Abstract

Although the majority of adult tissues express only hexokinase 1 (HK1) for glycolysis, most cancers express hexokinase 2 (HK2) and many coexpress HK1 and HK2. In contrast to HK1–HK2+ cancers, HK1–HK2+ cancer subsets are sensitive to cytostasis induced by HK2shRNA knockdown and are also sensitive to synthetic lethality in response to the combination of HK2shRNA knockdown, an oxidative phosphorylation (OXPHOS) inhibitor diphenyleneiodonium (DPI), and a fatty acid oxidation (FAO) inhibitor perhexiline (PER). The majority of human multiple myeloma cell lines are HK1–HK2+. Here we describe an antisense oligonucleotide (ASO) directed against human HK2 (HK2-ASO1), which suppressed HK2 expression in human multiple myeloma cell cultures and human multiple myeloma mouse xenograft models. The HK2-ASO1/DPI/PER triple-combination achieved synthetic lethality in multiple myeloma cells in culture and prevented HK1–HK2+ multiple myeloma tumor xenograft progression. DPI was replaceable by the FDA-approved OXPHOS inhibitor metformin (MET), both for synthetic lethality in culture and for inhibition of tumor xenograft progression. In addition, we used an ASO targeting murine HK2 (mHK2-ASO1) to validate the safety of mHK2-ASO1/MET/PER combination therapy in mice bearing murine multiple myeloma tumors. HK2-ASO1 is the first agent that shows selective HK2 inhibition and therapeutic efficacy in cell culture and in animal models, supporting clinical development of this synthetically lethal combination as a therapy for HK1–HK2+ multiple myeloma.

Significance: A first-in-class HK2 antisense oligonucleotide suppresses HK2 expression in cell culture and in vivo, presenting an effective, tolerated combination therapy for preventing progression of HK1–HK2+ multiple myeloma tumors.

Introduction

Multiple myeloma, a clonal proliferation disorder of malignant plasma cells, is the second most common hematologic malignancy. Despite application of currently available therapies (e.g., proteasome inhibitors, immunomodulatory drugs, tumor cell-targeting monoclonal antibodies, autologous stem cell transplantation), multiple myeloma is still regarded as incurable (1); moreover, nearly all patients exhaust available therapeutic options, including clinical trials. The projected 60% increase in new multiple myeloma cases between 2010 and 2030 highlights an urgent need for effective therapies (2).

Nearly all cancers exhibit increased glycolysis—originally described almost 90 years ago as the "Warburg effect" (3). Although suggested to provide adequate energy (ATP), reducing equivalents, and/or precursors for synthesizing building blocks for cancer cell survival and proliferation, the reason(s) for increased glycolysis in cancer cells is/are still ambiguous and controversial (4).

Despite many attempts to inhibit the increased glycolysis observed in cancers, no clinical therapy based on this approach has been successful, partially because of the conserved glycolytic pathways present in normal and cancer cells, and existence of alternative metabolic pathways in cancers (5). The first enzymatic step in glycolysis, conversion of glucose to glucose-6-phosphate, is catalyzed by members of the hexokinase (HK) family (6). Most tissues express only HK1; liver expresses only HK4 (also known as glucokinase). However, although HK2 is expressed in only a few normal tissues (e.g., heart, muscle, adipose tissue) and is expendable when globally deleted in adult mice (7), most tumors, regardless of tissue of origin, express HK2 in addition to HK1 (7–11).

In a search for cancers that depend primarily on HK2 expression, we observed that cancers from nearly all tissues have subsets of HK1−HK2+ tumors (11). HK2shRNA expression had no effect on cell proliferation or xenograft tumor progression for HK1−HK2+ tumors of differing origin; in contrast, HK2shRNA expression suppressed cultured cell proliferation and xenograft tumor progression of these HK1−HK2+ tumors (11).

Using both HK1−HK2+ and HK1+HK2+ liver cancer cell lines as well as HK1−HK2+ isogenic cancer cell lines derived from parental HK1−HK2+ cancer cells by CRISPR Cas9 deletion, a high throughput screen identified diphenylenediiodonium (DPI), a mitochondrial complex I inhibitor, as a synergistic partner in inhibiting HK1−HK2+ tumor progression (12). Fatty acid oxidation (FAO) inhibition by the clinical drug perhexiline (PER) reduces ATP synthesis, and results in effective blockade of HK1−HK2+ tumor progression by the HK2shRNA/DPI/PER combination. In contrast, HK1+HK2+ tumor progression was unaffected by this combination treatment (12).

Although HK2shRNA used in our previous studies lacks translational potential, it served as a valuable research tool to establish a proof-of-concept precision therapeutic strategy, using the HK2shRNA/DPI/PER combination, for HK1−HK2+ liver cancer cells. However, the therapeutic challenges for this potential therapy include extending its efficacy to HK1−HK2+ cancer subsets from other tissues of origin, identifying a therapeutically tractable method to preferentially inhibit HK2, and finding appropriate clinical alternatives to inhibit ATP generation by OXPHOS.

In examining the Cancer Cell Line Encyclopedia (CCLE) dataset, we found that multiple myeloma has the highest percentage of HK1−HK2+ tumor subset members. Our objectives in this study were fourfold: (i) to extend our combination of inhibition of HK2 expression/activity, OXPHOS, and FAO to HK1−HK2+ multiple myeloma cancers; (ii) to identify a potential clinically applicable therapeutic agent, as opposed to the research tool HK2shRNA, to specifically suppress HK2 expression/activity; (iii) to identify a more suitable clinical therapeutic alternative to inhibit OXPHOS; and (iv) to determine the tolerability of the combination by normal tissues in living animals. Here we used an HK2 antisense oligonucleotide (ASO), HK2-ASO1, to suppress human HK2 expression. Using human HK1−HK2+ multiple myeloma cell lines as a model, we demonstrate that the HK2-ASO1/DPI/PER combination potently suppresses tumor progression. We also demonstrate that metformin (MET), an FDA-approved mitochondrial complex I inhibitor, can replace DPI in the synthetically lethal combination, improving the translational potential of the combination therapy. Finally, we used a mouse HK2 ASO to demonstrate, in HK1−HK2+ mouse multiple myeloma tumor bearing mice, the efficacy and safety of the HK2-ASO/MET/PER combination therapy.

Materials and Methods

Cell lines

Human multiple myeloma cell lines OPM1, OPM2, RPMI8226, and XG1 from the ATCC were cultured in Advanced RPMI1640 + 10% FBS. Human multiple myeloma cell lines H929, U266, MM144, and S6B43 from ATCC were cultured in RPMI1640 + 10% FBS. Mouse multiple myeloma P3 × 63Ag (P3) cells were cultured in IMDM + 10% FBS. Cells were maintained at 37°C in 5% CO₂/95% air. Cell lines were used between passages 1 and 20, and were routinely authenticated based on morphology, growth characteristics, and HK expression profiles according to CCLE gene expression dataset. Mycoplasma contamination was routinely examined using MycoAlert (Lonza, #LT07-318).

ASOs

Gen 2.5 ASOs with constrained ethyl (cEt) chemistry were synthesized and used as described previously (13, 14). Scrambled ASOs were included in each study as a negative control. In cell culture, ASOs were delivered to the cells via free uptake, without using any transfecting agents. In animal studies, ASOs were dissolved in PBS and injected subcutaneously.

Cell proliferation assay

Cell proliferation in 96-well plates was measured by CellTiter 96 AQueous One Solution Assay (MTS; Promega, #G5430) following the manufacturer’s instructions.

Annex V apoptosis assay

Cells were pretreated with ASOs for 3 days before the addition of DPI, MET, or PER. Three days later, cells were harvested, washed, and stained using the Vybrant Apoptosis Kit (ThermoFisher Scientific) according to the manufacturer’s protocol. Stained samples were then examined on a Becton Dickinson FACSVerse flow cytometer and analyzed using FlowJo software.

Assessment of xenograft multiple myeloma progression

In subcutaneous models, 3 × 10⁶ cells suspended in 100 μL RPMI/Matrigel (1:1) were implanted subcutaneously in NSG
mice under aseptic conditions. Multiple myeloma progression was assessed by biweekly measurement of tumor diameters with a Vernier caliper. Tumor volume ($mm^3$) was calculated as $V = \frac{d_1 \times d_2 \times d_3}{6}$, where $d_1$ and $d_2$ are the longest and shortest tumor diameters. Treatments started when tumors reached 200 mm$^3$. In disseminated multiple myeloma models, $1 \times 10^6$ P3/1K-mCherry-L1210 cells or $3 \times 10^6$ RPMI8226-L1210 cells suspended in 100 µL PBS were injected intravenously. Multiple myeloma progression was monitored once weekly by bioluminescence imaging (BLI). Treatments started when tumors were detected by BLI. To test our treatments, mice were randomized into indicated treatment groups to receive daily treatment for 5 days per week, with 2-day breaks between weeks. ASOs were given by subcutaneous injection at 50 mg/kg. DPI and PER were dissolved in DMSO as stock solutions at 30 and 300 mg/mL, respectively, and then diluted in 5% (w/v) hydroxyl-propyl-beta-cyclodextrin (Sigma). MET was dissolved in 5% (w/v) hydroxyl-propyl-beta-cyclodextrin. All solutions for injection were filtered. DPI, PER, and MET were given at 2, 30, and 250 mg/kg through intraperitoneal injection. All reported animal studies were approved by the UCLA Chancellor’s Animal Research Committee (ARC) under protocol number 2015-067-11.

**In vivo assessment of tumor glucose consumption by $^{18}$F-FDG PET/CT**

Animals without fasting were warmed on a heating pad for 30 minutes and then injected via the tail vein with 2.8 MBq of clinical-grade $^{18}$F-fluorodeoxyglucose ($^{18}$F-FDG). Animals underwent a 1-hour conscious $^{18}$F-FDG biodistribution period on a heating pad prior to imaging. PET and CT scans were conducted on a G8 combined PET/CT instrument (Sofie Biosciences, Inc.) with a 600-s PET acquisition and maximum-likelihood expectation maximization reconstruction, and with a 50-s CT acquisition and Feldkamp reconstruction. PET data were converted to percent-injected dose per gram (%ID/g) and PET/CT images were co-registered. Mean values of PET signal intensity from tumor region-of-interest (ROI) were analyzed using AIMDE software v1.0.4.

**Statistical analysis**

The Student t test was used for statistical analysis. P values were determined using Prism 7 (GraphPad Software, Inc.). Differences were considered statistically significant at $P < 0.05$.

**Results**

A substantial subset of multiple myeloma cell lines does not express HK1

Analysis of HK1 and HK2 mRNA expression in the CCLE database revealed that 54% of the human multiple myeloma cell lines in this collection are HK1+/HK2+ (Fig. 1A and B). Among all human cancer types in the CCLE, multiple myeloma has the largest percentage of HK1+/HK2+ cell lines (54%; 14/26), followed by liver cancer (38%; 9/24) and colorectal cancer (10%; 6/56; Fig. 1B). Existence of the HK1+/HK2+ phenotype in clinical multiple myeloma samples.

**Development of an HK2 ASO to suppress HK2 expression and HK1+/HK2+ multiple myeloma cell proliferation**

Extensive efforts have been made to develop HK2-specific small-molecule inhibitors (17), but no specific HK2 inhibitor has been reported to exhibit in vivo systemic efficacy. To translate our previous findings, using genetic approaches, that HK2 is targetable to slow the progression of HK1+/HK2+ subsets of cancer, we used our latest Generation 2.5 Chemistry technology to make HK2 ASOs as pharmacologic HK2-targeting agents.

We identified two active HK2 ASOs (HK2-ASO1 and HK2-ASO2; Supplementary Fig. 5A) after in vitro screening and tolerability study in mice. In cell culture, delivered via free uptake without using any transfecting agents, HK2-ASO1 was more effective than HK2-ASO2 in suppressing HK2 expression, in a dose-dependent manner, in a broad panel of multiple myeloma cell lines of both the HK1+/HK2+ and the HK1+HK2+ subtypes, without altering HK1 protein levels (Fig. 2A).

Glucose consumption and lactate production are metabolic markers of HK enzymatic activity in driving glycolysis. Treatment with HK2-ASO1 reduced both glucose consumption and lactate production (Fig. 2B). However, although HK2-ASO1 and HK2-ASO2 suppressed HK2 expression in both HK1+/HK2+ and HK1+/HK2+ multiple myeloma cell lines, both ASOs only reduced proliferation of multiple myeloma cells with the HK1+/HK2+ characteristic (Fig. 2C); they had no significant effect on HK1+/HK2+ multiple myeloma cell proliferation (Fig. 2C), despite comparable HK2 knockdown in all cell lines. Cell-cycle analyses showed that HK2-ASO1, compared with a control ASO (ASO-Ctrl), significantly decreased S-phase proliferating cell...
population in HK1^−HK2^+ multiple myeloma cells, but not in HK1^+HK2^+ multiple myeloma cells (Supplementary Fig. S1B). In addition, HK2-ASO1 had only minor effect on increasing multiple myeloma cell death, as indicated by the <10% sub-G1 cell population (Supplementary Fig. S1C).

The selective growth inhibitory effect of HK2-ASO1 in HK1^−HK2^+ multiple myeloma cells in cell culture was validated both by cell counting (Supplementary Fig. S1D) and by colony formation assays (Supplementary Fig. S1E), compared with ASO-Ctrl. These observations with ASO HK2-selective inhibitors are consistent with our previous findings with other cancer cells using HK2shRNA (11, 12), demonstrating that the cytostatic effect of HK2 knockdown or knockout is limited to the HK1^−HK2^+ cancer subsets.

Figure 1.
A subset of human multiple myeloma cell lines are HK1^−HK2^+. A, HK1^−HK2^+ multiple myeloma cell lines are present in the CCLE collection (http://oasis-genomics.org). HK1 and HK2 mRNA expression of 935 cancer cell lines, including 26 multiple myeloma cell lines, are shown. Each data point represents a cell line. The box indicates “HK1^−HK2^+” cell lines, defined as HK2 > 1 TPM and HK1 < 10 TPM. TPM, transcripts per million. B, Multiple myeloma has the largest percentage of HK1^−HK2^+ cell lines among all CCLE cancers from different tissues of origin. C, Validation of HK1 and HK2 protein levels in representative human multiple myeloma cell lines. D, A comparison of HK1 and HK2 expression profiles between multiple myeloma cell lines (CCLE) and multiple myeloma patient samples (the CoMMpass RNA-Seq datasets). E, Differential gene expression profiles of HK1^−HK2^+ and HK1^+HK2^+ multiple myeloma cell lines. All multiple myeloma cell lines in the CCLE dataset were analyzed for differential gene expression across 18,920 genes. Sixty-three genes with significant differences (adjusted P < 0.05) between the two populations are shown. F, Pathway enrichment analysis of differentially expressed genes in E (http://amp.pharm.mssm.edu/Enrichr/).
The combination of HK2-ASO1, partial inhibition of OXPHOS, and FAO is synthetically lethal for HK1 ‘HK2’ multiple myelomas

We previously identified a small-molecule mitochondrial complex I inhibitor, DPI, from a high throughput screen as a synthetically lethal partner with HK2 shRNAs in HK1 ‘HK2’ liver cancer cells (12). At concentrations (<100 nmol/L) we used in our subsequent cell culture experiments DPI partially, but not completely, inhibited mitochondrial OXPHOS (Supplementary Fig. S2A). The synthetic lethality of the HK2 shRNA + DPI combination could be enhanced by the addition of the FAO inhibitor PER (12). Targeting the major bioenergy generation pathways in HK1 ‘HK2’ multiple myeloma cell lines (HK2-driven glycolysis and OXPHOS) with HK2-ASO1 and DPI triggered expression of an apoptosis marker, cleaved PARP. Addition of PER to the HK2-ASO1 + DPI combination further increased PARP cleavage (Fig. 3D).

We also examined the effect of this triple combination on human peripheral blood mononuclear cells (PBMC). Compared with HK1 ‘HK2’ multiple myeloma OCI-Myl5 cells, PBMCs have high HK1 expression and low HK2 expression (Fig. 3E). Although HK2-ASO1 reduced HK2 levels in PBMCs (Fig. 3E), the combination of HK2-ASO1/DPI/PER had no significant toxicity in PBMCs (Fig. 3F), suggesting its potential safety for in vivo utility.

To further evaluate the specificity of our combination therapy for HK1 ‘HK2’ multiple myeloma cells, we created an HK1 ‘HK2’ isogenic cell line (RPMI8226/HK1 ‘HK2’) from the parental HK1 ‘HK2’ RPMI8226 cell line (Fig. 3G). Stable
expression of HK1 resulted in acquired resistance of RPMI2266 (HK1+ HK2+) cells to the cytotoxicity of the HK2-ASO1/DPI/PER combination in this isogenic cell line experiment (Fig. 3H), confirming the specificity of the synthetic lethality in HK1+ HK2+ multiple myeloma cells.

HK2-ASO1 reduces HK2 expression and 18F-FDG accumulation in xenograft multiple myeloma tumors in vivo

We next examined the ability of HK2-ASO1 to suppress HK2 expression in human multiple myeloma tumors in mouse xenografts. Subcutaneous injection of HK2-ASO1 effectively reduced HK2 protein levels in both xenograft HK1+ HK2+ OPM2 tumors and HK1+ HK2+ U266 tumors, without affecting HK1 expression (Fig. 4A). To demonstrate the biochemical consequences of HK2-ASO1-suppressed HK2 expression in human HK1+ HK2+ multiple myeloma tumors in vivo, we examined 18F-FDG accumulation in HK1+ HK2+ OPM2 multiple myeloma xenograft tumors, by 18F-FDG microPET analysis, in the presence of HK2-ASO1 or ASO-Ctrl. Decrease in HK2 protein levels by HK2-ASO1 (Fig. 4A) significantly reduced OPM2 tumor 18F-FDG accumulation, as determined non-invasively by 18F-FDG PET imaging (Fig. 4B and C).

HK2-ASO1 synergizes with DPI and PER to suppress HK1+ HK2+ xenograft human multiple myeloma tumor progression

We previously demonstrated the efficacy of HK2shRNA-mediated suppression of HK2 expression in a therapeutic combination with DPI and PER for HK1+ HK2+ liver cancer tumor progression (12). Here we tested HK2-ASO1 efficacy, alone and in combination with DPI and PER, on HK1+ HK2+ multiple myeloma xenograft tumor progression. HK2-ASO1 treatment was started when subcutaneous OPM2 HK1+ HK2+ multiple myeloma tumors reached 200 mm3 (day 1); DPI and PER treatments were initiated on day 4. As a single agent, HK2-ASO1 did not reduce OPM2 tumor progression to a statistically significant level (Fig. 4D). However, the HK2-ASO1/DPI combination significantly suppressed tumor progression, and addition of PER resulted in a further reduction in tumor volume (Fig. 4D). HK2-ASO1, both alone and in combination with DPI/PER, is tolerated by the animals; no significant change in body weight was detected among the experimental groups (Supplementary Fig. S3A). However, it is important to note that HK2-ASO1 is specific for human HK2 and does not match the mouse HK2 sequence. Therefore, tolerability of human HK2-targeting HK2-ASO1 in xenograft...
experiments does not indicate tolerability of HK2 silencing in the triple combination in normally HK2 expressing tissues (e.g., heart and skeletal muscle).

At the end of the experiment, tumors were collected (Supplementary Fig. S3B) and weighed (Supplementary Fig. S3C). Significant reductions in both tumor volume and weight occurred. In contrast, DPI and PER, as single agents or in combination, did not significantly affect OPM2 tumor progression (Supplementary Fig. S3B). The HK2-ASO1/MET combination triggered apoptosis in HK1 "HK2" multiple myeloma cells, but had no significant effect on HK1 "HK2" U266 xenograft tumor progression. N = 10/group. Treatment schedule and dosages were the same as those for OPM2 xenografts. * P < 0.05; ** P < 0.001; *** P < 0.0001. NS, not significant.

Figure 4.
HK2-ASO1/DPI/PER combination therapy effectively suppresses HK1 "HK2" multiple myeloma xenograft tumor progression. A, HK2-ASO1 treatment suppresses HK2 expression both in xenograft HK1 "HK2" OPM2 and HK1 "HK2" U266 tumors. When xenograft tumors reached 200 mm³, 50 mg/kg ASO-Ctrl or HK2-ASO1 was given subcutaneously once daily for 2 weeks, prior to analyses of tumor HK1 and HK2 protein expression. H460 lung cell tumor extract was used as a HK1 "HK2" control for the OPM2 samples. B, HK2-ASO1 treatment decreases [18F-FDG]PET accumulation in xenograft OPM2 tumors. When xenograft tumors reached 200 mm³, 50 mg/kg ASO-Ctrl or HK2-ASO1 was administered subcutaneously once daily for 10 days, prior to [18F-FDG] microPET imaging. C, Quantification of PET signal in B. D, The HK2-ASO1/DPI/PER combination therapy effectively suppresses HK1 "HK2" OPM2 xenograft tumor progression. When tumors reached 200 mm³ (day 1), xenografts were randomized into indicated groups (n = 10/group). ASO-Ctrl and HK2-ASO1 treatments started on day 1 at 50 mg/kg subcutaneously daily. DPI (2 mg/kg, daily i.p.) and PER (30 mg/kg, daily i.p.) started on day 3. Treatments were given for 5 days per week, with a 2-day break between weeks. E, Treatment effects on OPM2 tumor HK1 and HK2 levels and PARP cleavage. H460 HK1 "HK2" lung cancer cell line lysate was used as a positive control for HK1 expression. F, The HK2-ASO1/DPI/PER combination therapy has no detectable effect on HK1 "HK2" U266 xenograft tumor progression. N = 10/group. Treatment schedule and dosages were the same as those for OPM2 xenografts.

DPI can be replaced by MET in this combination therapy

Our data suggest that ASOs that suppress HK2 expression are a potential clinical therapeutic approach to treating HK1 "HK2" multiple myeloma. Although DPI is a potent OXPHOS inhibitor and has been demonstrated to synergize therapeutically with HK2shRNA (12) and HK2-ASO1, DPI has not been tested in humans. To move this combination therapy towards clinical development, we tested the replacement of DPI with the FDA approved OXPHOS inhibitor MET. Like DPI, MET partially inhibited mitochondrial respiration (Supplementary Fig. S4A), and demonstrated synthetic lethality with HK2-ASO1 in cultured HK1 "HK2" multiple myeloma cells, but had no significant effect on HK1 "HK2" U266 multiple myeloma cells (Fig. 5A; Supplementary Fig. S4A). The HK2-ASO1/MET combination triggered apoptosis in HK1 "HK2" multiple myeloma cells (Fig. 5B), and the apoptotic effect was enhanced by PER (Fig. 5C; Supplementary Fig. S4C).

Multiple myeloma tumors are found in the bone (1), an environment proposed to protect the tumor cells from therapeutic agents (18). Using culture conditions, we next examined the effect of bone marrow microenvironment interactions on the efficacy of our HK2-ASO1/MET/PER triple combination therapy. Cocultures of luciferase (LUC) expressing HK1 "HK2"...
RPMI8226 multiple myeloma cells with human bone marrow stromal cells (BMSC), using a 1:2 ratio of multiple myeloma cells to BMSCs (19), did not affect the cytotoxicity of our triple combination therapy, although the presence of BMSCs lowered the sensitivity of RPMI8226 cells to HK2-ASO1 as a single agent (Fig. 5D and E).

**Figure 5.**

**A**, MET can replace DPI in the synthetically lethal combination in HK1⁻HK2⁺ multiple myeloma cells. The combination of HK2-ASO1 and MET causes selective synthetic lethality in HK1⁻HK2⁺ multiple myeloma cells. Cells were pretreated with HK2-ASO1 (10 μmol/L) for 3 days, followed by the addition of MET (5 μmol/L) for another 3 days. Cell viability was determined trypan blue staining. **B**, The combination of HK2-ASO1 and MET causes selective apoptosis in OPM2 multiple myeloma cells. Cells were pretreated with HK2-ASO1 (30 μmol/L) for 3 days, followed by the addition of MET (5 μmol/L) for another 3 days. Apoptosis (APO) was determined by quantification of all Annexin V-positive events. **C**, PER sensitized OPM2 cells to apoptosis induced by the HK2-ASO1/MET combination. Cells were pretreated with HK2-ASO1 (5 μmol/L) for 3 days, followed by the addition of MET (2.5 μmol/L) and PER (5 μmol/L) for another 3 days. Apoptosis (APO) was determined by quantification of all Annexin V-positive events. **D**, Effects of single agents and combination treatments on RPMI8226/LUC cells with and without BMSC coculture. In cocultures, RPMI8226/LUC cells and BMSCs were in a 1:2 ratio. Cells were exposed to 10 μmol/L ASOs for an additional period of 3 days, prior to the exposure of 15 nmol/L DPI, 2.5 μmol/L MET, and/or 5 μmol/L PER for another 3 days. RPMI8226/LUC cell proliferation was determined by measuring luminescence intensity. **E**, Representative images of cocultures of RPMI8226/LUC and BMSCs with indicated treatments shown in **D**. **F**, The combinations of HK2-ASO1/MET/PER and HK2-ASO1/DPI/PER show no demonstrably significant differences in suppressing xenograft OPM2 tumor progression. When tumors reached 200 mm³ (day 1), xenografts were randomized into indicated groups (n = 10/group). HK2-ASO1 treatment was started on day 1 at 50 mg/kg s.c. daily. DPI (2 mg/kg, daily i.p.), MET (250 mg/kg, daily i.p.), and PER (30 mg/kg, daily i.p.) were started on day 3. Treatments were given for 5 days per week, with a 2-day break between weeks. NS, not significant. **G**, Disease progression in the HK1⁻HK2⁺ RPMI8226/LUC disseminated xenograft model was monitored by BLI. BLI measurement in photons per second per cm² per steradian (p/s/cm²/sr) was translated to color to indicate disease activity in the mice by the scales shown at far right. **H**, Quantification of whole mouse BLI photons in **G**.

RPMI8226 multiple myeloma cells with human bone marrow stromal cells (BMSC), using a 1:2 ratio of multiple myeloma cells to BMSCs (19), did not affect the cytotoxicity of our triple combination therapy, although the presence of BMSCs lowered the sensitivity of RPMI8226 cells to HK2-ASO1 as a single agent (Fig. 5D and E). The in vivo activity of OXPHOS inhibitors can be noninvasively monitored by 18F-FDG PET, because OXPHOS inhibition forces...
cells to upregulate glycolytic activity to compensate loss in energy production, resulting in an increase in 18F-FDG PET signal. MET and DPI treatments comparably increased 18F-FDG accumulation in HK1−HK2+ OPM2 multiple myeloma tumors (Supplementary Fig. S4D).

Although MET alone did not significantly affect OPM2 tumor progression (Fig. 5F), the HK2-ASO1/MET/PER combination was comparable to the HK2-ASO1/DPI/PER combination both in suppression of subcutaneous HK1−HK2+ tumor progression (Fig. 5F) and in PARP cleavage induction (Supplementary Fig. S4E). These results support replacing DPI with MET to translate this combination therapy into a precision medicine therapy alternative to treat patients with HK1−HK2+ multiple myeloma.

Multiple myeloma is a systemic hematopoietic disease. To examine the efficacy of the triple therapy on systemic multiple myeloma progression, we used a previously validated systemic multiple myeloma model with human HK1−HK2+ RPMI8226/LUC cells (19). Following intravenous injection of multiple myeloma cells, cohorts of mice were treated either with ASO-Ctrl or with the HK2-ASO1/MET/PER combination therapy, and disease progression was monitored by BLI at the times indicated in Fig. 5G. As observed for subcutaneous human HK1−HK2+ OPM2 tumors (Fig. 5F), systemic HK1−HK2+ RPMI8226/LUC tumor progression was dramatically reduced by the triple combination (Fig. 5G and H).

HK2-ASO1/DPI/PER and HK2-ASO1/MET/PER combination therapies have similar impacts on HK1−HK2+ multiple myeloma cell metabolism

By targeting OXPHOS, both DPI and MET increased glycolysis in OPM2 cells, whereas HK2-ASO1 blocked HK2-driven glycolysis (Fig. 6A). Consistent with these observations, co-inhibition of HK2-driven glycolysis and OXPHOS reduced cellular energy metabolism, with HK2-ASO1/MET/PER combination therapy resulting in significantly lower ATP/AMP+ADP ratios (Fig. 6B). OPM2 cell viability assay by trypan blue staining showed no significant differences between the vehicle control and any of the experimental treatment groups (Fig. 6C).

Metabolomics analysis of 129 important metabolites in OPM2 cells revealed that HK2-ASO1/DPI/PER and HK2-ASO1/MET/PER treatments decreased amino acid levels, fatty acid intermediates, and purines and pyrimidines (Fig. 6D). Furthermore, effects on relative changes in 13C portions of amino acids, TCA cycle metabolites, purines, and pyrimidines were quantified (Fig. 6E).

Figure 6.

Impact of HK2-ASO1, DPI, MET, and PER on HK1−HK2+ OPM2 cell metabolism. Effects of HK2-ASO1, DPI, MET, and PER, alone and in combination for 24 hours, on OPM2 glucose consumption and lactate production (A), and cellular ATP/(AMP+ADP) ratios (B). C, OPM2 cell viability after 24-hour treatments with HK2-ASO1, DPI, MET, and PER, alone and in combination, determined by trypan blue staining. No significant differences could be detected between the vehicle control and any of the experimental treatment groups. D, Effects of HK2-ASO1, DPI, MET, and PER, alone and in combination for 24 hours, on the levels of 129 important metabolites in OPM2 cells. E, Effects of 24-hour treatments with HK2-ASO1/DPI/PER and HK2-ASO1/MET/PER on relative changes in cellular pool sizes of amino acids, TCA cycle metabolites, fatty acid intermediates, purines and pyrimidines in OPM2 cells. F, Effects of 24-hour treatments with HK2-ASO1/DPI/PER and HK2-ASO1/MET/PER on relative changes in 13C portions of amino acids, TCA cycle metabolites, purines, and pyrimidines in OPM2 cells.
ATP/(AMP+ADP) ratios more than single pathway inhibition. Although FAO inhibition alone by PER has no significant effect on the ATP/(AMP+ADP) ratio, FAO inhibition reduced the ATP/(AMP+ADP) ratios in HK1′ HK2′ P3 tumors, mHK2-ASO1 and mHK2-ASO2 both reduced HK2 levels in tumors and to a lesser extent in the heart (Supplementary Fig. S7F). In contrast, neither mHK2-ASO1 nor mHK2-ASO2 affected HK2 expression in skeletal muscle (Supplementary Fig. S7F). As expected, neither mHK2-ASO1 nor mHK2-ASO2 affected HK1 expression (Supplementary Fig. S7F). 18F-FDG PET scans demonstrated significantly decreased 18F-FDG accumulation in subcutaneous HK1′ HK2′ P3 tumors after mHK2-ASO1, mHK2-ASO1/MET/PER, or mHK2-ASO1/DPI/PER treatments (Fig. 7C). mHK2-ASO1 alone significantly reduced HK1′ HK2′ P3 tumor progression (Fig. 7D). Moreover, mHK2-ASO1/MET/PER and mHK2-ASO1/DPI/PER substantially and equivalently decreased subcutaneous HK1′ HK2′ P3 tumor progression compared with mHK2-ASO1 alone (Fig. 7D). At the experiment endpoint, tumors were collected (Supplementary Fig. S7G), weighed (Supplementary Fig. S7H), and analyzed for HK2 expression (Supplementary Fig. S7I). Both mHK2-ASO1/MET/PER and mHK2-ASO1/DPI/PER triple-combinations were tolerated for human HK1′ HK2′ multiple myeloma therapy.

We also established a disseminated mouse multiple myeloma model, using intravenous injected P3 HK1′ HK2′ cells expressing both LUC (for BLI imaging) and mCherry (for fluorescent quantification of multiple myeloma cells in bone marrow extracts). Bone marrow extraction on day 18 post-injection identified 27.2 ± 4.2% of the cells as mCherry-labeled multiple myeloma cells (Supplementary Fig. S7J). The mHK2-ASO1/MET/PER combination significantly suppressed the progression of this highly aggressive disseminated mouse multiple myeloma model, as determined by BLI (Fig. 7F and G). The experiment was terminated following euthanization of the last control mouse; all treated mice were alive and appeared healthy at the end of the experiment (Fig. 7H). These data demonstrate, in the mouse systemic model, that the triple-combination shows efficacy in suppressing HK1′ HK2′ multiple myeloma tumor progression and is tolerated by normal tissues.

Discussion

It is only relatively recently that HK2 expression has been recognized as a common feature of many cancers (7, 8, 10, 21). Because HK2 is not expressed in most normal tissues, targeting HK2 has become a popular goal as an approach to cancer management. In the absence of systemically effective selective HK2 inhibitors, several laboratories, using HK2-targeted shRNAs, reported success in retarding, reducing, or eliminating HK1′ HK2′ xenograft tumor progression (7, 8, 10, 21). However, when this question was reexamined, both with alternative HK2 shRNAs and with isogenic HK1′ HK2′ and HK1′ HK2′ cancer cell lines created by CRISPR-Cas9 deletion, it became clear that HK1 and HK2 can compensate each other; either is sufficient to support cancer cell proliferation in culture and for xenograft tumor progression in vivo (11). Consistent with these observations, neither HK2 nor HK1 were identified as essential genes for cell proliferation in an unbiased systematic CRISPR-Cas9 screen of HK1′ HK2′ cancer cell lines (22). In contrast, however, HK2 shRNA expression was cytostatic for HK1′ HK2′ cancer cells, and similar synthetic lethality responses in cultured HK1′ HK2′ P3 HK1/10O cells (Fig. 7B).

In mice bearing subcutaneous isogenic HK1′ HK2′ and HK1′ HK2′ P3 tumors, mHK2-ASO1 and mHK2-ASO2 both reduced HK2 levels in tumors and to a lesser extent in the heart (Supplementary Fig. S7F). In contrast, neither mHK2-ASO1 nor mHK2-ASO2 affected HK2 expression in skeletal muscle (Supplementary Fig. S7F). As expected, neither mHK2-ASO1 nor mHK2-ASO2 affected HK1 expression (Supplementary Fig. S7F). 18F-FDG PET scans demonstrated significantly decreased 18F-FDG accumulation in subcutaneous HK1′ HK2′ P3 tumors after mHK2-ASO1, mHK2-ASO1/MET/PER, or mHK2-ASO1/DPI/PER treatments (Fig. 7C). mHK2-ASO1 alone significantly reduced HK1′ HK2′ P3 tumor progression (Fig. 7D). Moreover, mHK2-ASO1/MET/PER and mHK2-ASO1/DPI/PER substantially and equivalently decreased subcutaneous HK1′ HK2′ P3 tumor progression compared with mHK2-ASO1 alone (Fig. 7D). At the experiment endpoint, tumors were collected (Supplementary Fig. S7G), weighed (Supplementary Fig. S7H), and analyzed for HK2 expression (Supplementary Fig. S7I). Both mHK2-ASO1/MET/PER and mHK2-ASO1/DPI/PER triple-combinations were tolerated by the mice as indicated by body weight (Fig. 7E). These data suggest that the HK2 ASO þ METþ PER combination is likely to be tolerated for human HK1′ HK2′ multiple myeloma therapy.

HK2 ASO and PER were used in combination to block both HK2 and HK1 pathways. HK2-ASO1 and HK2-ASO2 suppressed mouse HK2 expression in mouse multiple myeloma P3 × 63Ag (P3) cells (20) without affecting HK1 expression (Supplementary Fig. S7C). To model human HK1′ HK2′ multiple myelomas, isogenic HK1′ HK2′ mouse P3 cells were generated using CRISPR-Cas9 deletion (Supplementary Fig. S7D). Both mHK2-ASO1 and mHK2-ASO2 suppressed HK2 expression to equivalent degrees in the parental P3 cells and in the P3 HK1/1O cells (Fig. 7A, Supplementary Fig. S7C). Although ASO-mediated HK2 knockdown did not affect proliferation of parental HK1′ HK2′ P3 cells in culture, both mHK2-ASO1 and mHK2-ASO2 inhibited proliferation of the isogenic HK1′ HK2′ P3 HK1/1O cells (Supplementary Fig. S7E). mHK2-ASO1/DPI/PER and mHK2-ASO1/MET/PER triple-combinations induced
reduced, but did not eliminate, HK1–HK2+ xenograft tumor progression in vivo (12).

In examining the HK isoform expression of human cancer cell lines in the CCLE collection it became clear that liver cancers and multiple myelomas have the greatest percentages of HK1/C0 HK2+ cell lines. Because examination of the TCGA data base revealed that primary liver cancer specimens are enriched in HK1/C0 HK2+ samples, we turned first to these tumors to develop an effective experimental therapy for HK1–HK2+ tumors that incorporates elimination of HK2 activity. We demonstrated that combined HK2shRNA knockdown and mitochondrial complex I inhibition achieves synthetic lethality in HK1–HK2+ liver cancer cells, and

Figure 7. In vitro and in vivo effects of mouse HK2 ASOs as single agents and in combination with DPI, MET, and PER. A, mHK2-ASO1 suppresses HK2 expression in HK1–HK2+ P3 cells. B, The combinations of mHK2-ASO1/DPI/PER and mHK2-ASO1/MET/PER induce apoptosis in HK1–HK2+ P3 cells. Cells were pretreated with mHK2-ASO1 (0.5 μmol/L) for 3 days, followed by the addition of MET (2 mmol/L), DPI (25 nmol/L), and PER (5 μmol/L) for another 3 days. Apoptosis (APO) was determined by quantification of the Annexin V-positive population. C, Eight-day treatments with mHK2-ASO1, mHK2-ASO1/MET/PER, and mHK2-ASO1/DPI/PER significantly reduced [18F]FDG PET signal in mouse HK1–HK2+ P3 tumors. Left, PET scan images are shown. Right, quantification of PET signal intensity from tumor ROI values. D, Effects of mHK2-ASO1, mHK2-ASO1/MET/PER, and mHK2-ASO1/DPI/PER on HK1–HK2+ P3 tumor progression. When tumors reached 200 mm³ (day 1), mice were randomized into indicated groups (n = 11/group). mHK2-ASO1 treatment started on day 1 at 50 mg/kg s.c. daily. DPI (2 mg/kg, daily i.p.), MET (250 mg/kg, daily i.p.), and PER (50 mg/kg, daily i.p.) started on day 3. Treatments were given for 5 days per week, with a 2-day break between weeks. NS, not significant. E, Body weight of the four indicated groups during treatments. F, Disease progression in the P3/HK1+/mCherry-LUC disseminated model was monitored by BLI. BLI measurement in photons per second per cm² per steradian (p/s/cm²/ sr) was translated to color to indicate disease activity in the mice by the scales shown at far right. G, Quantification of whole mouse BLI photons in F. H, Kaplan–Meier survival curves of mice in F. * P < 0.05; ** P < 0.01; *** P < 0.001; **** P < 0.001.
In this study our goals were to determine whether HK1*HK2* multiple myelomas were also susceptible to synthetic lethality mediated by inhibition of HK2 expression, OXPHOS and FAO, and to identify inhibitory agents for each component that are more appropriate for clinical application. Despite substantial attempts (17), no systematically efficacious targeted HK2 inhibitor has been reported. To move the HK2shRNA/DPI/PER combination therapy described previously (12) toward treatment for HK1*HK2* multiple myelomas, we replaced HK2 shRNA with HK2-ASO1 to reduce HK2 expression. To our knowledge, HK2-ASO1 is the first pharmaceutical agent with a systemic in vivo ability to reduce HK2 activity, with little or no effect on HK1 activity, in tumors.

A significant advantage of ASOs relative to traditional small molecule-based drugs is their exquisite target specificity. Metabolic reprogramming in cancer frequently results from metabolic enzyme isoform switches (12, 23–25). The mRNA sequences of these cancer-specific isoforms can be exploited to target cancer cells, with minimal effects on normal tissues that express different enzyme isoforms. Because of the extensive similarities in protein structures and substrate binding sites between these enzyme isoforms, targeting the cancer-specific isoforms by ASOs to exploit isoform-specific differences in mRNA sequences provides a promising therapeutic strategy.

Again, to use more clinically relevant agents for the HK2i/OXPHOSi/FAOi combination therapy, we replaced the potent mitochondrial complex I inhibitor DPI (12) with an FDA-approved inhibitor, MET. MET can replace DPI in proliferation and viability studies, global metabolomics analyses, [18F]FDG/microPET imaging, and tumor xenograft progression. PER is in clinical use as an antiangiinal drug in Asia and Australia, and in phase II/III clinical trials in the United States.

Tumor cell expression of shRNAs targeting human HK2 in xenograft models (7, 8, 10, 21) cannot properly evaluate adverse effects of HK2 inhibition in normal tissues, because of differences in human and mouse HK2 mRNA sequences, ASOs that target human HK2 have no effect on mouse HK2 expression (Supplementary Fig. S7B). However, using a mouse multiple myeloma tumor/host model, the mouse HK2-ASOs/MET/PER therapeutic combination exhibits both potency and safety, suggesting that HK2-ASO1/MET/PER could be tolerated by normal tissues in patients. Consequently, an HK2-ASO/MET/PER combination could be a promising translational precision medicine therapy for HK1*HK2* multiple myelomas. Additional studies need to be done to further identify HK2-ASOs suitable for clinical investigation. In addition, the clinical potential of our observations can be further validated by future experiments that use primary patient-derived HK1*HK2* multiple myeloma cells and patient-derived xenograft models of HK1*HK2* multiple myelomas.

Stratification of patients with multiple myeloma to identify those individuals whose tumors are HK1*HK2* would be required for the clinical success of this precision medicine therapy. Due to HK1 expression in most normal tissues, and consequent contamination with noncancer HK1-expressing cells in tumor biopsies, single-cell analyses with multiple myeloma marker staining (e.g., CD138, BCMA) are likely to be required for patient stratification. In addition to multiple myeloma, other cancers also have HK1*HK2* subsets (11). These HK1*HK2* cancers are also susceptible to HK2 inhibition, regardless of their tissues of origin (11). Therefore, in combination with patient stratification strategies, an HK2-ASO/MET/PER combination has potential as a precision medicine therapy to treat HK1*HK2* tumors, regardless of their tissue of origin.

Disclosure of Potential Conflicts of Interest

J.M. Timmerman reports receiving commercial research grant from Bristol-Myers Squibb, Kite Pharma, and Merck; is a consultant/advisory board member of BMS, Kite Pharma, Partner therapeutics, and Immune Design.
