln(^{34}\alpha_{A-B})} \quad (11)$$

We will generically refer to values of $^{33/34}\theta$ and $^{36/34}\theta$ as the “exponents of mass
dependence” associated with particular equilibrium isotope exchange reactions.
Similar relationships can be applied to exponents derived from β -factors for a
particular compound (e.g., compound A):

$$^{33/34}\kappa_A = \frac{\ln(^{33}\beta_A)}{\ln(^{34}\beta_A)} \quad (12)$$

$$^{36/34}\kappa_A = \frac{\ln(^{36}\beta_A)}{\ln(^{34}\beta_A)} \quad (13)$$

where we follow the kappa-notation of [Cao & Liu \(2011\)](#). In the present study,
polynomial fits to values of $^{33}\beta$ and $^{36}\beta$ as a function of temperature will be
tabulated in terms of their corresponding $^{33/34}\kappa$ and $^{36/34}\kappa$ values to minimize
spurious errors.

We can also define values of $\Delta^{33}\text{S}$ and $\Delta^{36}\text{S}$ in terms of fractionations be-
tween specific compounds:

$$\Delta^{33}\text{S} = \left(\frac{^{33}R_A}{^{33}R_B} - \left(\frac{^{34}R_A}{^{34}R_B} \right)^{0.515} \right) \times 1000 \quad (14)$$

$$\Delta^{36}S = \left(\frac{{}^{36}R_A}{{}^{36}R_B} - \left(\frac{{}^{34}R_A}{{}^{34}R_B} \right)^{1.90} \right) \times 1000 \quad (15)$$

Where Δ -values are in units of permil and the values of 0.515 and 1.90 are the conventional reference exponents. For equilibrium Δ -values between compounds the above isotope ratios can be replaced by the appropriate β -factors (*cf.* Eq. 7-9). Note that when values of $\Delta^{33}S$ and $\Delta^{36}S$ are reported in terms of a sample relative to a reference standard the isotope ratios of A in the above equations can be replaced by the isotope ratios of the sample and the isotope ratios for B can be replaced by the isotope ratios of the reference standard.

For aqueous sulfur molecules such as the polythionates ($S_xO_6^{2-}$) that contain sulfur atoms that have different oxidation states and therefore very different RPFRs, we will not use the concept of β to describe fractionation behavior. Instead, we will examine the isotope partitioning behavior of the unique sites within these molecules. The polythionates contain relatively reduced ‘inner’ sulfur atoms that we will schematically refer to as $^*S_x(SO_3)_2^{2-}$ ($x = 1$ or 2 in this study, corresponding to tri- and tetrathionate) and the two equivalent ‘sulfonate’ sulfur atoms that we will schematically refer to as $S_x(^*SO_3)_2^{2-}$ (in both instances, *S refers to the atomic site of interest undergoing isotope substitution). The α -notation will be used to refer to fractionation factors between specific atomic sites within the polythionates and between these sites and other sulfur compounds.

2.6. General sources of uncertainty in the theoretical calculations

As summarized in our prior study (Eldridge et al., 2016), uncertainty in our theoretically estimated fractionation factors can arise from three primary sources: (1) errors arising from the harmonic and other approximations inherent to the RPFR as formulated in Eq. 5 (Bigeleisen & Mayer, 1947; Urey, 1947), (2) errors introduced by the choice of theoretical method and basis set size used to compute electronic potential energy surfaces to obtain harmonic vibrational frequencies, and (3) errors/variability arising from the water cluster geometry. We evaluated the relative sources of error introduced by (1) and (2) in our pre-

vious study (Eldridge et al., 2016) by performing exercises with calculations of model gaseous species. Gaseous species were chosen for these exercises because analogous computations involving solutes in water clusters (≥ 30 H₂O) are not feasible due to the high computational demands associated with these calculations. The exercises related to points (1) and (2) in Eldridge et al. (2016) apply to the current study because we use the same theoretical method and basis set (B3LYP/6-31+G(d,p)).

Regarding (1) we evaluated the magnitude of the anharmonic corrections to the zero point energy (AnZPE; cf. Liu et al., 2010) on RPFR/ β values for gaseous sulfur species computed at the B3LYP/6-31+G(d,p) level of theory and basis set (e.g., H₂S, SO₂, SO₃; Eldridge et al., 2016). We observed relative differences in RPFR/ β values no greater than 1 ‰ at temperatures $\geq 25^\circ\text{C}$ (Eldridge et al., 2016). Due to the low magnitudes of these corrections and the inability to apply appropriate anharmonic corrections to the large aqueous clusters investigated, all RPFR/ β values reported in Eldridge et al. (2016) and the current study have been computed in the harmonic approximation. For further information/discussion regarding point (1) we refer the reader to Eldridge et al. (2016) (their Sections 3.5 and 5.1.1).

Regarding (2) we evaluated the relative magnitude of error introduced by theoretical method and basis set following approaches in previous studies (e.g., Li & Liu, 2011). Specifically, we calculated the harmonic vibrational frequencies of a handful of gaseous sulfur compounds (H₂S, S₂, SO, SO₂) using a high level theoretical method and large basis set (CCSD/aug-cc-pVTZ) and compared them to the harmonic vibrational frequencies obtained for the same molecules computed at the utilized theoretical method and basis set (B3LYP/6-31+G(d,p)). This exercise yielded a relatively small harmonic frequency scaling factor of 1.01-1.02 (Eldridge et al., 2016). Application of this scaling factor to calculations of solutes in water clusters resulted in differences in computed RPFR/ β values that are dependent on the species and temperature considered but that amount to differences in $^{34}\alpha$ values no greater than 1-2‰ at temperatures $\geq 25^\circ\text{C}$ (Eldridge et al., 2016). Additionally, we observed that the

harmonic vibrational frequencies of some gaseous molecules appear to scale differently than others between computational methods (e.g., SO₂ vs. H₂S, S₂, and SO; see Eldridge et al., 2016) meaning that harmonic scaling factors obtained are dependent on the model molecules chosen (similar to observations made in prior studies; e.g., Li & Liu, 2011). We raised related concerns that model gaseous compounds may not capture the full range of error introduced by theoretical method due to the greater complexity of aqueous species/anions in water clusters (Eldridge et al., 2016). Due to the small magnitude of these harmonic scaling corrections and the potential issues associated with this practice, we chose in Eldridge et al. (2016) and in the current study not to scale our harmonic frequencies. For further information/discussion regarding point (2) we again refer the reader to Eldridge et al. (2016) (their Sections 3.5 and 5.1.2).

Regarding (3) we evaluate the error/variability arising from the water cluster geometry for most of the investigated sulfur solutes by performing optimization and frequency calculations in water clusters of varying sizes (30-52 H₂O; Table 1). We estimate the uncertainty of any given computed quantity (e.g., geometric parameters, RPFRs, and β -factors) as the standard deviation of values derived from the different cluster sizes/conformations. We propagate these uncertainty estimates into derived quantities such as fractionation factors.

3. Results

3.1. Structures and Geometries

Examples of two-dimensional representations of optimized geometries of solute H₂O clusters are presented in Fig. 1-3 that are organized according to polysulfides, polysulfur radicals, and elemental sulfur (Fig. 1), sulfide compounds (Fig. 2), and sulfate and polythionate compounds (Fig. 3). The geometric parameters of the explicitly solvated sulfur solutes are summarized in Table 2 and represent mean values derived from the numerous water cluster configurations. Similar parameters for S_{x(g)}²⁻ modeled as similar structures in vacuum

also computed at the B3LYP/6-31+G(d,p) level are listed for reference. A detailed description of the computed molecular geometries and their comparison to available theoretical and experimental data can be found in [Appendix A.1](#)

3.2. Overview of RPFRs and β values

Table [3](#) contains the mean and standard deviation of the mean (1 s.d.) of RPFRs computed at 25°C for aqueous sulfide compounds ($\text{H}_2\text{S} \cdot n\text{H}_2\text{O}$, $\text{HS}^- \cdot n\text{H}_2\text{O}$, $\text{FeS}^0 \cdot n\text{H}_2\text{O}$, $\text{FeSH}^+ \cdot n\text{H}_2\text{O}$, $(\text{Na}^+\text{HS}^-)^0 \cdot n\text{H}_2\text{O}$) and the component isotopologues of each polysulfide ($\text{S}_x^{2-} \cdot n\text{H}_2\text{O}$ and $\text{HS}_x^- \cdot n\text{H}_2\text{O}$) and polysulfur radicals ($\text{S}_x^{\cdot-} \cdot n\text{H}_2\text{O}$) based on the different water cluster size configurations. Table [3](#) additionally includes the mean number (range in parentheses) of water molecules that appear to be directly coordinated with each molecular sulfur atom in the clusters *via* an apparent intermolecular hydrogen bond (i.e., $\text{H-O-H} \cdots \text{S}$), which is generally observed to vary for a given sulfur atom in compounds contained within $n\text{H}_2\text{O}$ clusters of different size (n) in a non-systematic fashion.

The mean and standard deviation of the mean of β -factors derived from RPFRs for all heavy stable isotope substitution (^{33}S , ^{34}S , and ^{36}S) have been computed as a function of temperature and are provided in Table [4](#) in the form of coefficients based on polynomial fits to values of $^{34}\beta$, $^{33/34}\kappa$, and $^{36/34}\kappa$ over the equivalent of 0-5000°C in the form of $A/T^4 + B/T^3 + C/T^2 + D/T + E$ (T in K). The coefficients of polynomial fits to the mean $^{33/34}\kappa$ and $^{36/34}\kappa$ values are given rather than the corresponding $^{33}\beta$ and $^{36}\beta$ values in order to avoid spurious errors in the exponents that may arise from rounding errors in β values. Similar coefficients of polynomial fits to the analogous RPFR values of trithionate are given in Table [5](#).

We do not observe any systematic changes in values of $^{34}\text{RPFRs}$ and/or $^{34}\beta$ for each solute with cluster size over the range we have studied (ca. 30-52 H_2O). The variability in values of RPFR and/or β values arising from different cluster sizes appears to be relatively small. For example, the variability in values of $^{34}\text{RPFR}$ and/or $^{34}\beta$ for a given solute is on the order of $\leq 0.5 \text{ ‰}$ (1 s.d.) at 25°C (Table [3](#) and [4](#)). The magnitude of this variability is comparable to the

variability that has been observed in previous computational studies of isotope partitioning behavior of numerous elements contained within anionic and other solutes modeled in water clusters of different size and geometric conformations, both for clusters that were built manually as in the present study (Li et al., 2009; Li & Liu, 2011) and for clusters generated from the subsequent optimization of “snap shots” from molecular dynamics simulations (Rustad et al., 2008, 2010; Hill et al., 2014). The slight variability in RPFRs and β values for explicitly solvated solutes can be viewed to arise from variability in the number of water molecules that appear to be coordinated with sulfur atoms via intermolecular hydrogen bonds that together contribute to the ‘first solvation shell’ (cf. Table 3), and the slight differences in the molecular geometry of sulfur solutes in the clusters of varying size that in some cases may be caused by the different direct interactions with water molecules in the clusters of varying size.

3.2.1. $^{34}\text{RPFRs}$ and $^{34}\beta$ values for Aqueous Polysulfide, Polysulfur Radical, and Sulfide Compounds

Mean values for $^{34}\text{RPFRs}$ and $^{34}\beta$ at 25°C from Table 3 are plotted in Fig. 4 for the explicitly solvated sulfide and polysulfide species (values for vacuum calculations of S_x^{2-} are also shown for reference). The singly substituted isotopologues of the polysulfide species (S_x^{2-}) exhibit slightly different RPFRs when $x > 2$, but appear to follow similar patterns for both the explicitly solvated and vacuum calculations. The $^{34}\text{RPFRs}$ for S_x^{2-} isotopologues that correspond to the isotope substitution of the outer-most sulfur atoms are generally lower than the $^{34}\text{RPFRs}$ for isotopologues corresponding to isotope substitution of inner sulfur atoms (Fig. 4). The isotopologues that exhibit the highest $^{34}\text{RPFRs}$ correspond to isotope substitution of the inner sulfur atoms that are directly bonded to the outermost sulfur atoms (e.g., S-*S-S for S_3^{2-} and S-*S-S-S-S-S-S and its symmetrical equivalent for S_8^{2-}) (Fig. 4). For longer chain length S_x^{2-} ($x = 5-8$), the isotopologues corresponding to isotope substitution of the innermost sulfur atoms (e.g., S-S-*S-S-S for S_5^{2-} , and S-S-*S-S-S-S for S_6^{2-}) have intermediate $^{34}\text{RPFR}$ values. The magnitude of RPFRs corresponding to iso-

414 tope substitution at a symmetrically equivalent site (e.g., *S-S-S and S-S-*S for
 415 S_3^{2-}) are generally comparable for $S_x^{2-} \bullet nH_2O$, but do not appear to exhibit the
 416 perfectly symmetrical behavior in the water clusters that might be expected
 417 from the considerations of the vacuum calculations and ideal molecular symme-
 418 try.

419 The $^{34}\beta$ factors derived from $^{34}RPFRs$ for $S_x^{2-} \bullet nH_2O$ generally increase
 420 with increasing chain length (' x '), and the magnitude of this increase appears to
 421 diminish with increasing ' x ' (Fig. 4). Similar behavior is observed in the vacuum
 422 calculations for S_x^{2-} . To a first order, the general increase in $^{34}\beta$ with increasing
 423 ' x ' for S_x^{2-} can be described to arise from the proportionality between the $^{34}\beta$ -
 424 factor and the number of $^{34}RPFR$ -contributing isotopologues that increases with
 425 ' x ' (e.g., Equation 6). Such an increase in the number of singly substituted
 426 isotopologues with increasing chain-length can result in an increase in $^{34}\beta$ when
 427 the magnitudes of $^{34}RPFR$ of the component isotopologues generally increases
 428 with ' x ' (as appears to be the case with the S_x^{2-} calculations in vacuum) or at
 429 least do not decrease with increasing ' x ' (as appears to be the case with the
 430 $S_x^{2-} \bullet nH_2O$ calculations). The largest increase in $^{34}\beta$ with ' x ' is between S_2^{2-}
 431 and S_3^{2-} (Fig. 4) and is the result of the contribution of the higher $^{34}RPFR$ of
 432 the centrally substituted isotopologue of S_3^{2-} (S-*S-S). With increasing ' x ' (x
 433 ≥ 4) the number of contributing inner substituted isotopologues increases, and
 434 due to their relatively higher $^{34}RPFR$ they appear to contribute to a relatively
 435 higher $^{34}\beta$. This effect appears to diminish among the longer chain length
 436 polysulfides ($x = 5-8$) due to the increasing contribution from isotopologues
 437 corresponding to inner-most sulfur atom substitution that have intermediary
 438 magnitude $^{34}RPFRs$. Roughly speaking, $^{34}\beta$ values appear to approach the
 439 $^{34}RPFR$ of the innermost sulfur atoms with increasing ' x ' for the longer chain-
 440 length polysulfides ($x = 5-8$).

441 The protonated polysulfide anions ($HS_x^- \bullet nH_2O$, $x = 2$ and 3) generally have
 442 larger magnitude $^{34}\beta$ than their unprotonated counterparts. This appears to
 443 arise from the generally higher $^{34}RPFRs$ of the component isotopologues of HS_2^-
 444 and HS_3^- relative to S_2^{2-} and S_3^{2-} , respectively, and especially from the higher

445 magnitude $^{34}\text{RPFR}$ of isotopologues that correspond to isotope substitution of
 446 the protonated sulfur atoms (Fig. 4, Table 3). Similar to $\text{S}_x^{2-} \bullet \text{nH}_2\text{O}$, the mag-
 447 nitude of $^{34}\beta$ for $\text{HS}_x^- \bullet \text{nH}_2\text{O}$ appears to increase slightly with increasing chain
 448 length over $x = 2-3$. The relative trends in RPFRs computed for isotopologues
 449 of polysulfides (S_x^{2-} , HS_x^-) that we have described at 25°C and are illustrated
 450 in Table 3 and Fig. 4 generally hold as a function of temperature. The only
 451 exception is for the HS_3^- species, which is predicted to have a crossover between
 452 its isotopologues (not shown). In this case, the isotopologue corresponding to
 453 isotope substitution of the H-S bonded site ($\text{S-S}^*\text{SH}$)- is predicted to exhibit
 454 a crossover in the RPFR with the isotopologue corresponding to isotope sub-
 455 stitution of the central sulfur site ($\text{S}^*\text{S-SH}$)- in proximity to $135 \pm 20^\circ\text{C}$ (not
 456 shown). This appears to be the only instance of an ‘intramolecular isotopologue
 457 crossover’ that we observe in our dataset.

458 The isotopologues of the explicitly solvated polysulfur radical anions ($\text{S}_2^{\cdot-}$
 459 and $\text{S}_3^{\cdot-}$) exhibit similar relative patterns to the analogous polysulfide species
 460 (S_2^{2-} and S_3^{2-}) but have slightly larger magnitude $^{34}\text{RPFR}$ s and, thus, have
 461 higher $^{34}\beta$ values (Table 3). For example, the $^{34}\text{RPFR}$ values for isotope sub-
 462 stitution of the outer sulfur atoms of $\text{S}_3^{\cdot-}$ are predicted to be 1.0098 ± 0.0003
 463 at 25°C (cf. 1.0089 ± 0.0003 for S_3^{2-}) and $^{34}\text{RPFR} = 1.0165 \pm 0.0003$ for iso-
 464 tope substitution of the central sulfur atom (cf. $^{34}\text{RPFR} = 1.0134 \pm 0.0002$
 465 for S_3^{2-}) (Table 3), which translates into a $^{34}\beta = 1.0120 \pm 0.0002$ for $\text{S}_3^{\cdot-}$ (cf.
 466 $^{34}\beta = 1.0104 \pm 0.0002$ for S_3^{2-}). The magnitude of $^{34}\beta$ increases with increas-
 467 ing chain length for the polysulfur radicals ($\text{S}_x^{\cdot-}$) over $x = 2-3$ that appears to
 468 arise from the contribution of the higher $^{34}\text{RPFR}$ of the centrally substituted
 469 isotopologue of $\text{S}_3^{\cdot-}$ ($\text{S}^*\text{S-S}$) similar to the analogous polysulfides. To a first
 470 order, the higher magnitude $^{34}\text{RPFR}$ s of the polysulfur radical anions may be
 471 a consequence of the different electronic structure and much shorter S-S bond
 472 lengths of the polysulfur radical species that may result in a ‘tighter’ bonding
 473 arrangement for sulfur in these compounds relative to the analogous polysulfide
 474 compounds.

475 For the aqueous sulfide species, the magnitude of $^{34}\beta$ (note for these species

$^{34}\text{RPFR} \approx ^{34}\beta$) increases with increasing coordination (due to either proto-
 nation or bonding with Fe) in a manner that is similar to our previous study
 (Eldridge et al., 2016). At 25°C, $\text{H}_2\text{S} \bullet \text{nH}_2\text{O}$ ($^{34}\beta = 1.0129 \pm 0.003$) $>$ $\text{HS}^- \bullet \text{nH}_2\text{O}$
 ($^{34}\beta = 1.0087 \pm 0.005$) $>$ $\text{S}^{2-} \bullet \text{nH}_2\text{O}$ ($^{34}\beta = 1.0076$; $\text{S}^{2-} \bullet \text{nH}_2\text{O}$ from Eldridge
 et al. (2016)). Similar patterns are observed for the Fe-S molecular species where
 $\text{FeSH}^+ \bullet \text{nH}_2\text{O}$ ($^{34}\beta = 1.0119 \pm 0.003$) $>$ $\text{FeS}_{(\text{aq})}^0 \bullet \text{nH}_2\text{O}$ ($^{34}\beta = 1.0089 \pm 0.003$),
 where the latter is indistinguishable from the $^{34}\beta$ of $\text{HS}^- \bullet \text{nH}_2\text{O}$ at 25°C. The
 Fe atom in the $\text{FeS}_{(\text{aq})}^0 \bullet \text{nH}_2\text{O}$ species is coordinated with the oxygen atoms of
 three water molecules in all computed clusters ($n = 31\text{-}50$) that is consistent with
 previous molecular dynamics simulations of this species (Haider et al., 2013),
 whereas the Fe atom of $\text{FeSH}^+ \bullet \text{nH}_2\text{O}$ is coordinated with four water molecules
 in all computed clusters ($n = 34\text{-}50$). The ion pair $(\text{Na}^+ \text{HS}^-)^0 \bullet \text{nH}_2\text{O}$ is com-
 puted to have β -values that are indistinguishable from those of $\text{HS}^- \bullet \text{nH}_2\text{O}$ at
 all temperatures and therefore will not be individually described or discussed in
 any further detail.

3.2.2. Relative error introduced by the approximation of β for polysulfur com- pounds

In this study, we approximate β values ($^{33}\beta$ or $^{34}\beta$ or $^{36}\beta$) for the com-
 putation of fractionation factors among polysulfides and polysulfur radicals by
 assuming that the bulk equilibrium isotopic composition of a given ‘x’-chain
 length polysulfur compound (i.e., S_x^- , S_x^{2-} , HS_x^-) can be represented by the
 RPFs of singly substituted ‘x’-number of isotopologues present in equal rel-
 ative abundance (Section 2.5). In this approximate form, it is expected that
 this assumption (equal abundance of major singly-substituted isotopologues)
 would introduce more error into β than the other common assumption in the
 computation of β that multiply substituted isotopologues (e.g., $^{34}\text{S}\text{-}^{34}\text{S}\text{-}^{32}\text{S}$, $^{34}\text{S}\text{-}$
 $^{34}\text{S}\text{-}^{34}\text{S}$ for S_3^{2-}) represent a negligible contribution (Richet et al., 1977). As an
 example, we will consider the impact of the assumption of equal abundance on
 the computation of $^{34}\beta$ for the trisulfur polysulfide, S_3^{2-} , which is chosen as
 exemplary because the unique sulfur atoms of S_3^{2-} (‘outer’ and ‘central’) ex-

hibit a range in RPFR values that is comparable to the range exhibited in other polysulfides of longer chain length (Fig. 4). At 25°C, the RPFRs computed for the three major ^{34}S -based isotopologues of S_3^{2-} are 1.0088 ± 0.0002 (^{34}S - ^{32}S - ^{32}S), 1.0134 ± 0.0002 (^{32}S - ^{34}S - ^{32}S), and 1.0090 ± 0.0003 (^{32}S - ^{32}S - ^{34}S), where the isotopologues with outer atom isotope substitution are predicted to have the same RPFR within the estimated uncertainty (based on numerous cluster conformations) as is expected by molecular symmetry and the equivalence of bonding environment. These RPFR values imply that the relative fractional abundances of these isotopologues corresponds to: 0.3328 ± 0.0001 and 0.3329 ± 0.0001 for the outer substituted isotopologues, and 0.3348 ± 0.0001 for the centrally-substituted isotopologue. Taking these relative abundances into consideration would yield a $^{34}\beta = 1.0104 \pm 0.0002$, which is indistinguishable from the value of $^{34}\beta = 1.0104 \pm 0.0002$ where equal abundance (i.e., 1/3) of these major isotopologues is assumed (Table 3). Similar computations of other polysulfides yield similar results. The similar exercise with the trisulfur radical anion S_3^- that is computed to exhibit a slightly larger range in RPFR between the ‘outer’ and ‘central’ sulfur atoms (Table 3) also yields essentially identical values for β (i.e., $^{34}\beta = 1.0120 \pm 0.0002$ at 25°C for both approaches). We thus conclude that our approximate form of β for the polysulfur compounds (S_x^- , S_x^{2-} , HS_x^-) is not likely to introduce any significant error into our estimations of fractionation factors involving these compounds.

3.2.3. Aqueous Polythionates

Trithionate ($\text{S}_3\text{O}_6^{2-}$, or $\text{S}(\text{SO}_3)_2^{2-}$) contains three sulfur atoms but only two unique atomic sulfur sites: two equivalent sulfur atoms in sulfonate groups ($\text{S}^*(\text{SO}_3)_2^{2-}$) that are bound to a unique and central sulfur atom ($^*\text{S}(\text{SO}_3)_2^{2-}$). Tetrathionate ($\text{S}_4\text{O}_6^{2-}$, or $\text{S}_2(\text{SO}_3)_2^{2-}$) is similar in that it also contains two equivalent sulfonate groups ($\text{S}_2^*(\text{SO}_3)_2^{2-}$) connected via two central sulfur atoms that are equivalent to each other ($^*\text{S}_2(\text{SO}_3)_2^{2-}$). The somewhat analogous thiosulfate dianion ($\text{S}_2\text{O}_3^{2-}$, or $\text{S}(\text{SO}_3)_2^{2-}$) contains sulfur in two different oxidation states where the formal charge on the outer sulfur atom is consistent with a -1

oxidation state and the sulfonate sulfur is consistent with a +5 oxidation state (Vairavamurthy et al., 1993), but a comparable experimental study for the polythionates has not been conducted to our knowledge. Similar to the thiosulfate dianion, the RPFRs for the two unique sulfur sites in polythionate are very different. For example, trithionate: $^{34}\text{RPFR} = 1.0142 \pm 0.0002$ for $^*\text{S}(\text{SO}_3)_2^{2-}$ and $^{34}\text{RPFR} = 1.0708 \pm 0.0005$ to 1.0714 ± 0.0002 for $\text{S}(^*\text{SO}_3)_2^{2-}$ at 25°C (equivalent for the ‘sulfonate’ sulfur atoms within the estimated uncertainty based on cluster size/geometry). Values of RPFRs for the two analogously unique atomic sites in tetrathionate (corresponding to $^*\text{S}_2(\text{SO}_3)_2^{2-}$ and $\text{S}_2(^*\text{SO}_3)_2^{2-}$) are computed to be essentially indistinguishable from those of trithionate at all temperature values (e.g., at 25°C the $^{34}\text{RPFR}$ for $^*\text{S}_2(\text{SO}_3)_2^{2-}$ is 1.0140 ± 0.0002 to 1.0150 ± 0.0002 for the two central sulfur atoms, and $^{34}\text{RPFR}$ for $\text{S}_2(^*\text{SO}_3)_2^{2-}$ is 1.0714 ± 0.0001 to 1.0704 ± 0.0002 for the two sulfonate sulfur atoms), and thus for the remainder of this manuscript we will describe fractionation factors involving the polythionates in generic terms of $^*\text{S}_x(\text{SO}_3)_2^{2-}$ and $\text{S}_x(^*\text{SO}_3)_2^{2-}$ where $x = 1$ and 2. Compared to thiosulfate, the reduced sulfur atoms ($^*\text{S}_x(\text{SO}_3)_2^{2-}$ vs. $^*\text{S}(\text{SO}_3)_2^{2-}$) and the sulfonate sulfur atoms ($\text{S}_x(^*\text{SO}_3)_2^{2-}$ vs. $\text{S}(^*\text{SO}_3)_2^{2-}$) in the polythionates are predicted to exhibit slightly larger RPFR values but are nevertheless relatively similar (cf. at 25°C the $^{34}\text{RPFR} = 1.0116$ for $^*\text{S}(\text{SO}_3)_2^{2-}$, and $^{34}\text{RPFR} = 1.0675$ for $\text{S}(^*\text{SO}_3)_2^{2-}$; Eldridge et al., 2016).

3.2.4. Aqueous Sulfate

The aqueous sulfate compounds and ion-pairs modeled herein all exhibit very similar β -values. The magnitude of $^{34}\beta$ appears to follow the relationship of $\text{HSO}_4^- \bullet \text{nH}_2\text{O}$ ($^{34}\beta = 1.0800 \pm 0.0002$) $>$ $(\text{Na}^+\text{SO}_4^{2-})^- \bullet \text{nH}_2\text{O}$ ($^{34}\beta = 1.0795$) $\approx$ $(\text{Mg}^{2+}\text{SO}_4^{2-})^0 \bullet \text{nH}_2\text{O}$ (1.0794 ± 0.0001) $\geq$ $\text{SO}_4^{2-} \bullet \text{nH}_2\text{O}$ (1.0792 ± 0.0002) (all $^{34}\beta$ -values at 25°C). Interestingly, $^{34}\beta$ -values for HSO_4^- and SO_4^{2-} appear to exhibit the opposite relationship than values theoretically predicted for the analogous $(\text{HO})\text{SO}_2^-$ (HO-bonded isomer of HSO_3^-) and SO_3^{2-} (Eldridge et al., 2016), i.e., $\beta\text{-HSO}_4^- > \beta\text{-SO}_4^{2-}$ vs. $\beta\text{-SO}_3^{2-} > \beta\text{-(HO)SO}_2^-$, but nevertheless are very similar in magnitude to each other. Ion-pairing of the sulfate dianion with Na^+ and

Mg²⁺ appears to have a similar and essentially negligible predicted effect on isotope partitioning of sulfur despite the observation that the Mg²⁺ appears to more strongly affect the bonding environment of the SO₄²⁻ dianion (Table 2). These results are consistent with the general expectation that aqueous speciation that does not directly affect the bonding environment of the element of interest (i.e., no changes in redox state and/or bonding-order of the sulfur atom) will not greatly affect isotope partitioning behavior.

3.3. β -values as a function of temperature: Proclivity for crossovers among reduced S compounds

The ³⁴ β values for all aqueous sulfur compounds computed herein are plotted as a function of inverse temperature (T^{-2}) in Fig. 5A-E where it can be readily observed that numerous crossovers are predicted among these compounds. For example: (1) the HS⁻ species is predicted to exhibit crossovers with S₂²⁻ (Fig. 5A) and FeS_(aq) (Fig. 5C) at ambient temperature (roughly 0-100°C) and numerous longer chain-length S_x²⁻ at higher temperatures (roughly 100-500°C; Fig. 5A), (2) the protonated polysulfide HS₂⁻ exhibits a crossover with higher order polysulfides (e.g., S₈²⁻) at ambient temperatures (roughly 0-100°C; Fig. 5A), (3) the FeSH⁺ species exhibits a crossover with S₈²⁻ and HS₃⁻ at ambient temperature, (4) crossovers are predicted among S_x⁻ ($x=2-3$) and HS⁻/H₂S (Fig. 5B), and (5) the more reduced sulfur atoms in the polythionates, *S_x(SO₃)₂²⁻, are predicted to exhibit crossovers with H₂S in rough proximity to 75°C (Fig. 5D). Many of the compounds that exhibit similar β -values at 25°C plotted in Fig. 4 are exhibiting crossovers at or near this temperature (the exception being S₂²⁻ and FeS_(aq) that exhibit similar magnitude β values at 25°C but do not crossover).

Crossovers in β or RPFR values among aqueous sulfur compounds that contain relatively reduced sulfur atoms arise because these compounds/atoms exhibit similar magnitude β /RPFR values but have different temperature dependencies. In particular, the temperature dependence of β or RPFR values associated with compounds having S-S and/or Fe-S bonds (i.e., contributions

from mostly lower magnitude stretching frequencies) result in more-linear relationships for β -values as a function of T^{-2} , whereas compounds having H-S bonds (i.e., contributions from high magnitude stretching vibrational frequencies) typically exhibit stronger curvature as a function of T^{-2} (Fig. 5A-D), and this difference in temperature dependence leads to crossover behavior. This also appears to be the explanation for the ‘intramolecular crossover’ that is predicted for the HS_3^- species (not shown).

3.4. Mass Dependence of RPFRs and β values

The exponents $^{33/34}\kappa$ and $^{36/34}\kappa$ that quantify the relationships of mass dependence among β factors are plotted as a function of temperature in Fig. 6A-B for all compounds computed in this study (for trithionate, similar values of $\ln(^{33}\text{RPFR})/\ln(^{34}\text{RPFR})$ and $\ln(^{36}\text{RPFR})/\ln(^{34}\text{RPFR})$ are plotted for the distinct sulfur sites). At the high temperature limit (i.e., as T^{-2} approaches ‘0’), we obtain mean values for all explicitly solvated sulfur compounds in this study of $^{33/34}\kappa = 0.51587 \pm 0.00006$ and $^{36/34}\kappa = 1.8904 \pm 0.0001$ (1 s.d.; Table 4), which are consistent with the expected values of 0.51588 and 1.8904 from the mass differences among the isotopic sulfur atoms (Matsuhisa et al., 1978). The values of $^{33/34}\kappa$ and $^{36/34}\kappa$ for the relatively reduced sulfur compounds/moieties examined in the present study (sulfide, S_x^{2-} , S_x^- , and $^*\text{S}_x(\text{SO}_3)_2^{2-}$) do not exhibit a strong temperature dependence compared to aqueous sulfur-oxygen anions containing sulfur in higher oxidation states that exhibit larger β/RPFR values (e.g., SO_2^{2-} , SO_3^{2-} , SO_4^{2-} ; Fig. 6A-B), which is similar to the observations made in our previous theoretical calculations (Eldridge et al., 2016). Values for $^{33/34}\kappa$ and $^{36/34}\kappa$ for the aqueous sulfate species exhibit the largest variations with temperature and are essentially indistinguishable from each other. Values of $\ln(^{33}\text{RPFR})/\ln(^{34}\text{RPFR})$ and $\ln(^{36}\text{RPFR})/\ln(^{34}\text{RPFR})$ as a function of temperature for the unique sulfur sites in the polythionates ($^*\text{S}_x(\text{SO}_3)_2^{2-}$ and $\text{S}_x(^*\text{SO}_3)_2^{2-}$) are predicted to be essentially identical to the analogous sulfur sites in thiosulfate: $^*\text{S}(\text{SO}_3)^{2-}$ and $\text{S}(^*\text{SO}_3)^{2-}$, respectively (Eldridge et al., 2016).

4. Discussion

4.1. Fractionation factors (α) between compounds

4.1.1. Aqueous sulfide compounds

Our prediction for the $\text{H}_2\text{S}/\text{HS}^-$ fractionation factor as a function of $1/T^2$ is shown in Fig. 7 alongside other direct and indirect experimental estimates and previous theoretical calculations. The predicted fractionation factor between aqueous H_2S and HS^- is $1000 \times \ln(^{34}\alpha) = 4.2 \pm 0.6 \text{ ‰}$ at 25°C (1 s.d.). Few direct experimental data exist for equilibrium fractionation factors among aqueous sulfide compounds (Fig. 7), and those that do exist correspond to ambient laboratory temperature conditions ($20\text{--}22^\circ\text{C}$). The most recent experimental determination (Sim et al., 2019) yields $1000 \times \ln(^{34}\alpha) = 3.1 \pm 0.2 \text{ ‰}$ at $20.6 \pm 0.5^\circ\text{C}$. This is within error of our earlier theoretical estimate at their experimental temperature utilizing singular 30 H_2O clusters (3.1 ‰; Eldridge et al., 2016) but slightly lower than our current estimate utilizing the mean values of multiple cluster conformations ($4.2 \pm 0.6 \text{ ‰}$, 1 s.d.). We note that our present theoretical estimate is still within error of Sim et al. (2019) at the 2 s.d. level, and is likely to better capture the error associated with the calculations due to the usage of multiple cluster sizes and conformations. Both studies (Eldridge et al., 2016; Sim et al., 2019) reviewed the earlier experiments in detail (Fry et al., 1986; Geßler & Gehlen, 1986) and highlight potential experimental issues. Despite potential issues with experimental design, the direct experimental determinations from Geßler & Gehlen (1986) appear to be within the estimated error of the theoretical calculations.

The indirect estimate of the $\text{H}_2\text{S}/\text{HS}^-$ fractionation factor that is based on the arithmetic analysis of experimentally estimated fractionation factors among $\text{ZnS}/\text{S}_{(g)}$, $\text{H}_2\text{S}/\text{S}_{(g)}$, and ZnS/HS^- from Ohmoto & Rye (1979) is generally lower than any other estimates (Fig. 7), and is within error of $1000 \times \ln(^{34}\alpha) = 0 \text{ ‰}$ (no fractionation) at the lowest temperature (50°C : $1.2 \pm 1.4 \text{ ‰}$, 1σ ; Ohmoto & Rye, 1979). The temperature dependence of our theoretical $1000 \times \ln(^{34}\alpha)$ value for $\text{H}_2\text{S}/\text{HS}^-$ exhibits pronounced curvature in $1/T^2$ space that is not reflected

in [Ohmoto & Rye \(1979\)](#). The estimates of [Ohmoto & Rye \(1979\)](#) might be affected by the propagation of uncertainties/errors from numerous experimental datasets and/or possible assertions made regarding the temperature dependence over the experimental temperature range (i.e., linear in $1000 \times \ln(^{34}\alpha)$ vs. $1/T^2$ space).

Previous theoretical estimates for the $\text{H}_2\text{S}/\text{HS}^-$ fractionation factor ([Sakai 1968](#); [Tossell, 2012](#); [Otake et al., 2008](#); [Eldridge et al., 2016](#)) exhibit variability that arises from the different approaches taken (Fig. [7](#)). Our recent calculations utilizing computations of single $\text{H}_2\text{S} \bullet 30\text{H}_2\text{O}$ and $\text{HS}^- \bullet 30\text{H}_2\text{O}$ clusters yield a comparable but slightly lower value of $1000 \times \ln(^{34}\alpha) = 3.3 \text{ ‰}$ at 25°C (not shown; [Eldridge et al., 2016](#)). Earlier calculations ([Otake et al., 2008](#); [Tossell, 2012](#)) suggest a larger fractionation factor of $1000 \times \ln(^{34}\alpha) = 6.2\text{-}6.6 \text{ ‰}$ at 25°C (Fig. [7](#)). In addition to differences in theoretical model and basis set, these two studies ([Otake et al., 2008](#); [Tossell, 2012](#)) utilized an implicit solvation model (IEF-PCM and/or PCM) that approximates the effect of solvation by encasing the solute in a cavity of specified dielectric constant that is solvent- and compositional-/condition-specific, and their implementation of these models for the H_2S and HS^- compounds yield very similar fractionation factors to those obtained from calculations in vacuum without any solvation model applied (e.g., $1000 \times \ln(^{34}\alpha) = 6.8 \text{ ‰}$ at 25°C from modeling these compounds in vacuum) ([Otake et al., 2008](#)). These values are comparable to vacuum calculations at the B3LYP/6-31+G(d,p) level of $1000 \times \ln(^{34}\alpha) = 6.8 \text{ ‰}$ at 25°C from our own calculations (not shown). In general, implicit solvation models such as IEF-PCM may be regarded as less effective in approximating the effects of solvation in the computation of RPFRs than the explicit or ‘supramolecular water cluster’ solvation models that can account for water-solute interactions in a more direct manner. The calculations of [Sakai \(1968\)](#) assumed the RPFR for $\text{H}_2\text{S}_{(aq)}$ can be approximated by the RPFR for $\text{H}_2\text{S}_{(g)}$ and were performed using older spectroscopic data, but nevertheless appear to yield similar magnitude fractionation factors to those of the present study and [Geßler & Gehlen \(1986\)](#) at ambient temperature but exhibit a slightly different temperature dependence.

Predictions for fractionation factors among discrete aqueous ferrous iron sulfide species and aqueous sulfide species are presented as a function of $1/T^2$ in Fig. 8. The predicted fractionation factor for $\text{FeS}_{(aq)}^0/\text{HS}^-$ is $1000 \times \ln(^{34}\alpha) = 0.1 \pm 0.6\text{‰}$ at 25°C , and its negligible magnitude is due to a crossover in proximity to this temperature (Fig. 8). The predicted fractionation factor for $\text{FeSH}^+/\text{H}_2\text{S}$ is $1000 \times \ln(^{34}\alpha) = -1.0 \pm 0.4\text{‰}$ at 25°C . The predicted equilibrium fractionation factor associated with $\text{FeSH}^+/\text{FeS}_{aq}$ is $1000 \times \ln(^{34}\alpha) = 3.0 \pm 0.4\text{‰}$ and is comparable to the somewhat analogous $\text{H}_2\text{S}/\text{HS}^-$ fractionation factor. To our knowledge, there are no other estimates of these fractionation factors in the literature for comparison.

Recent experimental studies (Syverson et al., 2013, 2015) revised the experimental value for the equilibrium fractionation factor between $\text{FeS}_{2(\text{pyrite})}/\text{H}_2\text{S}$ under hydrothermal conditions obtaining a value of $1000 \times \ln(^{34}\alpha) = -1.9 \pm 0.8\text{‰}$ (1 s.d.) at 350°C , which is in contrast in direction to previous estimates of ca. $1000 \times \ln(^{34}\alpha) = 1.0\text{‰}$ at 350°C that is from the assessment of Ohmoto & Rye (1979) based on earlier experimental data. The direction of the newly revised $\text{FeS}_{2(\text{pyrite})}/\text{H}_2\text{S}$ fractionation factor from Syverson et al. (2015) is consistent with the direction of our predicted fractionation factors between the discrete aqueous ferrous sulfide species (FeSH^+ , $\text{FeS}_{(aq)}$) and H_2S at comparable temperatures (Fig. 8). We additionally note that the direction of the predicted fractionation factor between $\text{FeS}_{(aq)}/\text{H}_2\text{S}$ at elevated temperature (e.g., $1000 \times \ln(^{34}\alpha) = -2.4 \pm 0.1\text{‰}$ at 350°C) is opposite from that of $\text{FeS}(\text{pyrrhotite})/\text{H}_2\text{S}$ (i.e., $1000 \times \ln(^{34}\alpha) = 0.3\text{‰}$ at 350°C) that is also compiled in Ohmoto & Rye (1979) that is based on earlier experimental data (Kajiwara & Krouse, 1971). Our estimates of homogeneous equilibrium isotope fractionations among modeled aqueous solutes are not directly comparable to the experimental heterogeneous equilibrium isotope fractionations between crystalline phases and aqueous solutes, and the factors that influence the magnitude and direction of isotope partitioning between crystalline and molecular ferrous iron sulfides are expected to be different due to differences in bonding environment. However, our computational results and the recent experimentation of Syverson et al. (2013, 2015)

may be potentially suggestive that equilibrium fractionation factors for certain ferrous sulfide solutes/phases relative to H_2S may exhibit different directions and/or exhibit a different temperature dependence than previously understood (i.e., [Ohmoto & Rye, 1979](#)). Further experimental work is clearly needed for a more complete assessment.

4.1.2. Aqueous Sulfide and Polysulfide Compounds

The equilibrium isotopic compositions of the polysulfides (S_x^{2-} and HS_x^-) are predicted to be within the range of the equilibrium isotopic compositions of H_2S and HS^- at 25°C (Fig. [4](#)), and therefore fractionations among aqueous sulfide and polysulfides are expected to be relatively small. The fractionation factors between $\text{S}_x^{2-}/\text{HS}^-$ are predicted to generally increase with increasing ‘ x ’ from $1000 \times \ln(^{34}\alpha) = -0.1 \pm 0.7\text{‰}$ for $\text{S}_2^{2-}/\text{HS}^-$ to $1000 \times \ln(^{34}\alpha) = 2.9 \pm 0.5\text{‰}$ for $\text{S}_8^{2-}/\text{HS}^-$ (1 s.d.). The negligible fractionation factor between $\text{S}_2^{2-}/\text{HS}^-$ at 25°C is due to a predicted crossover in proximity to this temperature, which is illustrated in Fig. [9](#). The fractionation factors between $\text{HS}_x^-/\text{HS}^-$ are predicted to be $1000 \times \ln(^{34}\alpha) = 2.9 \pm 0.5\text{‰}$ for $\text{HS}_2^-/\text{HS}^-$ and $1000 \times \ln(^{34}\alpha) = 3.5 \pm 0.6\text{‰}$ for $\text{HS}_3^-/\text{HS}^-$ (25°C , 1 s.d.). The predicted fractionation factors between $\text{S}_x^{2-}/\text{H}_2\text{S}$ are in the opposite direction relative to $\text{S}_x^{2-}/\text{HS}^-$. Thus, they exhibit an opposing trend with respect to magnitude and ‘ x ’ relative to $\text{S}_x^{2-}/\text{HS}^-$ and yield fractionation factors that range between $1000 \times \ln(^{34}\alpha) = -4.3 \pm 0.5\text{‰}$ for $\text{S}_2^{2-}/\text{H}_2\text{S}$ and $1000 \times \ln(^{34}\alpha) = -1.2 \pm 0.3\text{‰}$ for $\text{S}_8^{2-}/\text{H}_2\text{S}$ at 25°C (i.e., the magnitude of the fractionation factor decreases with increasing ‘ x ’).

The temperature dependence of fractionation factors among aqueous sulfide and polysulfide compounds exhibit interesting behavior due to the predicted proclivity for crossovers among these compounds (Fig. [9](#)). In the current dataset, crossovers in fractionation factors corresponding to a specific isotope ratio occur at specific temperatures (the crossover temperature, T_c) and lead to apparent inverse temperature dependence above the T_c whereby the fractionation factor increases in magnitude with increasing temperature until a relative maximum in magnitude is reached. At temperatures above the relative maximum, the

fractionation factor decreases in magnitude with increasing temperature until approaching nil fractionation (i.e., $\alpha = 1$, or 0 ‰) at the high-temperature limit. Fractionation factors computed among aqueous sulfur compounds that exhibit crossovers over the temperature ranges studied ($T \geq 0^\circ\text{C}$) or that appear to exhibit crossovers below 0°C have the characteristics of this type of temperature dependence. This type of temperature dependence associated with a crossover appears to have been previously described (e.g., Stern et al., 1968). Examples of these types of crossovers among aqueous sulfide/polysulfide compounds include $\text{S}_x^{2-}/\text{HS}^-$ ($x = 2-8$, where T_c may increase with ‘ x ’; Fig. 9) and $\text{FeS}_{(aq)}/\text{HS}^-$ (Fig. 8). Examples of fractionation factors that appear to exhibit crossovers below 0°C include $\text{FeSH}^+/\text{H}_2\text{S}$ (Fig. 8) and $\text{S}_x^{2-}/\text{H}_2\text{S}$ ($x = 3-8$) (Fig. 9). Fractionation factors that appear to exhibit crossovers below 0°C appear to generally have larger magnitude relative maximum fractionation factors at $T > T_c$ (e.g., 2-3 ‰ for $\text{S}_x^{2-}/\text{H}_2\text{S}$ $x = 3-8$) than those exhibiting crossovers $\geq 0^\circ\text{C}$ (e.g., ca. < 1 ‰ for $\text{S}_x^{2-}/\text{HS}^-$ $x = 2-8$, and $\text{FeS}_{aq}/\text{HS}^-$).

Fig. 10A contains calculations of the experimentally constrained distribution (in terms of concentration, μM) of aqueous polysulfide and sulfide compounds in a model S^0 -saturated aqueous solution (pure water, total aqueous sulfide concentration = $100\mu\text{M}$; Kamyshny et al., 2004, 2007). Fig. 10A reveals that the major polysulfide species under these conditions are HS_2^- and S_x^{2-} ($x = 3-8$), and the bulk of the aqueous sulfur mass balance can be accounted for by considering only these species and the major aqueous sulfide compounds (H_2S and HS^-). In terms of molecular concentration, HS_2^- dominates polysulfide speciation at lower pH (ca. 6-8.5) and S_x^{2-} dominate polysulfide speciation above a pH of about 8.5 and follow a relative distribution of $\text{S}_5^{2-} > \text{S}_4^{2-} > \text{S}_6^{2-} > \text{S}_3^{2-} > \text{S}_7^{2-} > \text{S}_8^{2-} > \text{S}_2^{2-}$. We note that even though the polysulfides stay below $10\mu\text{M}$ under these model conditions (where total dissolved sulfur = $100\mu\text{M}$) they dominate sulfur mass balance under high pH conditions (pH $\geq \approx 9.5$) because of their high sulfur content per molecule. For example, at pH = 11 the sulfur compound in highest concentration, pentasulfide (S_5^{2-}), has a molecular concentration of only $7.8\mu\text{M}$ under these modeled conditions but

779 comprises nearly 40% of the total dissolved sulfur content.

780 In Fig. 10B we combine the relative distributions of the polysulfides as com-
 781 puted in Fig. 10A with our theoretical calculations to compute a bulk aqueous
 782 polysulfide/sulfide isotope fractionation factor as a function of pH. In terms of
 783 bulk fractionation factors, the isotopic compositions of total polysulfides relative
 784 to aqueous sulfide species are predicted to be relatively constant above a pH of
 785 about 8 (i.e., $1000 \times \ln(^{34}\alpha) = 2.2 \pm 0.5\text{‰}$ at 25°C). This is due largely to the
 786 similarity in the predicted equilibrium isotopic compositions of the dominant
 787 polysulfides (i.e., $x = 4-6$; cf. Fig. 4) and their constant relative distribution
 788 under these conditions, and the constancy of aqueous sulfide speciation under
 789 these conditions (i.e., principally HS^- above a $\text{pH} \approx 8-8.5$). The predicted rever-
 790 sal in the direction of the bulk polysulfide/sulfide fractionation factor around
 791 $\text{pH} = 6.5-7$ in Fig. 10B is due principally to the shift in the dominant sulfide
 792 species (HS^- vs. H_2S ; pK_d is 6.98 at 25°C and low ionic strength; Hershey et al.,
 793 1988) and the relative direction of fractionation factors between the polysulfides
 794 and the two principle sulfide species (cf. Fig. 4). The speciation of polysulfides
 795 varies as a function of temperature and ionic strength, but the general relation-
 796 ships that we illustrate in Fig. 10B are predicted to change only subtly as a
 797 function of ionic strength (up to $\mu = 0.7$ mol/kg at 25°C) and temperature over
 798 5-75°C. Thus, despite their complex speciation in aqueous solution the polysul-
 799 fides are predicted to closely track the isotopic composition of aqueous sulfide
 800 at equilibrium under fairly wide ranges of environmental conditions.

801 Amrani et al. (2006) is the only experimental study that we are aware of
 802 that reports the isotopic composition of polysulfide compounds of specific chain
 803 length isolated from aqueous solutions. They report the isotopic compositions
 804 (in terms of $\delta^{34}\text{S}$) of the methylated derivatives of polysulfides (i.e., $\text{H}_3\text{C-S}_x\text{-}$
 805 CH_3) of chain length $x = 4-7$ that were generated by the rapid derivatization
 806 reaction of methyl triflate and precursor aqueous polysulfides. They observed
 807 that the isotopic compositions of polysulfides in terms of $\delta^{34}\text{S}$ increase with
 808 increasing chain length ' x '. The increase in $\delta^{34}\text{S}$ with increasing ' x ' is consis-
 809 tent with our theoretical calculations that predict a general increasing trend in

the compound specific fractionation factors (β) with increasing ' x ' (Fig. 4). If we make the assumption that the isotopic composition of the sulfur extracted from the methylated polysulfanes represents the equilibrium isotopic compositions of the precursor aqueous polysulfides, then the data of Amrani et al. (2006) imply an equilibrium fractionation factor between S_7^{2-}/S_4^{2-} on the order of $1000 \times \ln(^{34}\alpha) = 3.2 \pm 0.7 \text{ ‰}$ at 25°C (1 s.d. from the duplicate experiments reported, based on data digitally extracted from their figures). This estimate based on experimental data is larger than the estimate based on our theoretical calculations of $1000 \times \ln(^{34}\alpha) = 0.7 \pm 0.2 \text{ ‰}$ for S_7^{2-}/S_4^{2-} at 25°C. This slight disagreement may suggest that uncertainty remains in the exact values of the fractionation factors among polysulfides of differing chain-length.

Despite the possible uncertainties in the exact values of fractionation factors among the polysulfides of different chain-length, the calculations provide detailed insight into the isotope partitioning behavior of polysulfides. The calculations newly reveal the relative patterns in values of RPFRs for singly substituted polysulfides at different atomic sites (Table 3, Fig. 4) and thus provide a more detailed explanation for earlier experimental observations (Amrani et al., 2006). The calculations illustrate that the general increase in $^{34}\beta$ with increasing ' x ' for S_x^{2-} can be described to arise from the proportionality between the $^{34}\beta$ -factor and the number of $^{34}\text{RPFR}$ -contributing isotopologues that increases with ' x ' (Section 3.2.1). The $^{34}\text{RPFR}$ values that correspond to isotope substitution of the outer sulfur atoms (exhibiting the lowest RPFR values of each polysulfide isotopologue) have comparable values for all polysulfides (e.g., mean $^{34}\text{RPFR} = 1.0090 \pm 0.0003$ for S_x^{2-} at 25°C, $x = 2-8$), and similarly the $^{34}\text{RPFR}$ values that correspond to isotope substitution of the interior sulfur atom that is immediately bonded to the outer sulfur atom (exhibiting the highest RPFR values of polysulfide isotopologues) have comparable $^{34}\text{RPFR}$ values for all pertinent polysulfides (e.g., mean $^{34}\text{RPFR} = 1.0132 \pm 0.0005$ for S_x^{2-} at 25°C, $x = 3-8$). Thus, the calculations predict some uniformity in the isotope partitioning behavior among comparable isotopologues of polysulfides irrespective of chain length. At 25°C, it is interesting to note that these values are predicted to be

indistinguishable from the $^{34}\text{RPFR}$ values of HS^- ($^{34}\text{RPFR} = 1.0087 \pm 0.0005$ at 25°C) and H_2S ($^{34}\text{RPFR} = 1.0129 \pm 0.0003$ at 25°C), respectively, which is actually the result of predicted crossovers in values of RPFR s among the sulfide compounds and these particular isotopologues of polysulfides at approximate ambient temperature. Thus, the calculations reveal many underlying details and complexities of the isotope partitioning behavior of the polysulfides relative to aqueous sulfide compounds that may not be expressed at the bulk level (e.g., Fig. 10).

One of two primary mechanisms that have been identified for pyrite precipitation from precursor aqueous sulfur compounds involves the polysulfides ('polysulfide mechanism'; e.g., Luther, 1991; Butler et al., 2004; Rickard & Luther, 2007). In the 'polysulfide mechanism', it has been proposed that pyrite precipitation proceeds *via* the nucleophilic bimolecular reaction between a polysulfide and a ferrous sulfide complex (either the discrete molecular species in solution as we have computed in the present study, or nano-particulate $\text{FeS}_{(aq)}$ phases), whereby the two sulfur atoms that eventually become the disulfide in pyrite (Tossell, 1983) are derived entirely from polysulfide (Luther, 1991). Using pentasulfide (S_5^{2-}) and the FeSH^+ species as the example reactants, this mechanism can be schematically represented as (*cf.* Luther, 1991; Chadwell et al., 1999):

The dashed red curves indicate where bonds are to be broken and the straight arrows indicate where new bonds are to be formed based on this type of mechanism (note that the positions of the charges are not deliberate and merely represent overall molecular charge). The overall reaction corresponding to this schematic mechanism is given by:

This type of mechanism suggests that the two sulfur atoms in polysulfide that are expected to have the highest and lowest RPFR values under equilibrium conditions (*cf.* Fig. 4) are those that are incorporated into pyrite, which our calculations predict have nearly uniform RPFR values for polysulfides irrespective of polysulfide chain-length (Fig. 4). Although the kinetic isotope effects that may be associated with pyrite precipitation/nucleation are unknown, this mechanism alongside our calculations may indicate that any apparent isotope fractionations that accompany the formation of pyrite from precursor compounds *via* a ‘polysulfide mechanism’ (e.g., apparent fractionations relative to ambient aqueous sulfide) are likely to be relatively small and potentially relatively uniform with respect to the specific polysulfides that may be involved.

We note that the mechanism expressed in Eq. 16-17 is only one simple example of many potential reactions that an aqueous ferrous iron species can undergo with polysulfide to form an initial nucleation of pyrite. The specific form of the ‘polysulfide mechanism’ that may occur or dominate in any given environment will likely depend on the activities of the various ferrous iron and polysulfide species and therefore solution conditions. It may also be noted that a heterogenous reaction involving aqueous polysulfide and a ‘solid’ FeS phase is possible and has been proposed to follow an analogous mechanism (e.g., Luther, 1991).

4.1.3. Aqueous Sulfide and Polysulfur Radical Compounds

Fractionation factors among polysulfur radicals ($S_x^{\cdot-}$, $x = 2-3$) and H_2S/HS^- are presented in Fig. 11 as a function of $1/T^2$. Fractionation factors among $S_2^{\cdot-}/HS^-$ and $S_3^{\cdot-}/HS^-$ are predicted to exhibit crossovers at elevated temperature around $175 \pm 70^\circ\text{C}$ and $455 \pm 125^\circ\text{C}$, respectively, which lead to very small fractionation factors at high-temperature (i.e., $1000 \times \ln(^{34}\alpha) \leq 0.7\text{‰}$ at $T \geq 200^\circ\text{C}$). Fractionation factors among $S_2^{\cdot-}/H_2S$ and $S_3^{\cdot-}/H_2S$ each appear to ex-

hibit a temperature dependence that is characteristic of a crossover occurring below 0°C. The type of temperature dependence associated with crossovers (or apparent crossovers) for these fractionation factors is the same as that described above for aqueous polysulfide/sulfide. Recent *in situ* Raman spectroscopic investigations of sulfur-rich aqueous fluids contained in fused silica capillaries and hydrothermal diamond anvil cells have documented that the S_3^- (and possibly S_2^-) exists as a nominally stable component in equilibrium with aqueous sulfide and sulfate compounds in appreciable amounts at least over the temperature range of ca. 200-500°C under particular pH and redox conditions (Pokrovski & Dubrovinsky, 2011; Pokrovski & Dubessy, 2015; Schmidt & Seward, 2017). Over this temperature range, the fractionation factor between S_3^-/H_2S is predicted to range between $1000 \times \ln(^{34}\alpha) = -1.9 \pm 0.2 \text{ ‰}$ at 200°C (near its predicted relative maximum in magnitude) to $-1.3 \pm 0.1 \text{ ‰}$ at 500°C. The fractionation factor between S_2^-/H_2S is predicted to be slightly larger in magnitude and for comparison ranges between $1000 \times \ln(^{34}\alpha) = -2.6 \pm 0.2 \text{ ‰}$ at 200°C to $-1.6 \pm 0.1 \text{ ‰}$ at 500°C. The polysulfur radicals may thus lead to subtle shifts in the sulfur isotope composition of aqueous sulfide (and sulfate) species depending on mass balance under conditions where they coexist in isotopic equilibrium. For reference, the magnitude and direction of the equilibrium fractionations that are predicted between the polysulfur radicals and H_2S at these elevated temperatures are comparable to those between pyrite and aqueous H_2S at 350°C obtained from Syverson et al. (2015) (Fig. 8).

4.1.4. Aqueous Sulfide and Sulfate Compounds

Fractionation factors among aqueous sulfate and select sulfide compounds are presented in Fig. 12 as a function of $1/T^2$ encompassing the temperature range of 200-400°C where experimental constraints presently exist for comparison. From 200 to 400°C, the predicted SO_4^{2-}/H_2S fractionation factor ranges between $1000 \times \ln(^{34}\alpha) = 28.3 \pm 0.2 \text{ ‰}$ and $14.5 \pm 0.1 \text{ ‰}$, respectively, and is essentially identical to our previous estimates utilizing $30H_2O$ clusters (El-dridge et al., 2016). The computed fractionation factor between HSO_4^- and

H₂S is similar in magnitude but is predicted to be slightly larger and ranges from $1000 \times \ln(^{34}\alpha) = 29.0 \pm 0.2 \text{ ‰}$ to $15.0 \pm 0.1 \text{ ‰}$ over 200 to 400°C, respectively. The fractionation factors between the two computed sulfate ion pairs, (Na⁺SO₄²⁻)⁻ and (Mg²⁺SO₄²⁻)⁰, and H₂S are indistinguishable from one another over all temperature values and have intermediary values between the SO₄²⁻/H₂S and HSO₄⁻/H₂S. Thus, the predicted fractionation factors between all computed sulfate species and H₂S are all very similar. Also shown in Fig. 12 is the fractionation factor between HSO₄⁻/S₃⁻ that ranges between $30.8 \pm 0.1 \text{ ‰}$ and 16.5 ± 0.1 from 200 to 400°C, respectively (i.e., slightly larger than fractionations among aqueous sulfate/sulfide species).

Previous experimental determinations of equilibrium sulfur isotope fractionations between aqueous sulfate and sulfide species are in agreement with our theoretical predictions at the level of $\leq 1 \text{ ‰}$ (Fig. 12). The compilation of Ohmoto & Lasaga (1982) that incorporates numerous experimental datasets over 200-400°C yields fractionation factors between aqueous sulfate and sulfide of $1000 \times \ln(^{34}\alpha) = 29.4 \pm 0.5 \text{ ‰}$ at 200°C and $14.8 \pm 0.5 \text{ ‰}$ at 400°C based on their $1000 \times \ln(^{34}\alpha)$ vs. $1/T^2$ linear fit to selected experimental data. The largest difference between Ohmoto & Lasaga (1982) and the SO₄²⁻/H₂S calculations presented here and in our previous study (Eldridge et al., 2016) is $\approx 1 \text{ ‰}$ at 200°C (Fig. 12). Under the experimental conditions of most experiments that are included in the compilation of Ohmoto & Lasaga (1982) the aqueous speciation of sulfate may largely be in the form of HSO₄⁻ due to the low *in situ* pH of experimental fluids that is necessary to facilitate feasible equilibration times due to higher rates of isotope exchange under acidic conditions. The computed HSO₄⁻/H₂S fractionation factor in Fig. 12 is in agreement with the experimental compilation of Ohmoto & Lasaga (1982) at the level of $\leq 0.46 \text{ ‰}$ over 200-400°C (see residual plot in Fig. 12), which is within the error reported by Ohmoto & Lasaga (1982). The slight divergence between our HSO₄⁻/H₂S estimate and Ohmoto & Lasaga (1982) at 200°C ($\leq 0.5 \text{ ‰}$) could reflect a true difference in the temperature dependence (e.g., arising from inadequacies in the theoretical calculations), or could reflect (a) the paucity of experimental

data at 200°C (e.g., 1 data point taken from Robinson (1973) corresponding to $1000 \times \ln(^{34}\alpha_{\text{HSO}_4^-/\text{H}_2\text{S}}) = 28.9 \text{ ‰}$) and/or (b) the assumption of Ohmoto & Lasaga (1982) that the temperature dependence of the fractionation factor is linear over 200-400°C in $1000 \times \ln(^{34}\alpha)$ vs. $1/T^2$ space (cf. the theoretical calculations that all exhibit subtle curvature in this space over 200-400°C; Fig. 12). Syverson et al. (2015) recently obtained a fractionation factor between aqueous sulfate/sulfide of $1000 \times \ln(^{34}\alpha) = 17.5 \pm 0.6 \text{ ‰}$ at 350°C (1 s.d., duplicate equilibrated experiments) judged to be at equilibrium based on constraints from complimentary $\Delta^{33}\text{S}$ measurements. The experiments of Syverson et al. (2015) were also performed under low pH conditions where HSO_4^- likely dominates the aqueous sulfate speciation. Their value is indistinguishable from our computed estimate of the $\text{HSO}_4^-/\text{H}_2\text{S}$ fractionation factor at 350°C of $1000 \times \ln(^{34}\alpha) = 17.3 \pm 0.1 \text{ ‰}$ (Fig. 12). Overall, the theoretical calculations presented here appear to reproduce established experimental observations of the aqueous sulfate/sulfide fractionation factor within the estimated errors of the approaches.

At 25°C, equilibrium fractionations between select aqueous sulfate and sulfide compounds are predicted to be $1000 \times \ln(^{34}\alpha) = 63.3 \pm 0.4 \text{ ‰}$ for $\text{SO}_4^{2-}/\text{H}_2\text{S}$, $64.1 \pm 0.4 \text{ ‰}$ for $\text{HSO}_4^-/\text{H}_2\text{S}$, and $67.5 \pm 0.6 \text{ ‰}$ for $\text{SO}_4^{2-}/\text{HS}^-$. It is notable that our theoretical calculation of the $1000 \times \ln(^{34}\alpha)$ corresponding to the $\text{SO}_4^{2-}/\text{H}_2\text{S}$ fractionation factor presented here and in Eldridge et al. (2016) is lower than previous theoretical estimates at 25°C by as much as $\approx 9 \text{ ‰}$ (e.g., those of Farquhar et al., 2003; Ono et al., 2007). We further note that these previous theoretical estimates (Farquhar et al., 2003; Ono et al., 2007) are systematically higher than our theoretical calculations at higher temperatures as well (e.g., by $\geq 2 \text{ ‰}$ over 200-400°C) and, thus, do not agree as well with experimental constraints. It is our judgement that the estimates of the aqueous sulfate/sulfide fractionation factors at lower temperatures derived from our calculations (i.e., the current study and Eldridge et al., 2016) are likely to be among the best estimates available to date for low temperature applications (e.g., in models of microbial metabolism such as dissimilatory sulfate reduction) due to the apparent agreement with established experimental constraints at higher

temperatures (Fig. 12). However, we emphasize that no experimental data exist to our knowledge that directly constrain the aqueous sulfate/sulfide equilibrium fractionation factor at temperatures $< 200^\circ\text{C}$ and thus the verification of any theoretical estimates at lower temperatures (either previously published or presented here) is not possible at this time.

From the analysis above, it can be inferred that the predicted equilibrium sulfur isotope fractionation among coexisting aqueous sulfate species is small in magnitude. For example, at 25°C the estimated fractionation factor between the direct magnesium sulfate ion pair $(\text{Mg}^{2+}\text{SO}_4^{2-})^0$ and SO_4^{2-} is $1000 \times \ln(^{34}\alpha) = 0.25 \pm 0.18 \text{ ‰}$ (similar for the direct sodium ion pair), and for HSO_4^- and SO_4^{2-} we estimate a value of $1000 \times \ln(^{34}\alpha) = 0.75 \pm 0.22 \text{ ‰}$. Thus, sulfate speciation in natural waters such as those of high ionic strength (e.g., seawater and naturally occurring brines) that could involve substantial formation of ion-pairs, and those containing high acidity (e.g., natural acid lakes or drainage) appears unlikely to have a significant effect on sulfur isotope partitioning.

4.1.5. Polythionates

Pertinent fractionation factors involving the unique atomic sites in the polythionates computed in this study ($\text{S}_3\text{O}_6^{2-}$ and $\text{S}_4\text{O}_6^{2-}$, or $\text{S}_x(\text{SO}_3)_2^{2-}$ where $x = 1$ or 2) are plotted in Fig. 13 as a function of $1/T^2$ alongside analogous fractionation factors involving thiosulfate ($\text{S}_2\text{O}_3^{2-}$ or $\text{S}(\text{SO}_3)^{2-}$) from Eldridge et al. (2016) for reference. The ‘intramolecular’ fractionation factor for polythionate that represents the difference in equilibrium isotopic composition between the unique sulfur sites within the molecule (i.e., the equivalent ‘sulfonate’ groups, $\text{S}_x(^*\text{SO}_3)_2^{2-}$, and the central ‘sulfanyl’ atoms, $^*\text{S}_x(\text{SO}_3)_2^{2-}$) is predicted to be $1000 \times \ln(^{34}\alpha) = 54.4 \pm 0.8 \text{ ‰}$ at 25°C . This is comparable to our earlier predictions of the ‘intramolecular’ fractionation factor for thiosulfate: $1000 \times \ln(^{34}\alpha) \approx 53.8 \text{ ‰}$ at 25°C (Eldridge et al., 2016). The predicted fractionation factor between the ‘sulfonate’ groups in trithionate and $\text{H}_2\text{S}_{(aq)}$ is predicted to be $1000 \times \ln(^{34}\alpha) = 55.8 \pm 0.6 \text{ ‰}$ at 25°C . This is also comparable to the analogous values for thiosulfate but perhaps slightly larger in magnitude: $1000 \times \ln(^{34}\alpha)$

1014 $= 52.5 \pm 0.3 \text{ ‰}$ at 25°C (Eldridge et al., 2016). The fractionation factors for
 1015 the ‘sulfanyl’ sulfur atoms in trithionate and thiosulfate relative to H_2S are
 1016 much smaller in magnitude and exhibit complex behavior as a function of tem-
 1017 perature due to crossovers. For example, at 25°C the fractionation factors for
 1018 the ‘sulfanyl’ sulfur atoms in the computed polythionates and thiosulfate rela-
 1019 tive to H_2S are predicted to be similar in magnitude but opposite in direction:
 1020 $1000 \times \ln(^{34}\alpha) = 1.4 \pm 0.7 \text{ ‰}$ for ‘sulfanyl’ in polythionate relative H_2S , and
 1021 $1000 \times \ln(^{34}\alpha) = -1.3 \pm 0.3 \text{ ‰}$ for ‘sulfanyl’ in thiosulfate relative to H_2S . How-
 1022 ever, above approximately 75°C the fractionation factors between the ‘sulfanyl’
 1023 groups in both trithionate and thiosulfate are both predicted to be in the same
 1024 direction relative to H_2S (Fig. 13) and agree with the direction of the experi-
 1025 mental constraints for thiosulfate (Uyama et al., 1985; Chu et al., 2004).

1026 4.1.6. Elemental Sulfur and Sulfate/Sulfide

1027 Data from hydrothermal experiments have been used previously to estimate
 1028 an equilibrium fractionation factor between elemental sulfur (generically S^0)
 1029 and aqueous sulfide and sulfate (Robinson, 1973; Kusakabe et al., 2000). These
 1030 data are plotted in Fig. 14 alongside our corresponding theoretical estimates.
 1031 The combined experimental data of Robinson (1973) and Kusakabe et al. (2000)
 1032 yield an estimate of the fractionation factor between S^0 and sulfate (HSO_4^-) of
 1033 $1000 \times \ln(^{34}\alpha) = 30.2 \text{ to } 19.3 \text{ ‰}$ (± 0.29 , 1 s.d.) over a temperature range of
 1034 200-230°C that is comparable to our theoretical calculations (Fig. 14A). The
 1035 data of Robinson (1973) can be used to estimate a fractionation factor between
 1036 S^0 and H_2S that yields values that range between $1000 \times \ln(^{34}\alpha_{\text{S}^0/\text{H}_2\text{S}}) = -1.2$
 1037 and $-2.3 (\pm 0.28) \text{ ‰}$ over 200-320°C that are essentially temperature-invariant
 1038 (mean over 200-320°C: $1000 \times \ln(^{34}\alpha_{\text{S}^0/\text{H}_2\text{S}}) = -1.7 \pm 0.4 \text{ ‰}$, 1 s.d.). Over
 1039 this same temperature range, our theoretical calculations predict an essentially
 1040 temperature-invariant fractionation factor of about $1000 \times \ln(^{34}\alpha_{\text{S}_{8(aq)}/\text{H}_2\text{S}}) =$
 1041 $-1.6 \pm 0.1 \text{ ‰}$ that corresponds to the maximum predicted magnitude of this
 1042 fractionation factor ($T \geq 0^\circ\text{C}$) that arises over this temperature range due to
 1043 crossover behavior at lower temperature (Fig. 14B). In short, our theoretical

calculations appear to capture the broad behavior of isotope partitioning exhibited experimentally in the $\text{S}^0\text{-H}_2\text{S-HSO}_4^-$ system.

4.2. Mass Dependence of Equilibrium Isotope Exchange at Crossovers

The crossovers in equilibrium fractionation factors among aqueous sulfide, polysulfur radical, and polysulfide compounds result in unusual exponents of mass-dependence ($^{33/34}\theta$, $^{36/34}\theta$) in proximity to the crossover temperatures. These effects have been previously described for theoretical isotopic exchange between exemplary gaseous sulfur molecules (Deines, 2003; Otake et al., 2008). Using the $\text{S}_{2(g)}/\text{H}_2\text{S}_{(g)}$ example, Deines (2003) recognized that exponents describing mass dependence (e.g., $^{33/34}\theta$) asymptotically approach values from $+\infty$ to $-\infty$ near temperature values that approach the crossover. In Fig. 15, we illustrate the effect of crossovers on values of $^{33/34}\theta$ and $\Delta^{33}\text{S}$ for numerous equilibrium isotope exchange reactions that have been theoretically computed in our study among aqueous sulfur compounds. The calculations of the $^{33/34}\theta$ reveal the expected asymptotic behavior in proximity to the T_c (Fig. 15A-C). Below the T_c , values for $^{33/34}\theta$ typically approach values of $-\infty$ with increasing temperature (Fig. 15A-C). Above the T_c , $^{33/34}\theta$ drop precipitously from $+\infty$ with increasing T until eventually approaching ≈ 0.5156 at the high-temperature limit. Despite these infinitely large shifts in values of $^{33/34}\theta$ at crossovers, these unusual exponents do not result in any notable deviations in values of $\Delta^{33}\text{S}$ arising from equilibrium isotope exchange as shown in the accompanying Fig. 15D-F that is due principally to the very small values of fractionation factors (α) in proximity to the T_c . We note that analogous relationships and conclusions can be drawn for computations of $^{36/34}\theta$ and $\Delta^{36}\text{S}$ values that are not illustrated here for reasons of economy.

Deines (2003) suggested that the unusual exponents of mass dependence in proximity to crossover temperatures for isotope exchange reactions could be amplified by subsequent Rayleigh processes to potentially generate compounds that have isotopic compositions exhibiting anomalous $^{33/34}\theta$ and/or $\Delta^{33}\text{S}$ values. This hypothesis can be examined in further detail using our theoretical frac-

tionation factors computed near crossovers. We perform an exercise where we compute the isotopic composition of a product that is generated via a Rayleigh process in a closed system that involves a reactant that has an isotopic composition that corresponds to a crossover. For the purposes of this example, we use S_2^{2-} as the reactant and consider its composition relative to HS^- where a crossover is predicted in rough proximity to ambient temperature ($\approx 16^\circ\text{C}$; *cf.* Fig. 9). The product of their reaction could hypothetically be anything that could irreversibly react with S_2^{2-} , but we point out that this example could be made relevant to a simplified polysulfide pyrite precipitation mechanism (e.g., Rickard & Luther, 2007):

According to the hypothesis implied by Deines (2003), in this example the isotopic composition of the product (i.e., pyrite) may obtain an anomalous isotopic composition (e.g., $\Delta^{33}\text{S} \neq 0$) relative to ambient HS^- if precipitation occurs via S_2^{2-} in proximity to the T_c .

We have run through a handful of scenarios where we compute the product of a closed-system Rayleigh process (e.g., in this example ‘pyrite’) involving S_2^{2-} where its initial composition is constrained as being in equilibrium with HS^- at 16°C (the approximate T_c), which corresponds to a composition of $\delta^{33}\text{S} = 0.0 \pm 0.4 \text{ ‰}$, $\delta^{34}\text{S} = 0.0 \pm 0.7 \text{ ‰}$, and $^{33}/^{34}\theta = 1.936$ (i.e., extremely anomalous relative to the reference exponent of 0.515) where all compositions are referenced to HS^- (e.g., $\delta^{34}\text{S} = ^{34}\text{R}/^{34}\text{R}_{HS^-} - 1$, where $^{34}\text{R} = ^{34}\text{S}/^{32}\text{S}$). We compute Rayleigh distillation scenarios in terms of the isotopic composition of the accumulated product relative to HS^- utilizing different assumptions of the value of the isotope effect associated with the unidirectional process (e.g., the isotope effect associated with FeS_2 precipitation in this simplified example). We assume for the purposes of the calculation that the isotope fractionations accompanying the Rayleigh process (e.g., unidirectional precipitation) are $\leq 20 \text{ ‰}$ (where 20 ‰ could be considered unrealistically large for this type of process) and ad-

ditionally assume that the process conforms to the conventions of a ‘normal’ isotope effect (i.e., products isotopically depleted relative to reactants). We additionally assume that the isotope effects associated with the unidirectional process conform to the reference exponent (i.e., 0.515), which is necessary in order to examine the effect of the initial crossover composition on the composition of the pooled product.

Our calculations reveal that the unusual exponents associated with crossovers do not lead to substantial $\Delta^{33}\text{S}$ effects in terms of the isotopic composition of a product resulting from a closed-system Rayleigh process. The maximum deviations occur for the largest assumed isotope effect for the Rayleigh process (-20 ‰) and approach a maximum of $\Delta^{33}\text{S} = 0.02$ ‰ (note that typical quoted external precision of $\Delta^{33}\text{S}$ based on SF_6 -IRMS is on the order of 0.01 ‰, 1 s.d.). We note that nearly identical results are obtained in this computation regardless of the assumed initial $^{33/34}\theta$ of the reactant (in this case S_2^{2-}). This suggests that the choice of initial composition in proximity to the crossover is not important and that any amplification of unusual exponents associated with crossovers via a closed-system Rayleigh process is likely insignificant. The evolution of the $\Delta^{33}\text{S}$ of the residual reactant over the full extent of the Rayleigh process is also not sensitive to values of $^{33/34}\theta$. In general, Rayleigh processes can lead to significant $\Delta^{33}\text{S}$ effects in the residual reactant but only when very small amounts of residual reactant remain (note: this will be illustrated in the following section in the context of modeled disproportionation reactions). These effects occur irrespective of crossovers and/or the initial isotopic compositions of reactants. Thus, it is difficult to imagine how crossovers may lead to any notable anomalous sulfur isotopic compositions among naturally occurring phases/compounds either as a result of equilibrium (Fig. 15) or subsequent Rayleigh distillation.

The more interesting aspect of crossover behavior in sulfur isotope systematics from our perspective is how crossovers lead to non-intuitive temperature dependencies of fractionation factors (cf. Fig. 8, 9, 11, 13, 14). Depending on the temperature at which they occur, crossovers can enable small but still relatively significant equilibrium isotope fractionations among compounds with respect to

a singular isotope ratio at relatively high temperature, despite instances where fractionation factors exhibit generally small to negligible fractionation factors at low temperature (e.g., for S_3^-/H_2S , $1000 \times \ln(^{34}\alpha) = -0.4 \pm 0.5 \text{ ‰}$ at 0°C but $-1.9 \pm 0.2 \text{ ‰}$ at 200°C ; Fig. 11).

4.3. Example Applications: Model Disproportionation Reactions

4.3.1. General Framework & First-Order Implementation Using Theoretical Equilibrium Isotope Effects

Sulfur compounds of intermediate oxidation state (i.e., S^{OS} where $-2 < OS < +6$; e.g., SO_2 , S_8) and mixed-valence (e.g., $S_2O_3^{2-}$; $OS = -1$ and $+5$) (Vairavamurthy et al., 1993) can undergo hydrolytic disproportionation reactions at elevated temperatures to form sulfur compounds of both higher and lower valence (e.g., SO_4^{2-} and H_2S , or SO_4^{2-} and S^0). Examples of hydrolytic disproportionation reactions include:

These reactions, especially those involving thiosulfate and elemental sulfur as the principle reactants, have long been exploited for experimental hydrothermal sulfur isotope partitioning studies (e.g., Thode et al., 1971; Robinson, 1973; Ohmoto & Lasaga, 1982; Uyama et al., 1985; Kusakabe et al., 2000; Syverson et al., 2015) and *in situ* spectroscopic thermodynamic/speciation studies (e.g., Pokrovski & Dubessy, 2015; Schmidt & Seward, 2017). Such investigations led to the discovery of the apparent stability of the S_3^- radical ion under hydrothermal conditions following (e.g., Pokrovski & Dubrovinsky, 2011; Pokrovski & Dubessy, 2015):

1155 The decomposition of the S_3^- radical ion (e.g., upon the cooling of a fluid)
 1156 presumably follows a reaction similar to the forward progress of Eq. 24 that
 1157 resembles hydrolytic disproportionation but as written also involves explicit
 1158 oxidation.

1159 Hydrolytic disproportionation reactions such as those represented in Eq.
 1160 19-24 can be modeled in a simple way as branching reactions following the
 1161 generalized network:

1162 Here, some sulfur compound of intermediate or mixed oxidation state, A, under-
 1163 goes a unidirectional reaction to compounds B and C. Reaction 1 and reaction
 1164 2 are associated with their respective kinetic isotope effects, $^i\alpha_1 \equiv ^ik_1/^{32}k_1$ and
 1165 $^i\alpha_2 \equiv ^ik_1/^{32}k_2$ (where $i = 33, 34$, or 36 ; NOTE: the symbol α is used here to
 1166 represent a kinetic isotope effect (format: $^i\alpha_{rxn}$) for the sake of simplicity and
 1167 should not be confused with other uses of α in this study). The general ana-
 1168 lytical solutions for the compositions (given as isotope ratios $^iR = ^iS/^{32}S$) for
 1169 sulfur phases A, B, and C in a closed system are given by (derivations provided
 1170 in the Appendix A.2):

$$^iR_{A,t} = ^iR_{A,0} \times f^{(b \times ^i\alpha_1 + (1-b) \times ^i\alpha_2 - 1)} \quad (26)$$

$$^iR_{B,t} = \frac{^i\alpha_1 \times ^iR_{A,0} \times \left(1 - f \times f^{(b \times ^i\alpha_1 + (1-b) \times ^i\alpha_2 - 1)}\right)}{(1 - f) \times (b \times ^i\alpha_1 + (1 - b) \times ^i\alpha_2)} \quad (27)$$

$${}^iR_{C,t} = \frac{{}^i\alpha_2 \times {}^iR_{A,0} \times \left(1 - f \times f^{(b \times {}^i\alpha_1 + (1-b) \times {}^i\alpha_2 - 1)}\right)}{(1 - f) \times (b \times {}^i\alpha_1 + (1 - b) \times {}^i\alpha_2)} \quad (28)$$

1171 The variable $b = \frac{[B]}{[B]+[C]}$ is the product branching ratio that can be related to
 1172 the reaction stoichiometries of the various disproportionation reactions (e.g., Eq.
 1173 [19](#)[24](#)) and f is the fraction of the reactant remaining at any given time point in
 1174 the reaction ($[A]_t/[A]_0$; see [Appendix A.2](#) for further details). At present, Eq.
 1175 [26](#)[28](#) cannot be solved completely and/or directly for most disproportionation
 1176 reactions (e.g., Eq. [19](#)[24](#)) because the overall kinetic isotope effects associated
 1177 with these reactions are not presently constrained to our knowledge (especially
 1178 for all three sulfur isotope ratios).

1179 An initial glimpse of the potential multiple sulfur isotope fractionation be-
 1180 havior associated with a variety of disproportionation reactions can be obtained
 1181 by substituting equilibrium isotope effects for the kinetic isotope effects required
 1182 by Eq. [26](#)[28](#) constrained by a combination of our calculations from the present
 1183 study and our previous study ([Eldridge et al., 2016](#)). Substituting equilibrium
 1184 isotope effects for kinetic isotope effects for the purpose of this exercise is equiv-
 1185 alent to assuming that the true kinetic isotope effects associated with these re-
 1186 actions are of comparable magnitude (and exhibit similar mass laws, $^{33/34}\theta$ and
 1187 $^{36/34}\theta$) and temperature dependence to the equilibrium isotope effects among
 1188 the considered species, which are recognized as important limitations. Solutions
 1189 to models applying this simplifying substitution corresponding to an example
 1190 each of SO_2 , S^0 , and S_3^{2-} are provided in Fig. [16](#). The purpose of this exercise is
 1191 to illustrate the subtle shifts in the $\Delta^{33}\text{S}$ and $\Delta^{36}\text{S}$ compositions of the reactants
 1192 and products of disproportionation-type processes that arise from mass balance
 1193 ('mass conservation effects'; e.g., [Farquhar et al., 2007](#)), which to-date have not
 1194 been systematically constrained by experiments. The true kinetic isotope effects
 1195 and corresponding 'mass laws' ($^{33/34}\theta$ and $^{36/34}\theta$) and their temperature depen-
 1196 dence associated with disproportionation reactions in Eq. [19](#)[24](#) are currently
 1197 unconstrained by either theory or experiments, and so the full range of $\Delta^{33}\text{S}$
 1198 and $\Delta^{36}\text{S}$ variations associated with these reactions are not yet known.

Given these limitations to understanding the multiple sulfur isotope behavior associated with hydrolytic disproportionation reactions, we explore in the following section a natural example that utilizes a simple mass balance approach and our new theoretical calculations to investigate how disproportionation reactions may manifest in measurable shifts in $\Delta^{33}\text{S}$ and $\Delta^{36}\text{S}$ compositions of naturally occurring compounds that may reflect the properties and dynamics of an example natural system.

4.3.2. Natural Example Based on Mass Balance Modeling: Volcanic (hyper-) acid crater Lakes

Hydrolytic disproportionation reactions can contribute to sulfur-cycling in magmatic-hydrothermal systems. A primary example we will highlight here are (hyper-) acid crater lakes associated with active arc volcanoes (e.g., see overview/reviews in Kusakabe et al., 2000; Marini et al., 2011; Delmelle & Bernard, 2015). Such lakes are often typified by low pH (e.g., pH = -0.6 to 4.9), high concentrations of dissolved sulfate (e.g., $[\text{SO}_4^{2-}] = 0.6\text{-}0.8$ mol/kg), and in some cases are characterized by elemental sulfur in the forms of floating cinders thought in some cases to be derived from molten pools of sulfur at the lake bottom (e.g., Delmelle et al., 2000; Kusakabe et al., 2000; Delmelle & Bernard, 2015, and references therein). The $\delta^{34}\text{S}$ values of dissolved sulfate ($\delta^{34}\text{S} = ({}^{34}R_{\text{sample}}/{}^{34}R_{\text{VCDT}} - 1) \times 1000$) in many (hyper-)acid crater lakes have been observed to be relatively high (e.g., $\delta^{34}\text{S}$ values as high as 20-25 ‰ reported relative to CDT in their study; Kusakabe et al., 2000) and in such cases exhibit relatively large fractionations relative to ambient/associated elemental sulfur: $1000 \times \ln({}^{34}R_{\text{HSO}_4^-}/{}^{34}R_{\text{S}^0})$ up to ≈ 30 ‰ (Kusakabe et al., 2000). Such compositions (and fractionations) in (hyper-)acid crater lakes cannot be explained by oxidation processes because in such a case the $\delta^{34}\text{S}$ values of reduced and oxidized sulfur species would be expected to more closely track each other. These compositions are instead generally explained by much of the sulfate originating from hydrolytic SO_2 disproportionation (e.g., Rye et al., 1992; Taran et al., 1996; Delmelle et al., 2000; Kusakabe et al., 2000; Marini et al.,

1229 [2011], [Delmelle & Bernard, 2015].

1230 Informed by their experimental investigations of SO₂ disproportionation in
 1231 the laboratory, [Kusakabe et al. (2000)] provided a mass balance model based
 1232 on the hydrolytic disproportionation of SO₂ to elemental sulfur and sulfate fol-
 1233 lowing Eq. [23] to account for the sulfur isotope compositions of (hyper-)acid
 1234 crater lake dissolved sulfate assuming that all sulfate originates from SO₂ dis-
 1235 proportionation. [Kusakabe et al. (2000)] based their model on [Taran et al.
 1236 (1996)] where a similar model was presented for Eq. [22] (i.e., where H₂S and
 1237 HSO₄⁻ are assumed to be the products). We additionally note that a compara-
 1238 ble model was also recently presented in [Marini et al. (2011)] where additional
 1239 sulfide oxidation processes are included, which we will omit for simplicity here.
 1240 We reproduce here a complete version of the model presented by [Kusakabe et al.
 1241 (2000)] in terms of isotope ratios ($^iR = ^iS/^{32}S$, where $i = 33, 34$, or 36) for both
 1242 disproportionation products of Eq. [23] (derivation provided in [Appendix A.3]):

$$^iR_{HSO_4^-} = \frac{^iR_T \times (r + 1)}{r \times ^i\alpha_{H_2S/HSO_4^-} + (1/3) \times ^i\alpha_{S^0/HSO_4^-} + (2/3)} \quad (29)$$

$$^iR_{S^0} = \frac{^iR_T \times (r + 1)}{r \times ^i\alpha_{H_2S/S^0} + (2/3) \times ^i\alpha_{HSO_4^-/S^0} + (1/3)} \quad (30)$$

1243 Where r is the molar H₂S/SO₂ ratio of the source gas ultimately fed from the
 1244 magmatic system, iR_T corresponds to the bulk isotope ratio of the gaseous
 1245 sulfur (assumed to be comprised solely of H₂S + SO₂), and the α 's are the
 1246 temperature dependent equilibrium fractionation factors between the designated
 1247 species (following the convention of $^i\alpha_{A/B} = ^iR_A/^iR_B$). The factors of 1/3 and
 1248 2/3 arise from the stoichiometry of the assumed SO₂ disproportionation reaction
 1249 (Eq. [23]). A key assumption of this model is that all species are isotopically
 1250 equilibrated at the temperature of disproportionation.

1251 [Kusakabe et al. (2000)] solved a simplified version of Eq. [29] for $\delta^{34}S$ (see [Ap-
 1252 pendix A.3]) using the experimental equilibrium $^{34}\alpha_{sulfide/sulfate}$ from [Ohmoto
 1253 & Lasaga (1982)] and the experimental equilibrium $^{34}\alpha_{S^0/HSO_4^-}$ derived from

their experimental data and Robinson (1973). They illustrated that dissolved sulfate (and perhaps elemental sulfur) associated with many (hyper-)acid crater lakes near the summits of active arc volcanoes exhibit $\delta^{34}\text{S}$ compositions that are broadly consistent with this type of mass balance model. Because of the agreement between our theoretical calculations and these experimental studies (Fig. 12 and 14) our solutions to these equations utilizing our theoretical fractionation factors yields essentially identical results to Kusakabe et al. (2000) with respect to $\delta^{34}\text{S}$. The advantage of using our theoretical calculations in the present exercise is that (i) we do not need to extrapolate experimental fractionation factors into temperature ranges that are not constrained by experiment, and (ii) we can directly solve these equations for $\delta^{33}\text{S}$ and $\delta^{36}\text{S}$ (and, thus, $\Delta^{33}\text{S}$ and $\Delta^{36}\text{S}$) using direct constraints for the minor isotope equilibrium fractionation factors from our theoretical calculations without having to make assumptions about the equilibrium mass laws.

In Fig. 17, we present solutions of Eq. 29 and 30 in terms of $\delta^{34}\text{S}$, $\Delta^{33}\text{S}$, and $\Delta^{36}\text{S}$ utilizing our theoretical fractionation factors as the principle constraints. For the purpose of this exercise, we follow Kusakabe et al. (2000) and assume $\delta^{34}\text{S}_T = +5\text{‰}$ (from Ueda & Sakai, 1984; Taylor, 1986) and we compute compositions over ranges of $r = \text{H}_2\text{S}/\text{SO}_2 = 0.1\text{--}10$ and over temperatures of $150\text{--}400^\circ\text{C}$. We further assume that $\Delta^{33}\text{S}_T = 0\text{‰}$ and $\Delta^{36}\text{S}_T = 0\text{‰}$ corresponding to $\delta^{33}\text{S}_T = +2.57\text{‰}$ and $\delta^{36}\text{S}_T = +9.52\text{‰}$. The resulting compositional fields presented in Fig. 17 for sulfate and elemental sulfur in multiple sulfur isotope space as a function of temperature and r result from the underlying mass balance of varying contributions of SO_2 disproportionation. As such, the shifts in $\Delta^{33}\text{S}$ and $\Delta^{36}\text{S}$ can be described as 'mass conservation effects' (e.g., Farquhar et al., 2007).

In Fig. 17 we also run through a related exercise undertaken by Kusakabe et al. (2000) where we use the empirical $\delta^{34}\text{S}$ -based fractionation between HSO_4^- and S^0 from a handful of (hyper-)acid crater lake localities as a thermometer to constrain the temperature of SO_2 disproportionation such that $r = \text{H}_2\text{S}/\text{SO}_2$ may be constrained. Localities include: Yugama (Japan), Kawah

1285 Ijen (East Java, Indonesia), Keli Mutu (East Nusa Tenggara, Indonesia), Mount
 1286 Ruapehu (New Zealand), and Maly Semiachik (Kamchatka Peninsula, Russia)
 1287 (all $\delta^{34}\text{S}$ data are taken from Kusakabe et al. (2000) and further details can be
 1288 found there and references therein). This exercise is identical to the exercise
 1289 conducted by Kusakabe et al. (2000) in their Fig. 11 only here we newly have
 1290 the additional capability of computing model output $\Delta^{33}\text{S}$ and $\Delta^{36}\text{S}$ values for
 1291 these localities. In Fig. 17 we predict subtle but potentially resolvable shifts in
 1292 $\Delta^{33}\text{S}$ and $\Delta^{36}\text{S}$ values for these localities within the simple model framework
 1293 of Eq. 29-30 that, again, arise from mass conservation effects. We emphasize
 1294 that the $\Delta^{33}\text{S}$ and $\Delta^{36}\text{S}$ compositions of sulfur species from these crater lake
 1295 localities have not been determined to the best of our knowledge. A predic-
 1296 tion from this simple model is that dissolved sulfate should exhibit higher $\Delta^{33}\text{S}$
 1297 relative to the bulk sulfur isotope composition of the magmatic-hydrothermal
 1298 sulfur source (up to 0.04-0.05 ‰ higher) and lower $\Delta^{36}\text{S}$ values (as much as 0.4
 1299 ‰ lower) depending on values of r and the temperature of disproportionation.
 1300 Similar but more subtle relationships are also predicted in values of $\Delta^{33}\text{S}$ and
 1301 $\Delta^{36}\text{S}$ between dissolved sulfate and associated/ambient elemental sulfur assum-
 1302 ing that SO_2 disproportionation at higher temperatures alone is responsible for
 1303 their origin in (hyper-)acid crater lakes (Fig. 17). We recognize that the sulfur
 1304 isotope compositions of elemental sulfur and sulfate in these environments are
 1305 not necessarily so tightly coupled and that other processes associated with the
 1306 sourcing and cycling of these species in the lakes would complicate this simple
 1307 prediction. To first order, the multiple sulfur isotope analyses ($\Delta^{33}\text{S}$ and $\Delta^{36}\text{S}$
 1308 in addition to $\delta^{34}\text{S}$) could provide additional constraints on the sources and
 1309 cycling of sulfur in these systems.

1310 The simple model presented in Fig. 17 highlights the potential sensitiv-
 1311 ity of $\Delta^{33}\text{S}$ and $\Delta^{36}\text{S}$ values of (hyper-)acid crater lake dissolved sulfate to
 1312 underlying hydrothermal-magmatic properties and processes that may serve as
 1313 additional parameters for monitoring volcanic gases and sulfur cycling processes
 1314 in these systems. Values of r are complex and depend on aspects of magma ex-
 1315 solution (i.e., magma sources, degassing dynamics, and vapor/melt partition

coefficients that are a function of temperature, pressure, and redox-properties
 of the magmatic system; e.g., [Oppenheimer et al., 2011](#) and other (secondary)
 processes occurring during gas transport through conduits to the surface (e.g.,
 wall rock interactions; [Giggenbach, 1987](#); [Christenson & Tassi, 2015](#); [Delmelle
 & Bernard, 2015](#), and references therein). Dramatic decreases in r have been
 inferred to be correlated with eruptive events using either dissolved polythionate
 concentrations in (hyper-)acid crater lakes (e.g., [Takano, 1987](#), see [Delmelle &
 Bernard, 2015](#)) for detailed summary and potential complications of this proxy)
 or $\delta^{34}\text{S}_{\text{HSO}_4^-}$ as described in the context of the model presented above (e.g., [Oh-
 sawa et al., 1993](#); [Kusakabe et al., 2000](#)). Using an unparalleled dataset from
 Yugama Lake (Japan) beginning with the work of [Sakai \(1957\)](#), [Ohsawa et al.
 \(1993\)](#) and [Kusakabe et al. \(2000\)](#) illustrated how dramatic shifts in $\delta^{34}\text{S}_{\text{HSO}_4^-}$
 (up to ≈ 10 ‰ overall) can be associated with eruptive events that were in-
 terpreted to reflect enhanced SO_2 fluxes to the system (and thus decreasing
 r) during eruptions. Interestingly, [Kusakabe et al. \(2000\)](#) illustrated that pre-
 eruption values of $\delta^{34}\text{S}_{\text{HSO}_4^-}$ appear to be largely recovered in Yugama Lake
 following eruption activity. Based on the simple model framework presented
 here (Fig. [17](#)), we would predict subtle shifts in $\Delta^{33}\text{S}$ (ca. 0.01 ‰) and $\Delta^{36}\text{S}$
 (ca. 0.1 ‰) corresponding to these observed shifts in $\delta^{34}\text{S}_{\text{HSO}_4^-}$ during those
 eruptive events at Yugama Lake ([Kusakabe et al., 2000](#)), which approach the
 current analytical precision of the measurements but may nevertheless allow fur-
 ther tracking capabilities under some circumstances. We propose that multiple
 sulfur isotope analyses ($\delta^{34}\text{S}$ and the precise measurement of $\Delta^{33}\text{S}$ and $\Delta^{36}\text{S}$)
 of sulfur phases in (hyper-)acid crater lakes, in addition to detailed character-
 ization of the concentrations and perhaps isotope compositions of other minor
 sulfur species (polythionates, polysulfides, thiosulfate, sulfite, etc.; cf. [Delmelle
 & Bernard, 2015](#)), may allow further testing of such models and reveal even
 more detail of the complexities of the fascinating aqueous sulfur chemistry and
 dynamics of (hyper-)acid crater lakes and its relation to volcanic eruptions in
 future work.

5. Summary and Conclusion

We present theoretical estimates of RPFRs (and/or site-averaged β -factors) for aqueous polysulfur compounds (S_x^{2-} , $x = 2-8$; HS_x^- , $x = 2, 3$; S_x^- , $x = 2, 3$; and $S_x(SO_3)_2^{2-}$, $x = 3, 4$; S_8) and associated aqueous sulfate (HSO_4^- , SO_4^{2-} , and select Na^+ - and Mg^{2+} -ion pairs) and sulfide compounds (H_2S , HS^- , select aqueous Fe^{2+} -complexes and Na^+ -ion pairs). We utilize the B3LYP/6-31+G(d,p) level of theory and basis set in conjunction with an explicit solvation model whereby solutes are modeled in water clusters of generally varying size in the range of 30-52 water molecules. We do not observe any systematic deviation in molecular geometries, mean water coordination number, or RPFR/ β values associated with water cluster size, and therefore estimate an uncertainty in these values based on the variability that we observe among different cluster sizes and conformations. The typical variability associated with cluster size is relatively small and on the order of ≤ 0.5 ‰ (1 s.d.) in estimates of $^{34}RPFR/^{34}\beta$ values at 25°C that generally keep estimated uncertainties in values of $^{34}\alpha < 1$ ‰ (1 s.d.). It is important to emphasize that these uncertainty estimates do not take into consideration any systematic errors due to inadequacies in the utilized B3LYP/6-31+G(d,p) theoretical method and basis set, which are difficult to determine. Instead, we emphasize comparing our theoretically calculated fractionation factors to available experimental determinations and find generally good agreement within the estimated errors of the approaches. For example, our calculations agree with experimental determinations of the HSO_4^-/H_2S fractionation factor within ≤ 0.5 ‰ over the experimental temperature range of 200-400°C. Because we utilize the same approach to computing RPFRs (and/or β -factors) to our previous study (Eldridge et al., 2016) these two datasets can be viewed as one larger dataset aiming to constrain the equilibrium isotope fractionations among many aqueous sulfur compounds for applications to natural and experimental systems.

Our calculations reveal a propensity for crossover behavior among reduced polysulfur and sulfide compounds/moieties, where fractionation factors switch

in direction at specific temperatures and thereby exhibit non-intuitive temperature dependences. Numerous crossovers are predicted among aqueous sulfide, polysulfide, polysulfur radical compounds, in addition to the central reduced atomic sites in select polythionates. The calculations likely do not precisely constrain the values of crossover temperatures for any of the fractionation factors computed (i.e., estimated uncertainties are on the order of several 10's of °C), but nevertheless reveal important and hitherto unrecognized fractionation relationships among the computed compounds. We document the expected so-called 'non-canonical' exponents of mass dependence associated with equilibrium isotope exchange that occur in close proximity to crossover temperatures that asymptotically approach values of $+\infty$ and $-\infty$, but illustrate that it is highly unlikely that these unusual exponents result in any significant deviations in the isotopic compositions of naturally occurring compounds as a result of either equilibrium isotope exchange or Rayleigh distillation occurring in close proximity to the crossover temperature.

We highlight two primary applications to natural systems in this study that are both poorly constrained by experiment and may represent new opportunities for future research: (i) low-temperature authigenic pyrite formation, and (ii) hydrolytic disproportionation reactions extended to a natural example of (hyper-)acid crater lakes associated with active volcanoes. We provide some explanation for why pyrite formation may be associated with relatively small isotope fractionation with respect to precursor aqueous sulfur compounds in the framework of established mechanisms (e.g., the polysulfide mechanism), but emphasize that the isotope fractionations in terms of fractionation factors associated with pyrite formation are yet to be experimentally constrained. Additionally, we highlight the potential utility of multiple sulfur isotope analysis (i.e., measurements of $\delta^{34}\text{S}$, $\Delta^{33}\text{S}$, and $\Delta^{36}\text{S}$) in monitoring volcanic gas output in active volcanoes using a model approach based primarily on the seminal work of Kusakabe et al. (2000). We illustrate that values of $\delta^{34}\text{S}$, $\Delta^{33}\text{S}$, and $\Delta^{36}\text{S}$ of dissolved HSO_4^- may all be sensitive to the amount of magmatic SO_2 supplied to (hyper-)acid crater lakes associated with active volcanoes (parameterized as

1407 $r = \text{H}_2\text{S}/(\text{SO}_2)$, and identify such measurements as targets for future study.

1408 6. Acknowledgements

1409 This work was primarily supported by a Carnegie Postdoctoral Fellowship
 1410 (Geophysical Laboratory; 2016-2018) awarded to D.L. Eldridge that is gratefully
 1411 acknowledged. J. Farquhar acknowledges support for computational resources
 1412 (computer and *Gaussian09* license) by the National Science Foundation (NSF
 1413 grant 1361945). We thank Bjørn Mysen, Doug Rumble, and George Cody for
 1414 valuable comments on earlier drafts of this manuscript. We additionally thank
 1415 Weifu Guo for illuminating discussions throughout the undertaking of this study.
 1416 We are thankful to the late Jack Tossell for early mentorship in aqueous cluster
 1417 electronic structure calculations and credit his 2012 publication (Tossell, 2012)
 1418 for partly spurring our interest in pursuing calculations of aqueous polysulfur
 1419 compounds in further detail. We thank Ruth Blake (Yale) for editorial handling,
 1420 and Drew Syverson (Yale) and two anonymous reviewers for comments and
 1421 suggestions that greatly improved the presentation in this manuscript.

Figure 1: Example two-dimensional ball-and-stick representations of the optimized aqueous polysulfide and polysulfur radical compounds: (A) disulfide, $\text{S}_2^{2-} \bullet 30\text{H}_2\text{O}$, (B) trisulfide, $\text{S}_3^{2-} \bullet 34\text{H}_2\text{O}$, (C) tetrasulfide, $\text{S}_4^{2-} \bullet 38\text{H}_2\text{O}$, (D) pentasulfide, $\text{S}_5^{2-} \bullet 42\text{H}_2\text{O}$, (E) hexasulfide, $\text{S}_6^{2-} \bullet 42\text{H}_2\text{O}$, (F) heptasulfide, $\text{S}_7^{2-} \bullet 50\text{H}_2\text{O}$, (G) octasulfide, $\text{S}_8^{2-} \bullet 50\text{H}_2\text{O}$, (H) hydrogen disulfide, $\text{HS}_2^- \bullet 34\text{H}_2\text{O}$, (I) hydrogen trisulfide, $\text{HS}_3^- \bullet 34\text{H}_2\text{O}$, (J) trisulfur radical, $\text{S}_3^{\bullet} \bullet 50\text{H}_2\text{O}$, (K) disulfur radical, $\text{S}_2^{\bullet} \bullet 50\text{H}_2\text{O}$, (L) elemental sulfur, $\text{S}_8 \bullet 50\text{H}_2\text{O}$. The general color scheme for atoms follows red = oxygen, gray = hydrogen, and yellow-orange = sulfur, but different colors were chosen for the trisulfur radical (sulfur = blue) and disulfur radical (sulfur = yellow) to visually distinguish these compounds from the analogous polysulfides.

Figure 2: Example two-dimensional ball-and-stick representations of the optimized aqueous sulfide compounds: (A) hydrogen sulfide, $\text{H}_2\text{S} \bullet 45\text{H}_2\text{O}$, (B) bisulfide, $\text{HS}^- \bullet 45\text{H}_2\text{O}$, (C) ferrous sulfide monomer, $\text{FeS}^0 \bullet 50\text{H}_2\text{O}$, (D) ferrous bisulfide, $\text{FeSH}^+ \bullet 50\text{H}_2\text{O}$, (E) sodium bisulfide ion-pair, $(\text{Na}^+ \text{HS}^-)^0 \bullet 45\text{H}_2\text{O}$. The general color scheme for atoms follows: red = oxygen, gray = hydrogen, yellow-orange = sulfur, purple = iron, and orange = sodium.

Figure 3: Example two-dimensional ball-and-stick representations of the optimized aqueous sulfate compounds and polythionates: (A) sulfate, $\text{SO}_4^{2-} \bullet 44\text{H}_2\text{O}$, (B) bisulfate, $\text{HSO}_4^- \bullet 44\text{H}_2\text{O}$, (C) sodium sulfate ion-pair, $(\text{Na}^+ \text{SO}_4^{2-})^- \bullet 43\text{H}_2\text{O}$, (D) magnesium sulfate ion-pair, $(\text{Mg}^{2+} \text{SO}_4^{2-})^0 \bullet 43\text{H}_2\text{O}$, (E) trithionate, $\text{S}_3\text{O}_6^{2-} \bullet 52\text{H}_2\text{O}$, (F) tetrathionate, $\text{S}_4\text{O}_6^{2-} \bullet 42\text{H}_2\text{O}$. The general color scheme for atoms follows: red = oxygen, gray = hydrogen, yellow-orange = sulfur, orange = sodium, black = magnesium.

Figure 4: Computed $^{34}\text{RPFR}$ s and $^{34}\beta$ values for aqueous sulfide and polysulfide compounds at 25°C. Larger symbols indicate $^{34}\beta$ values (square = aqueous sulfide compounds, diamond = polysulfide compounds). Smaller circles with connecting lines indicate $^{34}\text{RPFR}$ values for singly-substituted polysulfides, and are plotted in a schematic fashion that imitates molecular structure. Calculations of $^{34}\text{RPFR}$ s and $^{34}\beta$ values for polysulfides modeled as similar structures in vacuum (in red) are shown for reference.

Figure 5: Computed $^{34}\beta$ values (and/or $^{34}\text{RPFR}$) plotted as a function of $1/T^2$. All plots (A)-(E) contain computations of aqueous sulfide (H_2S , HS^- , S^{2-} ; solid black curves) for reference. (A) aqueous polysulfide compounds (yellow-orange = S_x^{2-} , gray = HS_x^-) and elemental sulfur (orange = S_8), (B) aqueous polysulfur radical anions (blue), (C) ferrous sulfide compounds (purple), (D) the central reduced ‘sulfanyl’ sulfur $^{34}\text{RPFR}$ for trithionate (dark green) and the outer reduced ‘sulfanyl’ sulfur for thiosulfate for reference (light green, from [Eldridge et al., 2016](#)), (E) aqueous sulfate species (all; red) and the ‘sulfonate’ sulfur for trithionate (dark green), alongside calculations of the ‘sulfonate’ sulfur of thiosulfate (light green), sulfoxylate (SO_2^{2-} ; gray), and sulfite (SO_3^{2-} ; gray) from [Eldridge et al., 2016](#) for reference.

Figure 6: Exponents quantifying ‘mass-dependence’ of β values (and/or RPFR s) for all compounds computed in this study as a function of $1/T^2$. Color scheme and labeling follows after Fig. 5 except where noted. (A) $^{33/34}\kappa$ values (or similar $\ln(^{33}\text{RPFR})/\ln(^{34}\text{RPFR})$ values), and (B) $^{36/34}\kappa$ values (or similar $\ln(^{36}\text{RPFR})/\ln(^{34}\text{RPFR})$ values).

Figure 7: Compilation of different estimates (theoretical, direct experimental, and indirect experimental) of the equilibrium fractionation factor between aqueous H_2S and HS^- as a function of $1/T^2$. The results of the current study are presented as the black curve where the shaded bounds reflect the error estimate (1 s.d.) based on the propagation of estimated errors on the aqueous sulfide calculations from numerous cluster sizes. See main text for descriptions of the different estimates from the literature (Section 4.1.1).

Figure 8: Estimated equilibrium fractionation factors among the ferrous sulfide compounds and HS^- or H_2S as a function of $1/T^2$. The shaded bounds represent the error estimates (1 s.d.) based on the propagation of estimated errors on the various aqueous sulfide calculations from numerous cluster sizes. The recent experimental estimate of the pyrite(FeS_2)/ $\text{H}_2\text{S}_{(aq)}$ fractionation factor of Syverson et al. (2015) is shown for reference.

Figure 9: Estimated equilibrium fractionation factors among select aqueous polysulfide and sulfide compounds as a function of $1/T^2$. The shaded bounds represent the error estimate (1 s.d.) based on the propagation of estimated errors on polysulfide and sulfide calculations from numerous cluster sizes.

Figure 10: (A) Equilibrium distribution of aqueous sulfide and polysulfide compounds at 25°C based on the experimental data of Kamyshny et al. (2004, 2007) in a S^0 -saturated system containing a total aqueous sulfur concentration of $100\mu\text{M}$. The inset plot has the same labelling as the bounding plot and is focused on a smaller concentration range to illustrate the polysulfide distributions in greater detail. Other polysulfides (e.g., S_2^{2-} and HS_x^- where $x > 2$) are in too low of concentration to be seen on this plot. (B) Computed bulk equilibrium fractionation factor between total aqueous polysulfide and sulfide as a function of pH under the same conditions illustrated in panel (A). The bounding dashed curves in panel (B) represent the error estimate (1 s.d.) based on the propagation of estimated errors on polysulfide and sulfide calculations from numerous cluster sizes.

Figure 11: Estimated equilibrium fractionation factors among aqueous polysulfur radicals and sulfide compounds as a function of $1/T^2$. The shaded bounds represent the error estimate (1 s.d.) based on the propagation of estimated errors on polysulfur radical and sulfide calculations from numerous cluster sizes.

Figure 12: Comparison of our theoretical equilibrium fractionation factors among various aqueous sulfate species and aqueous H_2S (and $\text{HSO}_4^-/\text{S}_3^{2-}$ for comparison) and experimental determinations (Ohmoto & Lasaga, 1982; Syverson et al., 2015) as a function of $1/T^2$. The residual plot shows the difference between the experimental studies and our theoretical $\text{HSO}_4^-/\text{H}_2\text{S}$ fractionation factor (experiment - theory), which is likely the most comparable to the experimental studies. See text for further explanation.

Figure 13: Theoretical estimates of equilibrium fractionation factors involving the two sulfur moieties in polythionate ($\text{S}_3\text{O}_6^{2-}$ and $\text{S}_4\text{O}_6^{2-}$; green curves) alongside analogous fractionation factors for thiosulfate (thiosulfate experimental data are from Uyama et al., 1985 and Chu et al., 2004 and theoretical calculations are from Eldridge et al., 2016). (A) The ‘intramolecular’ fractionation factor between the two different sulfur moieties in polythionate (green curves) compared to the analogous fractionation factor predicted for thiosulfate. (B) Fractionation factors between the sulfonate moieties in polythionate ($\text{S}_x(*\text{SO}_3)_2^{2-}$ where $x = 2$ or 3 corresponding to $\text{S}_3\text{O}_6^{2-}$ and $\text{S}_4\text{O}_6^{2-}$, respectively) and H_2S (green curves). The analogous fractionation factor for thiosulfate ($\text{S}(*\text{SO}_3)/\text{H}_2\text{S}$) is shown for reference. (C) Fractionation factors between the reduced moieties in polythionate ($*\text{S}_x(\text{SO}_3)_2^{2-}$ where $x = 2$ or 3 corresponding to $\text{S}_3\text{O}_6^{2-}$ and $\text{S}_4\text{O}_6^{2-}$, respectively) and H_2S (green curves). The analogous fractionation factor for thiosulfate ($*\text{S}(\text{SO}_3)/\text{H}_2\text{S}$) is shown for reference. The shaded bounds on the theory curves are the error estimate (1 s.d.) based on the propagated error estimates of the polythionate and H_2S calculations from numerous cluster sizes.

Figure 14: Comparison of theoretical (orange curves) and experimental (orange squares) fractionation factors between elemental sulfur (S^0 or S_8) and (A) sulfate (HSO_4^-) and (B) sulfide (H_2S). Experimental data are from the studies of Robinson (1973) and Kusakabe et al. (2000). Panel (A) also includes the theoretical $\text{HSO}_4^-/\text{H}_2\text{S}$ fractionation factor (grey dashed curve) for reference. The shaded bounds on the theory curve in panel (B) represent the error estimate (1 s.d.) based on the propagated error estimates of the aqueous H_2S calculations from numerous cluster sizes.

Figure 15: Quantities relating to the ‘mass dependence’ of equilibrium isotope exchange ($^{33/34}\theta$ and $\Delta^{33}\text{S}$ values) among various aqueous sulfur compounds that exhibit crossovers: (A)-(C) $^{33/34}\theta$ exponent associated with the equilibrium fractionation between select aqueous polysulfide, polysulfur radical, and sulfide compounds. The vertical dashed lines indicate the temperature of the crossover (T_c) for each exchange reaction (note all computed $\text{S}_x^{2-}/\text{HS}^-$ exhibit crossovers where T_c increases with ‘ x ’). (D)-(F) The corresponding $\Delta^{33}\text{S}$ values for equilibrium fractionation among the compounds represented in panels (A)-(C).

Figure 16: Solutions to a simple closed-system disproportionation model (Eq. 26-28) using equilibrium fractionation factors constrained here (rather than kinetic isotope effects that are currently unconstrained) in terms of $\delta^{34}\text{S}$ vs. $\Delta^{33}\text{S}$ (A, C, E) or $\Delta^{36}\text{S}$ (B, D, F) for: (A)-(B) SO_2 to HSO_4^- and H_2S (Eq. 22); (C)-(D) elemental sulfur to SO_4^{2-} and H_2S (Eq. 21); (E)-(F) S_3^{2-} to SO_4^{2-} and H_2S (Eq. 24).

Figure 17: $\Delta^{33}\text{S}$ and $\Delta^{36}\text{S}$ vs. $\delta^{34}\text{S}$ values for elemental sulfur and sulfate generated from the quantitative disproportionation of sulfur dioxide as a function of temperature and r (the molar $\text{H}_2\text{S}/\text{SO}_2$ ratio of the magmatic source) from the mass balance model described in the text (Eq. 29 - 30) that is based on Kusakabe et al. (2000) and constrained by the theoretical calculations of the current study. For illustrative purposes we also plot model-generated composition predictions (based on the same mass balance model) of sulfate and elemental sulfur in select (hyper-)acid crater lakes associated with active volcanoes based on the $\delta^{34}\text{S}$ data and assumptions of Kusakabe et al. (2000) (see text for further explanation). Note that the $\Delta^{33}\text{S}$ and $\Delta^{36}\text{S}$ compositions of sulfur phases from these crater lake localities have not been determined to the best of our knowledge.

1423 Appendix A.

1424 Appendix A.1. Geometries

1425 Mean geometric parameters for aqueous sulfur compounds modeled herein
 1426 can be found in Table 2. The direct coordination of polysulfide anions with
 1427 water molecules in supermolecular clusters ($\geq 30 \text{ H}_2\text{O}$) affects the resulting
 1428 polysulfide geometries relative to vacuum, but exhibit similar patterns to com-
 1429 putations in vacuum. The mean sulfur-sulfur bond lengths ($R(\text{S-S})$) for the
 1430 explicitly solvated polysulfides ($\text{S}_x^{2-} \cdot n\text{H}_2\text{O}$) range from $2.167 \pm 0.008 \text{ \AA}$ ($x = 2$)

to 2.099 ± 0.015 Å ($x = 8$) and are generally lower than those obtained from S_x^{2-} having similar structures modeled in vacuum. For both the explicitly solvated ($S_x^{2-} \bullet nH_2O$) and vacuum computations of S_x^{2-} ($x = 2 - 8$), the mean $R(S-S)$ appears to generally decrease with increasing chain-length ' x ' (Table 2). The $R(S-S)$ of $HS_2^- \bullet nH_2O$ is 2.124 ± 0.003 Å and is shorter than the $R(S-S)$ of its unprotonated counterpart $S_2^{2-} \bullet nH_2O$. The $R(S-S)$ for $HS_3^- \bullet nH_2O$ differs for the protonated (2.120 ± 0.003 Å) and unprotonated (2.085 ± 0.003 Å) outer sulfur atoms. The mean $\angle(S-S-S)$ bond angle for all $S_x^{2-} \bullet nH_2O$ of $110.0 \pm 0.9^\circ$ is comparable between the different polysulfides ($S_x^{2-} \bullet nH_2O$, $x = 3 - 8$; i.e., does not appear to vary systematically with ' x ') and is generally lower than the value for the vacuum calculations (mean vacuum: $114.7 \pm 1.2^\circ$). The mean $\angle(S-S-S)$ for $HS_3^- \bullet nH_2O$ ($109.8 \pm 0.4^\circ$) is comparable to its unprotonated counterpart $S_3^{2-} \bullet nH_2O$ ($111.1 \pm 1.0^\circ$) (Table 2). The mean dihedral angle $\angle(S-S-S-S)$ of $87 \pm 7^\circ$ is comparable among the pertinent $S_x^{2-} \bullet nH_2O$ ($x = 4 - 8$) and is also comparable to the value of $89 \pm 4^\circ$ from the calculations in vacuum (i.e., close to $\approx 90^\circ$).

The polysulfur radicals ($S_x^{\cdot-}$, $x = 2, 3$) modeled in water clusters exhibit different geometries than the analogous polysulfides in water clusters (S_x^{2-} , $x = 2, 3$). The mean sulfur-sulfur bond lengths $R(S-S)$ for the explicitly solvated polysulfur radicals $S_2^{\cdot-} \bullet nH_2O$ (2.032 ± 0.001 Å) and $S_3^{\cdot-} \bullet nH_2O$ (2.031 ± 0.011 Å) are computed to be significantly shorter than the polysulfides ($S_x^{2-} \bullet nH_2O$). The $\angle(S-S-S)$ for the trisulfur radical $S_3^{\cdot-} \bullet nH_2O$ ($114.3 \pm 1.1^\circ$) is computed to be larger than the value for $S_3^{2-} \bullet nH_2O$ and the other $S_x^{2-} \bullet nH_2O$. The geometric parameters for the trisulfur radical $S_3^{\cdot-}$ are comparable to previous theoretical studies that obtain S-S bond lengths of 1.99-2.04 Å and $\angle(S-S-S) = 113.4^\circ$ - 116.1° (Koch et al., 1995; Chen et al., 2001; Tossell, 2012) based on numerous theoretical methods with and without different solvation models applied.

The geometric parameters for the modeled aqueous sulfide species appear to compare well to the available experimental data. The $R(H-S)$ for the aqueous sulfide species $H_2S \bullet nH_2O$ (1.347 ± 0.002 Å) and $HS^- \bullet nH_2O$ (1.349 ± 0.002 Å) are similar to one another and to the experimental value for $H_2S_{(g)}$ of 1.352 Å

1462 (Cook et al., 1975). The $R(\text{H-S})$ for the FeSH^+ species of 1.349 Å is indistin-
 1463 guishable from $\text{HS}^- \bullet n\text{H}_2\text{O}$, and the $R(\text{H-S})$ for the $(\text{Na}^+\text{HS}^-)^0 \bullet n\text{H}_2\text{O}$ ion-pair
 1464 is also very similar (1.345 ± 0.003 Å). The computed $\angle(\text{H-S-H})$ for $\text{H}_2\text{S} \bullet n\text{H}_2\text{O}$
 1465 is $92.9 \pm 0.5^\circ$ and is similar to the experimental value for $\text{H}_2\text{S}_{(g)}$ of 92.13°
 1466 (Cook et al., 1975). The $R(\text{Fe-S})$ for $\text{FeSH}^+ \bullet n\text{H}_2\text{O}$ (2.27 ± 0.02 Å) is signifi-
 1467 cantly larger than the value for $\text{FeS}_{(aq)} \bullet n\text{H}_2\text{O}$ (2.140 ± 0.004 Å). The values for
 1468 $R(\text{Fe-S})$ are consistent with a covalent bond between the iron and sulfur atoms
 1469 and are similar to (or shorter than) the $R(\text{Fe-S})$ for ferrous sulfide/polysulfide
 1470 minerals mackinawite (2.256 Å; Rickard & Luther, 2007) and pyrite (2.266 Å;
 1471 Wu et al., 2004). The $\angle(\text{H-S-Fe})$ bond angle for $\text{FeSH}^+ \bullet n\text{H}_2\text{O}$ is computed to be
 1472 $103.7 \pm 0.9^\circ$. The $\angle(\text{H-S-Na})$ for $(\text{Na}^+\text{HS}^-)^0 \bullet n\text{H}_2\text{O}$ is more variable and ranges
 1473 between $75\text{-}105^\circ\text{C}$ (mean = $95 \pm 11^\circ$) and the $R(\text{S-Na})$ is computed to be 2.76
 1474 ± 0.02 Å.

1475 The geometric parameters for the modeled aqueous sulfate species are similar
 1476 to each other and to the available experimental data. The $R(\text{S-O})$ for all sulfate
 1477 species is similar and ranges between 1.49 ± 0.01 Å ($\text{HSO}_4^- \bullet n\text{H}_2\text{O}$) to 1.52 ± 0.01
 1478 Å ($\text{SO}_4^{2-} \bullet n\text{H}_2\text{O}$ and $(\text{Na}^+\text{SO}_4^{2-})^- \bullet n\text{H}_2\text{O}$). These values compare well to ex-
 1479 perimental constraints for SO_4^{2-} (1.495 ± 0.006 Å; Vchirawongkwin et al., 2007).
 1480 The calculations predict that protonation of an oxygen atom in $\text{HSO}_4^- \bullet n\text{H}_2\text{O}$
 1481 causes an extension of the S-OH bond (i.e., $R(\text{S-OH}) = 1.596 \pm 0.002$ Å) rel-
 1482 ative to the other S-O bonds associated with unprotonated oxygen atoms that
 1483 is analogous to our previous computations of the HO-bonded isomer of aqueous
 1484 bisulfite, $(\text{HO})\text{SO}_2^-$, from Eldridge et al. (2016). Direct ion-pairing with Mg^{2+}
 1485 also appears to cause a slight extension of the S-O bond associated with the
 1486 oxygen atom that is directly coordinated with the Mg^{2+} cation ($R(\text{S-O}(\text{Mg})) =$
 1487 1.547 ± 0.001 Å), but ion-pairing with Na^+ does not appear to have this effect
 1488 ($R(\text{S-O}(\text{Na})) = 1.496$ Å). The $\angle(\text{O-S-O})$ bond angles for all aqueous sulfate
 1489 species corresponds to 109.5° and is indistinguishable from expectations of
 1490 tetrahedral molecules where the central atom is four-fold bonded with atoms of
 1491 the same element (i.e., $\cos^{-1}(-1/3) \approx 109.47^\circ$).

1492 The geometric parameters for the computed aqueous polythionates do not

appear to have experimental counterparts in the literature but compare well to those of trithionate salts such as $\text{K}_2\text{S}_3\text{O}_6$ (Zachariasen, 1934). The computed $R(\text{S-S})$ for trithionate ($\text{S}_3\text{O}_6^{2-} \cdot n\text{H}_2\text{O}$) of $2.17 \pm 0.02 \text{ \AA}$ is similar to the value for $\text{K}_2\text{S}_3\text{O}_6$ of $2.15 \text{ \AA}$ (Zachariasen (1934)). Additionally, the $R(\text{S-O})$ for $\text{S}_3\text{O}_6^{2-} \cdot n\text{H}_2\text{O}$ of $1.49 \pm 0.01 \text{ \AA}$ is similar to the value for $\text{K}_2\text{S}_3\text{O}_6$ of $1.50 \text{ \AA}$ (Zachariasen, 1934). The $\angle(\text{S-S-S})$ for $\text{S}_3\text{O}_6^{2-} \cdot n\text{H}_2\text{O}$ of $104.2 \pm 1.3^\circ$ is also comparable to the value of 103.1° for $\text{K}_2\text{S}_3\text{O}_6$ (Zachariasen, 1934). Geometric parameters for tetrathionate ($\text{S}_4\text{O}_6^{2-} \cdot n\text{H}_2\text{O}$) are similar to analogous parameters in trithionate, except the central S-S bond in tetrathionate is computed to be significantly shorter ($2.036 \pm 0.003 \text{ \AA}$) than S-S bonds corresponding to sulfonate groups ($\text{'S-S(O}_3\text{' = } 2.20 \pm 0.02 \text{ \AA}$; Table 2). The sulfur dihedral in tetrathionate is computed to be $104.0 \pm 2.9^\circ$.

The S_8 ring that we compute in a water cluster has a mean $R(\text{S-S}) = 2.10 \pm 0.01 \text{ \AA}$, which is slightly longer than S-S bond lengths in S_8 rings comprising crystalline forms of elemental sulfur ($2.06 \text{ \AA}$) (Meyer, 1976). Our aqueous S_8 ring exhibits a mean $\angle(\text{S-S-S}) = 108.7 \pm 1.1^\circ$ and a mean dihedral angle of $97.8 \pm 3.3^\circ$ (Table 2), which compare well to S_8 rings in crystalline forms of sulfur ($108.0 \pm 0.7^\circ$ and 98.3° , respectively) (Meyer, 1976).

Appendix A.2. General Hydrolytic Disproportionation Model in a Closed System

The overall, generalized reaction network describing the hydrolytic disproportionation of some sulfur-bearing compound, A , into two sulfur-bearing products, B and C , can be given in a simple form by:

The exact sulfur isotope mass balance corresponding to Eq. A.1 is given by:

$$[A]_0 \times {}^i\chi_{A,0} = [A]_t \times {}^i\chi_{A,t} + [B]_t \times {}^i\chi_{B,t} + [C]_t \times {}^i\chi_{C,t} \quad (\text{A.2})$$

Where ${}^i\chi = {}^i\text{S}/({}^{32}\text{S} + {}^{33}\text{S} + {}^{34}\text{S} + {}^{36}\text{S})$ ($i = 33, 34$, or 36) and is the mole or atom fraction of a given minor sulfur isotope. The subscripts 0 and t indicate quantities at the initial time point ($t = 0$) and at some arbitrary time point of reaction t , respectively. In strict terms, the relationship between ${}^i\chi$ and iR (${}^iR = {}^i\text{S}/{}^{32}\text{S}$) is:

$${}^i\chi = \frac{{}^iR}{1 + {}^{33}R + {}^{34}R + {}^{36}R} \quad (\text{A.3})$$

For simplicity, we make the approximation that ${}^i\chi \approx {}^iR$ transforming the exact mass balance of Eq. A.2 into an approximate form:

$$[A]_0 \times {}^iR_{A,0} = [A]_t \times {}^iR_{A,t} + [B]_t \times {}^iR_{B,t} + [C]_t \times {}^iR_{C,t} \quad (\text{A.4})$$

We define two terms: the fraction of reactant remaining, f , and a product branching ratio, b :

$$f = \frac{[A]_t}{[A]_0} \quad (\text{A.5})$$

$$b = \frac{[B]_t}{[B]_t + [C]_t} = \frac{k_1}{k_1 + k_2} \quad (\text{A.6})$$

The branching ratio, b , can be related to the reaction stoichiometry of a given sulfur disproportionation reaction. In the simple framework of this model, k_1 and k_2 are first order rate constants associated with the reaction of $A \xrightarrow{1} B$ and $A \xrightarrow{2} C$, respectively. Substituting Eq. A.5 and A.6 into Eq. A.4 yields:

$${}^iR_{A,0} = f \times {}^iR_{A,t} + (1 - f) \times (b \times {}^iR_{B,t} + (1 - b) \times {}^iR_{C,t}) \quad (\text{A.7})$$

Eq. A.7 is the generalized mass balance relationship that will be the basis for modeling disproportionation reactions herein.

Next, we derive the equation describing the evolution of the isotopic composition of the reactant using a simple kinetic approach. From Eq. A.1 we have:

$$-\frac{d[^{32}A]}{dt} = [^{32}A] \times (^{32}k_1 + ^{32}k_2) \quad (\text{A.8})$$

$$-\frac{d[^iA]}{dt} = [^iA] \times (^ik_1 + ^ik_2) \quad (\text{A.9})$$

Where $[^{32}A]$ is the ^{32}S -bearing isotopologue of compound A and the $[^iA]$ is the ^iS -bearing isotopologue of compound A (again where $i = 33, 34, \text{ or } 36$). Accordingly, the rate constants (k) are also now written in terms of these specific isotopic molecules. Taking the ratio of Eq. A.9 to Eq. A.8 followed by rearrangement yields:

$$\left(\frac{1}{[^iA]}\right) d[^iA] = \left(\frac{^ik_1 + ^ik_2}{^{32}k_1 + ^{32}k_2}\right) \times \left(\frac{1}{[^{32}A]}\right) d[^{32}A] \quad (\text{A.10})$$

Integrating both sides (bounds: 0, t) yields:

$$\ln\left(\frac{[^iA]_t}{[^iA]_0}\right) = \left(\frac{^ik_1 + ^ik_2}{^{32}k_1 + ^{32}k_2}\right) \times \ln\left(\frac{[^{32}A]_t}{[^{32}A]_0}\right) \quad (\text{A.11})$$

For simplicity, we will use α to symbolize a kinetic isotope effect (i.e., $^i\alpha_{rxn} = ^ik_{rxn}/^{32}k_{rxn}$) but we note that a ratio of forward rate constants should not be confused with other uses of α in this study. For this problem, we also apply an approximate form of the product branching ratio ($b \approx \frac{^{32}k_1}{^{32}k_1 + ^{32}k_2}$). Taking this definition of a kinetic isotope effect and the approximate b into account, it is easily shown that:

$$\frac{^ik_1 + ^ik_2}{^{32}k_1 + ^{32}k_2} = b \times ^i\alpha_1 + (1 - b) \times ^i\alpha_2 \quad (\text{A.12})$$

1547 Making this substitution and subtracting $\ln \left(\frac{[^{32}A]_t}{[^{32}A]_0} \right)$ from each side of Eq. A.11
 1548 followed by rearrangement yields:

$$\left(\frac{[^iA]}{[^{32}A]} \right)_t = \left(\frac{[^iA]}{[^{32}A]} \right)_0 \times \left(\frac{[^{32}A]_t}{[^{32}A]_0} \right)^{(b \times {}^i\alpha_1 + (1-b) \times {}^i\alpha_2 - 1)} \quad (\text{A.13})$$

1549 Where again the ${}^i\alpha$ terms in this case are fractionation factors corresponding
 1550 to kinetic isotope effects (i.e., ${}^i\alpha_1 \equiv {}^ik_1/{}^{32}k_1$, ${}^i\alpha_2 \equiv {}^ik_2/{}^{32}k_2$).

1551 In Eq. A.13, it is clear that the term $\frac{[^{32}A]_t}{[^{32}A]_0}$ is equivalent to $\frac{[^{32}S]_{A,t}}{[^{32}S]_{A,0}}$ regardless
 1552 of what compound A may represent. However, it is notable that the terms
 1553 $\left(\frac{[^iA]}{[^{32}A]} \right)_0$ and $\left(\frac{[^iA]}{[^{32}A]} \right)_t$ represent the ratio of isotopic molecules of A at time 0
 1554 and t , respectively, rather than sulfur isotope ratios corresponding to A . To
 1555 relate these ratios of isotopic molecules to sulfur isotope ratios, we will assume
 1556 a random distribution of isotopes among the singly substituted molecules of A
 1557 (i.e., iA) and will further assume that sulfur isotope substitution in A does not
 1558 affect its symmetry. Under these assumptions, $\frac{[^iA]}{[^{32}A]} \approx \left(\frac{[^iS]}{[^{32}S]} \right)_A = {}^iR_A$. Eq.
 1559 A.13 can thus be re-written as:

$${}^iR_{A,t} = {}^iR_{A,0} \times \left(\frac{[^{32}S]_{A,t}}{[^{32}S]_{A,0}} \right)^{(b \times {}^i\alpha_1 + (1-b) \times {}^i\alpha_2 - 1)} \quad (\text{A.14})$$

1560 For our purposes, we make the additional approximation:

$$\frac{[^{32}S]_{A,t}}{[^{32}S]_{A,0}} = f \times \left(\frac{1 + {}^{33}R_{A,0} + {}^{34}R_{A,0} + {}^{36}R_{A,0}}{1 + {}^{33}R_{A,t} + {}^{34}R_{A,t} + {}^{36}R_{A,t}} \right) \approx f \quad (\text{A.15})$$

1561 Applying this approximation yields a familiar form of the Rayleigh equation:

$${}^iR_{A,t} = {}^iR_{A,0} \times f^{(b \times {}^i\alpha_1 + (1-b) \times {}^i\alpha_2 - 1)} \quad (\text{A.16})$$

1562 Thus, the evolution of the sulfur isotope composition of a sulfur intermediate
 1563 undergoing hydrolytic disproportionation in a closed system under the simple
 1564 framework of Eq. A.1 follows Rayleigh distillation dictated by a composite

fractionation factor ($b \times {}^i\alpha_1 + (1-b) \times {}^i\alpha_2$) that is a function of the branching ratio to the products (in this case, related to overall reaction stoichiometry) and the two kinetic isotope effects corresponding to the formation of the two disproportionation products.

The substitution of Eq. A.16 into Eq. A.7 while also recognizing that ${}^iR_{B,t}/{}^iR_{C,t} = {}^i\alpha_1/{}^i\alpha_2$ yields the following relationships that describe the evolution of the disproportionation products, B and C , as a function of f , ${}^iR_{A,0}$, and other reaction-specific quantities (i.e., b , ${}^i\alpha_1$, and ${}^i\alpha_2$):

$${}^iR_{B,t} = \frac{{}^i\alpha_1 \times {}^iR_{A,0} \times \left(1 - f \times f^{(b \times {}^i\alpha_1 + (1-b) \times {}^i\alpha_2 - 1)}\right)}{(1-f) \times (b \times {}^i\alpha_1 + (1-b) \times {}^i\alpha_2)} \quad (\text{A.17})$$

$${}^iR_{C,t} = \frac{{}^i\alpha_2 \times {}^iR_{A,0} \times \left(1 - f \times f^{(b \times {}^i\alpha_1 + (1-b) \times {}^i\alpha_2 - 1)}\right)}{(1-f) \times (b \times {}^i\alpha_1 + (1-b) \times {}^i\alpha_2)} \quad (\text{A.18})$$

Appendix A.3. Derivation of the (hyper-)acid crater Lake Mass Balance Model (SO_2 -disproportionation)

Equations 29 and 30 in the main text (solutions in Fig. 17) are based on a mass balance model presented by Kusakabe et al. (2000) (developed from Taran et al., 1996) that predicts the compositions of sulfate (HSO_4^-) and elemental sulfur produced by the hydrolytic disproportionation of SO_2 corresponding to an initial (or magmatic) $r = \text{H}_2\text{S}/\text{SO}_2$ molar ratio and total magmatic/volatile sulfur isotope composition (${}^{34}R_T$ or $\delta^{34}\text{S}_T$) as a function of the temperature at which disproportionation of SO_2 occurs in the subsurface hydrothermal-magmatic system. We illustrate the derivation of these equations here in full and in terms of isotope ratios (iR) and fractionation factors (${}^i\alpha$).

We begin with the assumption that the total source of sulfur in the (hyper-)acid crater lake system is given by magmatic H_2S and SO_2 having a bulk sulfur isotope composition (given as isotope ratio) of iR_T ($i = 33, 34$, or 36):

$$S_{TOTAL} = [\text{H}_2\text{S}] + [\text{SO}_2] \quad (\text{A.19})$$

$${}^iR_T = f_{H_2S} \times {}^iR_{H_2S} + f_{SO_2} \times {}^iR_{SO_2} \quad (A.20)$$

Equation [A.19](#) could instead be written in terms of partial pressures or fugacities but we forego such description here. The mass balance of Eq. [A.20](#) contains the same approximation as Eq. [A.4](#) (i.e., ${}^i\chi \approx {}^iR$). The f -terms in Eq. [A.20](#) represent mole fractions of each phase and are given by:

$$f_{H_2S} = \frac{[H_2S]}{[S_T]} = \frac{r}{r+1} \quad (A.21)$$

$$f_{SO_2} = \frac{[SO_2]}{[S_T]} = \frac{1}{r+1} \quad (A.22)$$

Where $r = [H_2S]/[SO_2]$ and represents the molar ratio of hydrogen sulfide to sulfur dioxide. We next assume that SO_2 undergoes quantitative disproportionation to form S^0 and HSO_4^- following the stoichiometry of Eq. [23](#) in the main text, which corresponds to the mass balance given by (${}^i\chi \approx {}^iR$ applied once again):

$${}^iR_{SO_2} = \frac{1}{3} \times {}^iR_{S^0} + \frac{2}{3} \times {}^iR_{HSO_4^-} \quad (A.23)$$

Substituting Eq. [A.21](#), [A.22](#) and [A.23](#) into Eq. [A.20](#) yields:

$${}^iR_T = \frac{r}{r+1} \times {}^iR_{H_2S} + \frac{1}{r+1} \times \left(\frac{1}{3} \times {}^iR_{S^0} + \frac{2}{3} \times {}^iR_{HSO_4^-} \right) \quad (A.24)$$

Finally, if we assume that H_2S , HSO_4^- , and S^0 isotopically equilibrate at the temperature of SO_2 disproportionation we can substitute equilibrium fractionation factors for isotope ratios (*via*, for example, ${}^i\alpha_{H_2S/HSO_4^-} = {}^iR_{H_2S}/{}^iR_{HSO_4^-}$ & ${}^i\alpha_{S^0/HSO_4^-} = {}^iR_{S^0}/{}^iR_{HSO_4^-}$, etc.) to obtain the final expressions:

$${}^iR_{HSO_4^-} = \frac{{}^iR_T \times (r+1)}{r \times {}^i\alpha_{H_2S/HSO_4^-} + \frac{1}{3} \times {}^i\alpha_{S^0/HSO_4^-} + \frac{2}{3}} \quad (A.25)$$

$${}^iR_{S^0} = \frac{{}^iR_T \times (r+1)}{r \times {}^i\alpha_{H_2S/S^0} + \frac{2}{3} \times {}^i\alpha_{HSO_4^-/S^0} + \frac{1}{3}} \quad (A.26)$$

$${}^iR_{H_2S} = \frac{{}^iR_T \times (r + 1)}{r + \frac{1}{3} \times {}^i\alpha_{S^0/H_2S} + \frac{2}{3} \times {}^i\alpha_{HSO_4^-/H_2S}} \quad (A.27)$$

The solutions to Eq. A.25 and A.26 over the specified r and T values are what is represented in Fig. 17 in the main text.

We note that Kusakabe et al. (2000) derived their version of this model in terms of $\delta^{34}S$ values (rather than isotope ratios) and the equivalent of ${}^{34}\epsilon$ values (rather than values of ${}^{34}\alpha$, where ${}^{34}\epsilon \equiv {}^{34}\alpha - 1$ in units of ‰). If the same approach is followed above but mass balance and fractionation factors are cast in these terms instead to derive the equivalent of Eq. A.25 the following is obtained:

$$\delta^i S_{HSO_4^-} = \frac{\delta^i S_T + \left(\frac{r}{r+1}\right) \times {}^i\epsilon_{HSO_4^-/H_2S} + \frac{1}{3} \times \left(\frac{1}{r+1}\right) \times {}^i\epsilon_{HSO_4^-/S^0}}{{}^i\alpha_{H_2S/HSO_4^-} \times \left(\frac{r}{r+1}\right) \times \left(\frac{1}{3} \times {}^i\alpha_{S^0/HSO_4^-} + \frac{2}{3}\right) \times \left(\frac{1}{r+1}\right)} \quad (A.28)$$

The numerator of Eq. A.28 is identical to Kusakabe et al. (2000)'s Eq. 11 ($i = 34$), indicating that Kusakabe et al. (2000) (and by extension Taran et al. 1996; Marini et al., 2011, in analogous models) omit the denominator terms in Eq. A.28 in their expressions. This approximation taken by these previous studies (Taran et al. 1996; Kusakabe et al. 2000; Marini et al. 2011) appears to impart minimal errors into computations of $\delta^i S$ values but does lead to spurious errors in the computation of $\Delta^{33}S$ and $\Delta^{36}S$ values and, thus, is avoided here.

Table 4: Coefficients of polynomial fits to mean β -values (or related κ values) and standard deviation of the mean (1 s.d.) of β -values for aqueous sulfur compounds computed at the B3LYP/6-31+G(d,p) level in numerous water clusters each over $T = 0-5000^\circ\text{C}$. Quantities are computed using the coefficients via: ${}^{34}\beta$ or ${}^{33/34}\kappa$ or ${}^{36/34}\kappa$ or 1 s.d. = $A/T^4 + B/T^3 + C/T^2 + D/T + E$ where T is temperature in Kelvin (K). Values for ${}^{33}\beta$ and ${}^{36}\beta$ are computed from the ${}^{33/34}\kappa$ and ${}^{36/34}\kappa$ exponents, respectively, using: ${}^{33}\beta = {}^{34}\beta({}^{33/34}\kappa)$ and ${}^{36}\beta = {}^{36}\beta({}^{36/34}\kappa)$ at a given temperature. Note that the 1 s.d. are given for ${}^{33}\beta$ and ${}^{36}\beta$ values rather than for κ values. To compute a coefficient, treat column headers and tabulated values as equations where you solve for the coefficient. For example, to compute A for the ${}^{34}\beta$ of S_2^{2-} we begin with $A \times 10^{-4} = -176.026$ from the table and then solve for A: $A = -176.026 \times 10^4 = -1.76026 \times 10^6$ (or -1760260). Extra significant figures are given for the coefficients to minimize rounding errors.

Compound	$n\text{H}_2\text{O}$	${}^{34}\beta$					${}^{33/34}\kappa$					${}^{36/34}\kappa$				
		$A \times 10^{-4}$	$B \times 10^{-2}$	C	$D \times 10^3$	E	$A \times 10^{-4}$	$B \times 10^{-2}$	C	$D \times 10^3$	E	$A \times 10^{-4}$	$B \times 10^{-2}$	C	$D \times 10^3$	E

Table 5: Coefficients from polynomial fits to mean and standard deviation of the mean of RPFR-values for polythionates computed at the B3LYP/6-31+G(d,p) level in numerous water clusters each over $T = 0-5000^\circ\text{C}$. Values are computed using the coefficients via: $^{34}\text{RPFR}$ or $\ln(^{33}\text{RPFR})/\ln(^{34}\text{RPFR})$ or $\ln(^{36}\text{RPFR})/\ln(^{34}\text{RPFR})$ or $1 \text{ s.d.} = A/T^4 + B/T^3 + C/T^2 + D/T + E$ where T is temperature in Kelvin (K). Extra significant figures are given for the coefficients to minimize rounding errors.

Compound	nH_2O	$^{34}\text{RPFR}$					$\ln(^{33}\text{RPFR})/\ln(^{34}\text{RPFR})$					$\ln(^{36}\text{RPFR})/\ln(^{34}\text{RPFR})$
