ABSTRACT

Isotopes of radium lighter than mass 215 were studied at the Heavy Ion Linear Accelerator by bombardment of \( ^{206}\)Pb with \(^{12}\)C and \(^{197}\)Au with \(^{19}\)F. Silicon (Au) surface-barrier detectors were used in on-line measurements to measure \( \alpha \)-decay characteristics. Mass number assignments of \(^{214}\)Ra through \(^{206}\)Ra were made on the basis of excitation functions and genetic relationships with francium, emanation, and astatine isotopes. Half-lives and accurate \( \alpha \) energies were determined for the radium isotopes, and the \( \alpha \) energy of \(^{214}\)Fr was corrected. Alpha and \( \beta \) branchings were measured for \(^{213}\)Ra and \(^{214}\)Ra. Some systematic trends in the alpha decay energies were interpreted in terms of a weakening of neutron and proton pairing energies near closed shells.
I. INTRODUCTION

We are engaged in an extensive study of the \( \alpha \)-decay properties of the neutron-deficient isotopes of elements between lead and thorium. Many nuclides in this region are known from previous reports\(^1\) but improved performance of the Berkeley Heavy Ion Linear Accelerator (HILAC) and further developments in on-line techniques have made it possible to collect more accurate information and to detect previously unknown activities. The information so obtained is interesting in its own right and is valuable in connection with the method of closed \( \alpha-\beta \) decay cycles for improving and extending estimates of atomic masses, \( \alpha \)- and \( \beta \)-decay energies, and neutron-and proton-binding energies. In addition, in experiments designed to investigate transuranium nuclides, \( \alpha \)-active nuclides in the lead to thorium region may appear either as the result of rapid and complex decay chains or, more usually, through the influence of trace impurities on the target materials. Hence it is desirable to have as complete a knowledge of these nuclides as is possible.

In three previous papers we have reported \( \alpha \)-decay properties of light isotopes of polonium and astatine,\(^2\), radon,\(^3\) and francium.\(^4\) In this report light radium isotopes are considered.

Griffioen and Macfarlane\(^5\) have obtained \( \alpha \) energies and half-lives for \( ^{212}\text{Ra} \), \( ^{213}\text{Ra} \), and \( ^{214}\text{Ra} \). From the systematic trends of \( \alpha \) decay in this region several more radium isotopes can be expected to have half-lives long enough to be detected with the present method. In this work we observed a number of new activities which, on the basis of half-lives, accurate \( \alpha \) energies, and excitation functions, can be attributed to \( ^{206}\text{Ra} \) through \( ^{214}\text{Ra} \). Excitation functions of the daughter activities were also determined. Careful inspection of the data provided multiple verification of most of the radium mass number assignments.
II. EXPERIMENTAL

Our experimental technique was a modification of the method used by Macfarlane and Griffioen. Essentially, the products recoiling from a thin target were slowed to thermal energies in a helium atmosphere and swept through a small nozzle onto a catcher foil in an adjacent vacuum chamber. The products thus deposited were then quickly positioned in front of a Si (Au) surface-barrier detector. Small amounts of activity were collected on the catcher foil in less than 50 msec while the collection time for the major part was of the order of seconds. In a typical experiment recoil activity was alternatively collected for a fraction of a second and counted for the same period, with the cycle repeated over a period of 10 to 20 minutes. The apparatus, the electronics, and the special energy calibration method are described in a previous article.

The reactions used in the study were:

\[ {^{197}}\text{Au}(^{19}_F, xn)^{216-}_x\text{Ra} \quad \text{and} \quad {^{206}}\text{Pb}(^{12}_C, xn)^{218-}_x\text{Ra} \]

where \( x \) refers to the number of evaporated neutrons. The targets were 2.5 mg/cm\(^2\) gold leaf and separated \( ^{206}\text{Pb} \) (97.2\% \( ^{206}\text{Pb} \), 1.3\% \( ^{207}\text{Pb} \), 1.39\% \( ^{208}\text{Pb} \), according to the supplier, Oak Ridge National Laboratory) electroplated on 2.3 mg/cm\(^2\) nickel foil. The thickness of the \( ^{206}\text{Pb} \) target was about 0.3 mg/cm\(^2\).

Maximum beam energy was 197 MeV for \( ^{19}_F \) and 125 MeV for \( ^{12}_C \). Lower energy beams were obtained by inserting stacks of 1.72 mg/cm\(^2\).
aluminum absorber foils in front of the target. The range-energy relationships of Northcliffe were used to calculate the energy degradation in the absorbers.

The excitation functions were measured starting at the Coulomb barrier and progressively increasing the beam energy until the maximum energy was reached, or vice versa, starting at full beam energy and ending at the barrier. The total integrated beam current was the same for all runs, each of which required about 15 minutes, with an interval of about three minutes between measurements. With this time schedule, some distortion of the excitation functions of the longer lived daughter activities was observed owing to the recording of residual activity from one measuring period to the next.

In separate experiments half-lives of individual α peaks were determined with the techniques outlined previously.
III. RESULTS

A number of representative α spectra obtained at different bombarding energies are shown in Figs. 1 and 2. Excitation functions derived from the complete sets of α spectra are presented in Figs. 3 and 4. The first of these shows the yield versus bombarding energy curves for individual radium and daughter activities from the reactions \( ^{206}\text{Pb}(^{12}\text{C},xn)^{218}\text{-Ra} \), while Fig. 4 displays the corresponding information for the \( ^{197}\text{Au}(^{19}\text{F},xn)^{216}\text{-Ra} \) reactions. The radium yield curves have the regular behavior expected of compound nucleus reactions so that tentative mass number assignments can be made to the unknown radium activities. These assignments are bolstered by the similarity in shape of the yield curves for francium daughters (produced by electron capture of the radium parents) and emanation daughters (produced by α decay of radium parents). In several cases even the astatine granddaughter was observed. The daughters in turn were identified on the basis of their α-particle energies and half-lives. The behavior of the radon daughter activity was particularly reliable since any radon produced by direct reactions would fail to collect; the observed radon activity must have been formed by the decay of radium on the catcher foil.

In the case of the radium isotopes with half-lives 3.8 sec or less (mass number below 211) the observed radium intensities are much less than the observed intensities for the daughters. This is a result of decay in flight of the short-lived radium parent before it can be swept from the chamber and collected on the catcher foil. When this occurs the longer-lived francium daughter or astatine granddaughter activity is collected and counted. This effect does not prevent
the observation and identification of the radium isotope but it interferes with the determination of $\alpha$/EC branch ratios and with the estimation of reaction cross sections for production of the shorter-lived isotopes.

Details of the analysis of the excitation curves are given in the following paragraphs where the individual radium isotopes are discussed. To aid the discussion some of the excitation function data have been replotted in Fig. 5 in a manner to classify the relation of parent and daughter activities. A summary of the new radium results is given in Table I. The quoted errors are conservative limits covering the total spread of many individual measurements and are substantially greater than the statistical uncertainty.

A. Radium-$^{214}_\text{Ra}$

Griffioen and Macfarlane$^5$ have reported an $\alpha$ energy of 7.17 MeV and a half-life of 2.6 sec for $^{214}_\text{Ra}$. The corresponding values obtained in the present investigation are 7.136 MeV and 2.6±0.2 sec. The peak is shown in Fig. 1. The assignment is based on the excitation function of the peak shown in Fig. 3. Additional evidence is provided by the excitation function of the composite $6.037$-MeV peak which belongs to $^{209}_\text{Rn}$ and to $^{210}_\text{Rn}$, the latter being the $\alpha$-decay daughter of $^{214}_\text{Ra}$.

An $\alpha$ energy of 8.55 MeV and a half-life of 3.9 msec have been reported for $^{214}_\text{Fr}$. The weak peak at 8.430 MeV in the spectra obtained from the $^{206}_\text{Pb} + ^{12}_\text{C}$ reactions (Fig. 1) must be the same activity in equilibrium with its $^{214}_\text{Ra}$ parent. Its apparent half-life is 2.6 sec, equal to that of $^{214}_\text{Ra}$, and its
excitation function in Fig. 3 follows that of $^{214}$Ra. From the intensity ratio of the peak at 8.430 MeV to that at 7.136 MeV the electron-capture branching of $^{214}$Ra was determined to be $0.09 \pm 0.03\%$.

**B. Radium-213**

The $\alpha$ spectrum of $^{213}$Ra is shown in Fig. 1. The energies and relative intensities of the three observed peaks are: 6.730 MeV, $45 \pm 2\%$; 6.623 MeV, $49 \pm 2\%$; and 6.520 MeV, $6 \pm 1\%$. The half-life was measured to be $2.75 \pm 0.15$ minutes. Values reported previously were: $\alpha$ energies 6.74 and 6.61 MeV, and half-life 2.7 minutes.$^5$

The excitation functions in Fig. 3 show clearly that the three peaks belong to one isotope. The yield maxima occur at the bombarding energy expected for the $^{206}$Pb($^{12}$C,5n)$^{213}$Ra reaction. Furthermore the yield curve of the electron-capture daughter, $^{213}$Fr, has the same shape at low beam energies, although at higher energies most of the $^{213}$Fr is probably produced by direct reactions. The composite $^{209,210}$Rn excitation curve also agrees with this assignment. The weak $\alpha$ peak at 8.090 MeV belongs to $^{213}$Rn, the electron-capture daughter of $^{213}$Fr.$^4$ Its excitation function is shown in Fig. 3.

The $\alpha$ and electron-capture branches of $^{213}$Fr are known to be 99.4 and $0.57\%$, respectively.$^4$ Thus, the $\alpha$ and electron-capture branches of $^{213}$Ra can be determined from the present spectra. Under the assumption that direct production of $^{213}$Fr is negligible at $^{12}$C-beam energies lower than 85 MeV, the $\alpha$ branch of $^{213}$Ra is $80 \pm 5\%$ and the electron-capture branch $20 \pm 5\%$.
In a few spectra taken close to 85-MeV beam energy (Fig. 1) where the contributions of $^{212}$Fr groups are small, a weak peak can be seen at $6.408\pm0.05$ MeV. It is reasonable to assign it to $^{213}$Ra. Unfortunately, no reliable half-life was obtained for this peak, and its excitation function (Fig. 3) cannot be determined separately from that of the interfering $^{212}$Fr groups. If the assignment to $^{213}$Ra is correct, the relative intensity of the peak is $0.4\pm0.2\%$.

C. Radium-$^{212}$ and Radium-$^{211}$

Systematic trends in $\alpha$ decay indicate that $\alpha$ energies of $^{212}$Ra and $^{211}$Ra should be nearly the same. An $\alpha$ peak at 6.90 MeV (Figs. 1 and 2) has a broad excitation function which is most logically explained as a composite curve for these two isotopes. Moreover, the composite excitation curve for the $^{208,207}$Em daughter pair (Fig. 5(a)) is similar to the composite parent curve. The excitation function of $^{211}$Fr (Fig. 5(a)), the electron-capture daughter of $^{211}$Ra, is combined with that of $^{210}$Fr because of the similarity in $\alpha$-particle energies, but the low energy part of the composite curve is chiefly $^{211}$Fr and it provides good evidence for the position of $^{211}$Ra in the composite $^{211,212}$Ra parent curve. The intensity of $^{212}$Fr $\alpha$ activity was too low to permit construction of good excitation functions because the electron-capture branching of $^{212}$Ra is low, the half-life of $^{212}$Fr is long (19.3 min), and its $\alpha$ decay is complex.

In careful measurements made at beam energies where $^{212}$Ra was predominant over $^{211}$Ra, we determined an $\alpha$ energy of 6.896 MeV and a half-life of $13\pm2$ sec.

At beam energies where $^{211}$Ra was the principal activity we determined values of
6.910 MeV and 15±2 sec. The values reported previously for \(^{212}\text{Ra}\) are 6.90 MeV and 18 sec\(^5\); no reports exist for \(^{211}\text{Ra}\).

**D. Radium-210 and Radium-209**

From the systematic trends in properties, the α energies of \(^{210}\text{Ra}\) and \(^{209}\text{Ra}\) are also expected to be very similar. A peak is seen at 7.01 MeV (Figs. 1 and 2) which we may attribute to these isotopes. The excitation function of this peak (Fig. 5(b)) is broad and is similar to the composite yield curve of the α daughters, \(^{206}\text{Rn}\) and \(^{205}\text{Rn}\) (Fig. 5(b)). The excitation functions of the β-decay daughters, \(^{210}\text{Fr}\) and \(^{209}\text{Fr}\) are combined with those of \(^{211}\text{Fr}\) and \(^{208}\text{Fr}\), respectively. Their behavior is in agreement with the radium assignments. The yield curve of the grand-daughter, \(^{205}\text{At}\), is also in agreement after allowance is made for its shift toward higher-beam energies caused by the 26-min half-life; i.e., by the persistence of some \(^{205}\text{At}\) α activity from one measuring period to the next.

From measurements made at a 105 MeV \(^{19}\text{F}\) beam energy where \(^{210}\text{Ra}\) predominates over \(^{209}\text{Ra}\) we measured an α energy of 7.018 MeV and a half-life of 3.8±0.2 sec. Properties of \(^{209}\text{Ra}\) were measured on samples prepared at a beam energy of 140 MeV. The α energy and half-life are 7.008 MeV and 4.7±0.2 sec, respectively.
E. Radium-208 and Radium-207

Another pair of radium isotopes with similar α energies is $^{208}$Ra and $^{207}$Ra. Alpha-energy calibrations were made at several beam energies to determine whether the peak at 7.131 MeV in Fig. 2 consists of two unresolved components. Only one value was observed, however, and it was attributed both to $^{208}$Ra and $^{207}$Ra. The half-life of the group was also determined at several beam energies. Values between 1.1 and 1.4 sec were observed, the shorter ones coming systematically from measurements at lower beam energies. Therefore, $1.3 \pm 0.2$ sec is reported for $^{207}$Ra and $1.2 \pm 0.2$ sec for $^{208}$Ra. Since these half-life errors overlap, the burden of proof for the existence of two isotopes falls on the observation of the daughter products.

The excitation function of the 7.131-MeV peak in Fig. 5(c) is broad which indicates that it belongs to two isotopes. If small deviations caused by experimental difficulties are ignored, the yield maxima of $^{207}$Fr and $^{205}$At in Fig. 5(c) fall at the same beam energy as the estimated excitation maximum of $^{207}$Ra. Similarly, the yield maxima of $^{208}$Fr and $^{204}$At fall at the beam energy expected for the maximum yield of $^{208}$Ra.
F. Radium-206

The weak α group at 7.270 MeV in Fig. 2 belongs to $^{206}$Ra. Its half-life was measured to be $0.4\pm0.2$ sec. The excitation function of this peak resembles those of $^{206}$Fr, $^{202}$At, and $^{202m}$At in Fig. 5(d). Francium-206 is the electron capture daughter of $^{206}$Ra; $^{202}$At and $^{202m}$At are granddaughters.

Radium isotopes lighter than $^{206}$Ra can be expected to have half-lives too short to be detected with the present equipment. The relatively strong $^{205}$Fr group at 6.917 MeV and $^{201}$At group at 6.342 MeV in Fig. 2 (see also Fig. 5(d)) indicate that $^{205}$Ra was produced but that it decayed to $^{205}$Fr and $^{201}$At before the recoil atoms were collected.

G. Polonium Isotopes

In the bombardment of gold with 172 MeV fluorine ions α activity of polonium appeared in the spectra (Fig. 2). The yield of these isotopes dropped off quickly with decrease in energy of the fluorine ions and do not show any clear relationship to the yields of the radium isotopes. As it is most likely these polonium isotopes were produced by some type of partial transfer reaction, not involving the initial production of radium isotopes, we do not discuss them in this paper.
IV. DISCUSSION

The general features of the radium isotopes are similar to those of the neighboring elements discussed in our previous reports.\(^{2-4}\) The dependence of α-decay energy on neutron number shown in Fig. 6 demonstrates this quite clearly. There is a sharp discontinuity at 126 neutrons and a regular step-like behavior below 126 neutrons. The decay energies of the even-neutron isotopes are higher and the decay energies of the odd-neutron isotopes lower than the averages corresponding to a smooth variation with mass number. This indicates that the steps are a consequence of the pairing of neutrons, and more specifically that the pairing energy is stronger in the daughter than in the parent. In other words, the neutron-pairing energy decreases as the 126-neutron closed shell is approached. This behavior has been noted by other authors,\(^{12,13}\) but the new radium isotopes provide additional evidence for the regularity of this feature. We note also that the curves for different elements are not equally spaced. The curve for an odd-proton element is closer to the one of the higher even-proton element; e.g., the francium curve is closer to radium than radon. This suggests that the unequal spacings are a consequence of the pairing of protons and that the proton pairing energy is greater in the parent than in the daughter. Stated another way, the proton-pairing energy increases as more protons are added beyond the 82 closed shell. Thus, the step-like behavior and the unequal spacings of the curves can be explained as a result of a weakening of the neutron- and proton-pairing energies as the closed shell configurations (126 and 82 nucleons) are approached.
A brief inspection of the existing data shows that this trend of weaker pairing near the shell is valid as well on the neutron-rich side of the 126-neutron shell. The step-like behavior is reversed in the sense that the even-neutron isotopes are depressed relative to the odd-neutron isotopes but the spacings between elements remain the same as on the neutron deficient side. The principle seems valid also around other closed shells although it is less pronounced. This behavior provides a useful method for predicting and checking experimental results.

The new data presented in this paper are useful for extending the table of nuclear masses by the general method of $\alpha$-$\beta$ decay energy cycles. The masses so obtained are valuable in turn for the derivation of other quantities such as neutron- and proton-separation energies. The most up-to-date published review of $\alpha$-$\beta$ decay cycles and masses is that of Viola and Seaborg.\(^{12}\) In Table II we compare our experimental $\alpha$ Q-values with the experimental and estimated values given by these authors. The results establish the quality of the previous estimates and permit an extension of them to even lighter nuclei.

In this paper we are concerned with the products of the heavy ion induced nuclear reactions rather than the reactions themselves. However, it is easy to extract one quantity of some interest for the excitation function curves. From the beam energy at the maximum yield of each radium isotope, from the Q-value of the reaction, and from the neutron separation energies of the isotopes involved in the evaporation chain, one can deduce the average amount of energy dissipated in neutron kinetic energy plus $\gamma$ energy in each neutron evaporation step. How this is done is covered in the discussion of a previous paper.\(^4\) It is known
from previous work of Alexander and Simonoff\textsuperscript{14} and of Kaplan\textsuperscript{15} that in heavy ion reactions involving rare-earth targets 4.8 to 6.3 MeV is dissipated for each neutron evaporated. In our analysis of the Au + F results in Fig. 4 we find that an average of 4.8 MeV is required in the evaporation of the first 4 neutrons and the energy dissipated in the evaporation of the next 6 neutrons varies between 6.0 and 8.1 MeV.

ACKNOWLEDGMENT

We thank Albert Ghiorso for his interest and encouragement in this work. We are indebted to Charles Corum for equipment design and to the HILAC crew for operation of the accelerator.
FOOTNOTE AND REFERENCES

This work was done under the auspices of the U. S. Atomic Energy Commission.

Table I. Present results compared with those of Griffioen and Macfarlane (Ref. 5). The following energy standards were used: $^{212}\text{Po}$ 8.7859 MeV, $^{213}\text{Po}$ 7.3841 MeV, $^{219}\text{Bi}$ 6.8176 MeV, $^{211}\text{Bi}$ 6.6221 MeV, $^{212}\text{Bi}$ 6.0896 MeV, $^{212}\text{Bi}$ 6.0506 MeV (Ref. 8); $^{216}\text{Po}$ 6.7772 MeV, $^{220}\text{Rn}$ 6.2884 MeV, $^{224}\text{Ra}$ 5.6840 MeV (Ref. 9).

$^a$The Q-value is the α-particle energy for the ground-state transition corrected for the recoil energy of the daughter nucleus.

$^b$In this case the assumption is made that the most energetic α group is a ground-state transition.
