Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

Exposure to diverse sarbecoviruses indicates frequent zoonotic spillover in human communities interacting with wildlife

ABSTRACT

Background: Sarbecoviruses are a subgenus of *Coronaviridae* that mostly infect bats with known potential to infect humans (SARS-CoV and SARS-CoV-2). Populations in Southeast Asia, where these viruses are most likely to emerge, have been undersurveyed to date.

Methods: We surveyed communities engaged in extractive industries and bat guano harvesting from rural areas in Myanmar. Participants were screened for exposure to sarbecoviruses, and their interactions with wildlife were evaluated to determine the factors associated with exposure to sarbecoviruses.

Results: Of 693 people screened between July 2017 and February 2020, 12.1% were seropositive for sarbecoviruses. Individuals were significantly more likely to have been exposed to sarbecoviruses if their main livelihood involved working in extractive industries (logging, hunting, or harvesting of forest products; odds ratio [OR] = 2.71, $P = 0.019$) or had been hunting/slaughtering bats (OR = 6.09, $P = 0.020$). Exposure to a range of bat and pangolin sarbecoviruses was identified.

Conclusion: Exposure to diverse sarbecoviruses among high-risk human communities provides epidemiologic and immunologic evidence that zoonotic spillover is occurring. These findings inform risk mitigation efforts needed to decrease disease transmission at the bat-human interface, as well as future surveillance efforts warranted to monitor isolated populations for viruses with pandemic potential.

Introduction

The COVID-19 pandemic, which has profoundly altered the health, livelihoods, and economies of the world, highlights the urgent need for a broad surveillance for zoonotic spillover, especially

for pathogens with pandemic potential in at-risk communities. The earliest known cases of COVID-19 from December 2019 were geographically centered on the Huanan Seafood Market in Wuhan, China [1–3]. Live SARS-CoV-2-susceptible mammals were sold at the market in late 2019 and SARS-CoV-2-positive environmental samples were spatially associated with vendors selling live mammals, suggesting zoonotic emergence at the market [3]. SARS-CoV-2, the virus causing COVID-19, is a betacoronavirus in the *Sarbecovirus* subgenus [4], which is composed of SARS-CoV-1, SARS-CoV-2, numerous bat viruses, and a small number of pangolin viruses [5,6]. The genome of SARS-CoV-2 has a 96.2% similarity to that

of a bat SARS-related coronavirus (SARSr-CoV; RaTG13) collected from an insectivorous Chinese horseshoe bat (*Rhinolophus affinis*) in Yunnan province, more than 1000 miles away from Wuhan, along the border with Myanmar [1]. *Rhinolophus spp.* bats in Asia, Europe, and Africa are considered the natural reservoirs of sarbecoviruses [7,8]; however, the concentrated numbers of SARSr-CoVs found in South and Southeast Asia make this a region of high significance for surveillance in wildlife. Genetically similar SARSr-CoVs have been found in other species of *Rhinolophid* bats in South and Southeast Asia, including *Rhinolophus pusillus* and *Rhinolophus malayanus* in China [9]; *Rhinolophus cornutus* in Japan [10]; *Rhinolophus shameli* in Cambodia [11]; *Rhinolophus acuminatus* in Thailand [12]; and *Rhinolophus malaanus*, *Rhinolophus pusillus*, and *Rhinolophus marshalli* in Laos [13].

Given the diversity of closely related sarbecoviruses in bats within the *Rhinolophus* genus in Asia, SARS-CoV-2 could have arisen from a single bat species or resulted from a recombination of SARSr-CoVs among animals in shared habitats. However, the epidemiologic circumstances surrounding the emergence(s) of SARS-CoV-2 and the ecology of potential pre-emergent viruses within the *Sarbecovirus* genus remain largely unknown. Investigations into sarbecovirus infections in humans with activities that place them in high contact with bats, such as extractive industries, guano harvesting, and hunting, have been insufficient to date [14]. Given the increasing interconnectedness of rural populations, more effort is needed to identify and characterize the currently unrecognized sarbecoviruses that circulate in wildlife and their potential to spill over to people to better understand the origin of SARS-CoV-2 and to evaluate the potential for the next novel CoV to emerge from wildlife.

CoV richness is strongly correlated with bat richness, suggesting that most CoVs will be found in regions where bat diversity is highest. Based on the distribution and diversity of *Rhinolophus* bats, Southeast Asia, including Myanmar, Cambodia, Laos, and Thailand, along with Southeastern China, are considered hotspots for sarbecoviruses of potential zoonotic concern [15]. This is supported by the number of CoVs, which have been discovered in China [16], Thailand [17], Cambodia, Lao People's Democratic Republic [18], and Myanmar [19]. The risk for zoonotic viral disease presence and emergence in humans also increases in geographic areas with higher mammal diversity, where previously pristine forests have been recently deforested [20]. This makes the areas of Southeast Asia, which support large, intact natural habitats and have ongoing ecosystem fragmentation, at high risk for disease emergence [21].

Myanmar has taken a proactive approach to diseases emerging from wildlife, partnering with the international community to conduct “upstream” surveillance of viral pathogens in both wildlife and high-risk communities for wildlife contact. In response to the COVID-19 pandemic, several ongoing human surveillance programs were used to evaluate the exposure to sarbecoviruses before the first recognized cases of SARS-CoV-2 in the country and to better understand the types of human behaviors, geographic regions, and potential species implicated in the spillover of sarbecoviruses from wildlife to humans in this important ecological region for CoV emergence.

Methods

Study population and procedures

Human subjects were enrolled in this research through three surveillance studies between July 2017 and February 2020 (before the first reported case of SARS-CoV-2 in Myanmar) (Figure 1). Written informed consent was obtained from all participants in accordance with the University of California, Davis and Department

of Medical Research, Myanmar approved protocols. As part of a United States-Myanmar partnership funded by the National Institutes of Health Fogarty International Center (NIH) to investigate the epidemiology of zoonotic viruses in key biodiversity areas of Myanmar, healthy people (N = 86) were enrolled from five elephant logging camps in the Yenwe Forest Reserve. Myanmar still uses the traditional method of elephant logging for timber harvest and as a result, has a large network of communities where loggers live together in temporary villages on the forest edges with their families and, occasionally, migrant laborers. Cases of acute febrile illness (N = 144) were enrolled from the closest local hospitals to the elephant camps. As part of the United States Agency for International Development Emerging Pandemic Threats PREDICT project, healthy people were enrolled in the study from two regions believed to have high levels of contact with bats, villages from the Hpa-an region (N = 169) and rural Northern Yangon villages (N = 198). As part of the dengue surveillance program conducted by the Department of Medical Research, cases of dengue hemorrhagic fever (N = 98) enrolled at Yangon Children's Hospital were included in the study as an urban non-bat-exposed control group. For the confirmation of assay performance as a validation step, samples from reverse transcription-polymerase chain reaction (RT-PCR)-confirmed cases of COVID-19 (n = 28) during the first COVID-19 wave in Yangon, Myanmar were collected serially at 7-day intervals for 4 weeks after the confirmation of infection status were used. For the NIH and PREDICT studies, a serum sample was collected from all study participants, and a behavioral questionnaire was administered to assess contact with wild animals. Efforts were taken to minimize recall bias by framing all questions in two separate time frames, both “in their lifetime” and “within the past year”. The questions were also repeated in different formats throughout the survey asking about wildlife exposure, both within the context of hunting (which could have legal consequences) and outside the context of hunting. Children enrolled from the city of Yangon were not administered a questionnaire because they were enrolled as part of an acute dengue surveillance program from an urban area of the study. Given the urban nature of this community in Central Yangon, they were considered to not be engaged in high-risk activities involving bats or extractive industries. Bats are not known to be widely distributed within the central metropolitan area of Yangon, and extractive industries are also not located there.

Diagnostic assays

SARS-CoV-2 surrogate virus neutralization assays

All specimens were tested using a commercially available SARS-CoV-2 surrogate virus neutralization (sVNT) assay that detects the total immunodominant neutralizing antibodies (NAbs) targeting the viral spike protein receptor-binding domain (RBD) in an isotype- and species-independent manner (cPass SARS-CoV-2 Neutralization Antibody Detection Kit, Genscript, Inc). The assay is based on antibody-mediated blockage of the interaction between the human angiotensin-converting enzyme 2 (ACE2) receptor protein and the receptor-binding domain. This assay was validated with two cohorts of patients with COVID-19 in two different countries, achieved 99.9% specificity and 95–100% sensitivity [22] for SARS-CoV-2, and has been shown to not cross-react to other circulating human CoVs, including SARS-CoV. This assay has not been validated for specificity against phylogenetically related sarbecoviruses not yet known to infect humans; therefore, positive cPass results were interpreted as a sample having seropositivity to a virus strain within the *Sarbecovirus* subgenus. The samples were tested in duplicate according to the manufacturer's instructions at the Department of Medical Research in Myanmar. The cut-off value for the cPass SARS-CoV-2 Neutralizing Antibody Detection Kit is

Figure 1. Locations of human communities within Myanmar.

30% signal inhibition. The percent signal inhibition for the detection of NAbs was calculated as:

$$\%Signal\ Inhibition = \left(1 - \frac{OD\ value\ of\ Sample}{OD\ value\ of\ Negative\ Control} \right) \times 100\%$$

Multiplex sVNT assay

A subset of sVNT cPass positive specimens (all positive specimens collected through the NIH surveillance project) was tested for multiple sarbecoviruses using a bead-based multiplex system. The assay measures RBD, targeting NAbs. The assay determines the extent to which NAbs block the interaction between AviTag-biotinylated RBD proteins coated on Luminex microspheres and human ACE2 (calculated as % inhibition). The RBDs included in this study were from (A) clade 2 sarbecoviruses: SARS-CoV-2 Ancestral (NC_045512), SARS-CoV-2 variants of concern (VOCs) (VOCs Alpha (EPI_ISL_2245907), Beta (EPI_ISL_2372356), Lambda (EPI_ISL_3320902), Gamma (EPI_ISL_8939421), Delta (EPI_ISL_5020183), Delta Plus (EPI_ISL_12386865), Mu (EPI_ISL_2897550), Omicron BA.1 (EPI_ISL_7456451), Omicron BA.2 (EPI_ISL_13019463), bat CoV BANAL-52 (MZ937000), Bat CoV BANAL-236 (MZ937003), pangolin CoV GD-1 (EPI_ISL_410721), bat CoV RaTG13 (MN996532), and pangolin CoV GX-P5L (EPI_ISL_410540) and (B) Clade-1 sarbecoviruses: SARS-CoV-1 (AY278488) and bat CoV WIV-1 (KF367457), bat CoV Rs2018B (MK211376), bat CoV LYRa11 (KF569996), and bat CoV RsSHC014 (KC881005). Biotinylated RBD proteins were produced as described previously [23]. Multiplex sVNTs were es-

tablished as previously described [24]. Briefly, AviTag-biotinylated RBD proteins were coated on MagPlex-Avidin microspheres (Luminex) at 5 μ g per 1 million beads. RBD-coated beads (600 per antigen) were preincubated with a testing serum final dilution of 1:20, 1:80, 1:320, 1:1280) for 15 minutes at 37°C with agitation, followed by an addition of 50 μ l of phycoerythrin-conjugated human ACE2 (2 mg/ml; Genscript) and incubated for an additional 15 minutes at 37°C, with agitation. After two washes with 1% bovine serum albumin in phosphate buffered saline, the final readings were acquired using the MAGPIX system (Luminex), following the manufacturer's instruction. The cut-off values were set at 30% inhibition, as described previously for cPass sVNTs.

SARS-CoV-2 plaque reduction neutralization assays

Human sera were thawed at 37°C and 30 μ l was heated in a water bath for 30 minutes at 56°C to inactivate the complement proteins. The serum was diluted four-fold with virus diluent consisting of phosphate buffered saline and 1% fetal bovine serum. Then, samples were serially two-fold diluted 11 times for a dynamic range of 1:4 to 1:4096. An equal volume of virus diluent containing 80 plaque-forming units of SARS-CoV-2 was added to each antibody dilution and a no-antibody control consisting of virus diluent only, resulting in a final dynamic range of 1:8-1:8192 with one no-antibody control. The virus strain used was SARS-CoV-2/human/USA/CA-CZB-59 \times 002/2020 (GenBank #MT394528), which was isolated from a patient in 2020 in Northern California and passaged once in Vero E6 cells (provided by Dr. Christopher Miller, University of California, Davis). To generate stocks for

the plaque reduction neutralization assay (PRNT), SARS-CoV-2 was passaged one additional time in Vero E6 cells to achieve a titer of 2.2×10^7 plaque-forming units/ml. Single-use virus aliquots were stored at -80°C . The antibody-virus dilution series were incubated for 1 hour at 37°C , after which they were applied to confluent Vero CCL-81 cells in single replicate and incubated for 1 hour at 5% CO_2 and 37°C in a humidified incubator. The cell monolayers were overlaid with 0.5% agarose dissolved in Dulbecco minimal essential medium with 5% fetal bovine serum and $1 \times$ antibiotic-antimycotic (Fisher Scientific, Waltham, MA, USA) and incubated for 3 days at 5% CO_2 and 37°C in a humidified incubator. Cells were fixed for >30 minutes with 4% formaldehyde, then agarose plugs were removed. Cells were stained with 0.05% crystal violet in 20% ethanol for 10 minutes, then rinsed three times with water. The plates were inverted to dry completely, and the number of plaques in each well was counted. The neutralization titer is defined as the reciprocal of the dilution for which fewer than 20% of plaques were detected versus the no-antibody control ($>80\%$ neutralization).

Conventional RT-PCR assays

All specimens collected as part of the NIH and PREDICT projects were tested for CoVs using two separate conventional RT-PCR assays. RNA was extracted using Direct-zol RNA kits (Zymo Research, Inc.), according to the manufacturer's instructions. RNA was reverse transcribed into cDNA using SuperScript III (Invitrogen), according to the manufacturer's instructions. Two broadly reactive consensus polymerase chain reaction assays targeting partial and nonoverlapping regions of the CoV ORF1b (containing the RNA-dependent RNA polymerase) were used [25,26]. Bands of the expected size were excised from 1% agarose, cloned into a Strat-aClone polymerase chain reaction cloning vector, sequenced using Sanger sequencing and compared with available nucleotide sequences in GenBank to confirm the identity.

Statistical analyses

To evaluate associations between human demographic and animal contact risk factors, all covariates were first evaluated for correlation to assess potential confounding. Pearson's chi-square tests were used to determine associations between seropositivity for sarbecoviruses and high-risk human-animal contact behaviors, such as hunting and slaughtering animals, bat guano harvesting, and other contact with wildlife or livelihoods. Statistical tests were considered significant at the level of P -value <0.05 . Mixed-effects multivariable logistic regression models were used to assess the association between high-risk wild animal contact behaviors and occupational risk factors that were significant in the bivariate analysis. Township was evaluated as a random variable to account for potential unmeasured risk factors varying by geographic location. Variables were included if they significantly improved the model fit based on the likelihood ratio test ($P < 0.1$) compared with a model without that variable. Variables were retained in the model if they improved the fit while minimizing the Akaike information criterion. All statistical analyses were performed using STATA/MP 16.1 (StataCorp, College Station, TX, USA).

Results

We identified previous exposure to sarbecoviruses among study participants but did not detect any active infections wherein all participants tested negative for CoVs by consensus RT-PCR or were a confirmed active dengue virus case within the city before the documented emergence of SARS-CoV-2. Among study participants, 12.1% (84/693) were seropositive for sarbecoviruses using the sVNT cPass assay (Table 1). Seroexposure was detected among all rural communities and there were no individuals from the urban Central Yangon communities that were seropositive for sarbecoviruses

(Figure 1). PRNTs for SARS-CoV-2 performed on seropositive individuals were all negative. A small fraction of study participants was collected during early 2020 before the documented first cases of SARS-CoV-2 in the country. Persons aged older than 20 years were significantly more likely to be seropositive for sarbecoviruses by sVNT (odds ratio [OR] = 2.9, $P = 0.009$) than those aged younger than 20 years, indicating a higher potential for exposure over time.

In the multivariable analysis, individuals who reported that their main livelihood involved extractive industries, including logging, hunting, or harvesting of forest products, were significantly more likely to have been exposed to sarbecoviruses as indicated by seropositivity on the sVNT cPass assay (OR = 2.71, $P = 0.019$; Table 2) compared with those involved in other occupations. When evaluating the specific animal taxa exposure and associated human behaviors, only activities involving bats remained significant in the mixed-effects multivariable logistic regression. Individuals who reported hunting or slaughtering bats in their lifetime were significantly more likely to have been exposed to sarbecoviruses as indicated by seropositivity on the sVNT cPass assay (OR = 6.09, $P = 0.020$; Table 2) than individuals not reporting these activities. The final mixed-effects multivariable model included hunting/slaughtering bats, extractive industry occupation, and age as fixed effects and township as a random effect (Hosmer-Lemeshow test for logit model without a random effect $X^2 = 0.4$; $P = 0.530$). Including township as a random effect significantly improved the model fit (likelihood ratio test vs logistic model: $X^2 = 13.72$; $P < 0.001$).

People who were enrolled in the study through the NIH surveillance project in the elephant logging camps and associated clinic catchment areas were also significantly more likely to be exposed to sarbecoviruses (OR = 3.31, $P < 0.001$) than those enrolled through other surveillance programs in different regions of the country. A subset of specimens ($n = 70$) from this study population was tested using a multiplex sVNT system to further investigate the diversity of sarbecovirus exposures occurring in this population. Preliminary evidence of exposure to a range of sarbecoviruses not yet known to infect humans were detected (Figure 2), including 32.8% (23/70) to RaTG13, 1.4% (1/70) to BANAL52, 2.9% (2/70) to LYRa11, 1.4% (1/70) to Rs2018B, 2.9% (2/70) to RsSHC014, and 1.4% (1/70) to WIV bat sarbecoviruses, 10% (7/70) to GxP5L, and 1.4% (1/70) to GD1 pangolin viruses. Low levels of exposure to SARS-CoV-2 VOCs were also detected, including 1.4% (1/70) to Delta, 4.3% (3/70) to Lambda, 2.9% (2/70) to Gamma, 2.9% (2/70) to Omicron BA.1, and 1.4% (1/70) to Mmicron BA.2 at the 30% inhibition cut-off. When evaluating the distributions of percent inhibition values by virus across all individuals tested, only RaTG13 had an interquartile range extending above the designated cut-off value of 30%. All individuals were significantly more likely to have antibodies against sarbecoviruses not yet known to infect humans than sarbecoviruses now known to circulate in humans (i.e., SARS-CoV and SARS-CoV-2 VOCs) ($P < 0.000$) and the detection of pre-emergent sarbecoviruses was not significantly correlated with the detection of sarbecoviruses already documented to have emerged ($R^2 = 0.099$, $P = 0.420$). People living or working in extractive industry logging camps were significantly more likely to have antibodies against bat CoV RaTG13 (OR = 2.76, $P = 0.050$) than those reporting other occupations. One individual within the subset of specimens who was evaluated using the multiplex sVNT system self-reported as being a pangolin hunter. This individual was seropositive for the pangolin sarbecovirus GxP5L.

Discussion

Our findings demonstrate exposure to diverse sarbecoviruses not yet known to infect humans in people exposed to wildlife in Myanmar. The exposure patterns that positively correlated with

seropositivity included extractive industries and bat contact, indicating a likely zoonotic transmission through animal contact as opposed to human-to-human transmission. The remote nature of these zoonotic exposure events or the absence of human-to-human transmission could explain why many of these viruses (*i.e.*, Gx-P5L, RsSHCo14, BANAL-52, B21065, LYRa11, WIV-1, GD-1, RaTG13, Rs2018B) are not yet recognized by the global community as having naturally infected humans. Our findings underpin the critical importance of continued surveillance at the rural wildlife-human interface in Southeast Asia, where some of the highest levels of known mammalian diversity exist and where future emergence of zoonotic diseases is likely.

The high relative sarbecovirus seropositivity rate in people engaged in extractive industries highlights the importance of vigilance and access to infectious disease diagnostics in these communities. Our findings are consistent with other studies, which have noted a high risk for infection with zoonotic diseases among people engaged in extractive industries worldwide [27], including

Myanmar [28]. The extractive forest industries bring people into contact with wildlife through bushmeat hunting and proximity to the forest, bringing new opportunities for exposure to zoonotic viruses [29]. Given their remote nature, people in these industries often live and work in underserved regions with weak public health and disease prevention infrastructure. Extractive industries, particularly logging, can further contribute to zoonotic disease emergence by altering wildlife habitats and forcing movement of animal populations to more human-dominated areas. Consequently, extractive industry workers and their surrounding communities are especially at risk for emerging infectious diseases.

Direct contact with bats through hunting or slaughtering was a significant risk factor for exposure to sarbecoviruses in our study populations. These findings are consistent with known sarbecoviruses being largely of bat origin. Similar studies conducted in neighboring China have found serological evidence of likely human infection by bat SARSr-CoVs or potentially related viruses in humans living near caves with a known high diversity of bat

Figure 2. Exposure to human angiotensin-converting enzyme 2-binding sarbecoviruses not yet known to infect humans among Myanmar extractive industry workers. *Greater than 30% inhibition of receptor-binding domain binding to human angiotensin-converting enzyme 2 is considered positive.

SARSr-CoVs [14]. Modeling efforts have also predicted a high richness of SARSr-CoV bat host species, as well as bat-human overlap in eastern Myanmar, increasing spillover risk [30]. Mammalian species in decline due to the loss of habitat quality or exploitation have shared more zoonotic viruses with people [31]. Thus, understanding the ecosystem changes that drive bat redistribution after habitat loss and the occupations that bring people and bats into close contact are important for informing public health mitigation measures.

We detected an sVNT antibody reactive to SARS-CoV-2 that did not neutralize SARS-CoV-2 in PRNT assays, indicating that the study participants were likely exposed to other virus strains within the *Sarbecovirus* genus and not SARS-CoV-2. The most likely explanation is that our findings represent cross-reactivity with closely related known or yet to be discovered sarbecoviruses, further highlighting the need for human and wildlife surveillance in this region. We note that the individuals in our study communities were more likely to have antibodies against sarbecoviruses not yet reported in humans than to sarbecoviruses now known to circulate in humans (*i.e.*, SARS-CoV-2 and SARS-CoV). We know very little about the clinical course of SARS-CoV-2 among isolated human communities with high levels of previous sarbecovirus exposure. An alternate hypothesis is that prior to a zoonotic transmission event from a market in the urban population of Wuhan, SARS-CoV-2 emerged in rural populations with pre-existing pan-sarbecovirus immunity; therefore, the cases were mild or asymptomatic, and stuttering chains of transmission were not detected through existing public health surveillance. This is, however, less likely given the number of documented cases of SARS-CoV-2 in these regions during subsequent stages of the pandemic during 2021–2022.

Antibodies against RaTG13 were the most identified antibodies among all sarbecovirus exposures identified in this study. RaTG13 is the closest known relative to SARS-CoV-2, previously identified in bats. Structural and molecular analysis of the RBD of RaTG13

shows binding affinity to the human receptor ACE2, as well as ACE2 orthologs in 24 other species, providing proof of concept that RaTG13 has the potential to infect humans [32]. Our data suggest that RaTG13 is the sarbecovirus that is most frequently spilling over to people in our study regions. Because RaTG13 was first discovered in a cave in Yunnan, China, along the border with Myanmar, this is not unexpected.

Exposure to sarbecoviruses from a diverse animal origin among biologically plausible high-risk communities, such as forest extractive industry workers and people in contact with bats, provides both epidemiologic and immunologic evidence that zoonotic spillover is occurring in these communities, providing further evidence for the natural origins of SARS-CoV-2 and potential emergence pathways for SARSr-CoVs. Given the worldwide impact of the SARS-CoV-2 pandemic, a better understanding of the transmission mechanisms and specific high-risk behaviors, as well as the impact that pre-existing immunity to sarbecoviruses may have on future SARS-CoV-2 variant exposure in these isolated populations is urgently needed.
