4 **Abstract**

5  
6  
7 **Background**

8  
9 Red blood cell (RBC) transfusion is common during infant cardiac surgery. A previous report of  
10 pediatric heart transplant recipients showed increased RBC transfusion volume was  
11 independently associated with increased length of ICU stay. It is unclear whether transfusion to  
12 infants as a subgroup carries similar risks. This study investigated relationships between  
13 intraoperative RBC transfusion during heart transplantation and postoperative length of stay,  
14 morbidity and mortality in infants.

17  
18  
19  
20  
21  
22

23  
24 **Methods**

25  
26 Retrospective analysis of medical records from infants <1 year old undergoing primary heart  
27 transplantation at Loma Linda University Medical Center from 1985 to 2012 was conducted.  
28  
29 Exclusion criteria included preoperative exchange transfusion or extracorporeal membrane  
30 oxygenation. Data sought included patient characteristics; intraoperative RBC transfusion  
31 volume and cardiopulmonary bypass details; and postoperative vasoactive support, ventilator  
32 support, morbidity, length of stay (LOS) and 30-day mortality. The relationship of RBC  
33 transfusion volume (ml/kg) to these postoperative variables was assessed by univariate analysis.  
34  
35 Multiple regression analysis of postoperative LOS included variables that were independent  
36 predictors of length of stay or associated with  $\geq 10\%$  change in the beta estimate for RBC effect.  
37  
38  
39  
40  
41  
42  
43  
44  
45  
46  
47

48 **Results**

49  
50 Data from 307 infants showed most (66.8%) had single ventricle physiology. Median age at  
51 transplant was 50 days; weight 3.95 kg; intraoperative transfusion volume 109 ml/kg.  
52  
53 Transfusion volume was inversely related to age and weight. Median postoperative LOS was  
54  
55  
56  
57  
58 18.2 days. Univariate linear regression analysis of transfused volume showed no relationship to  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 log transformed postoperative LOS ( $F(1,305)=0.00$ ;  $p=0.960$ ;  $R^2=0.000$ ; Beta Coefficient =  
5  
6  
7 0.004; 95% CI = -0.1542 to 0.1623). Transfused volume was not related to 30-day mortality  
8  
9 (difference -0.162; -0.048 to 0.371 ml/kg;  $p=0.112$ ) nor to postoperative ventilator support  
10  
11 ( $R^2=0.047$ ) but was greater in patients who required reoperation (difference -0.246; -0.494 to -  
12  
13 0.025;  $p=0.004$ ). Multiple regression analysis for all patients revealed age, preoperative  
14  
15 ventilator support, prolonged postoperative ventilatory or vasoactive support, transplant year and  
16  
17 30-day mortality but not major adverse events to be significant confounding variables. Adjusting  
18  
19 for these variables, transfused volume was not associated with prolonged postoperative LOS.  
20  
21  
22

### 23 **Conclusions**

24  
25  
26 In contrast to a prior report, we found no correlation between intraoperative RBC transfusion and  
27  
28 postoperative LOS when studying only infants. Infants have maturing organ systems, less  
29  
30 physiologic reserve and increased surgical blood loss (evaluated as ml/kg) during cardiac surgery  
31  
32 than their larger, older counterparts, distinguishing them from the general pediatric population.  
33  
34 These differences necessitate additional studies to determine outcome impact of transfusion  
35  
36 strategies in the infant subgroup.

## Introduction

Pre-existing anemia and surgical blood loss make red blood cell (RBC) transfusion a common and necessary perioperative intervention for the pediatric cardiac surgical patient.

Despite ongoing surgical losses, oxygen carrying capacity must be maintained. For small infants requiring cardiopulmonary bypass (CPB), the pump priming volume is quite large relative to the patient's blood volume; the resultant hemodilution often necessitates RBC transfusion.<sup>1,2</sup>

Although transfusions may be lifesaving, there is increasing concern regarding the deleterious effects of blood product administration. Some studies in the pediatric population have associated perioperative RBC transfusions with increased postoperative morbidity.<sup>3-10</sup> In a retrospective study of RBC transfusion to heart transplant recipients  $\leq 18$  years old, multiple regression analysis revealed that increased RBC transfusion volume was independently associated with increased length of ICU stay and higher initial inotrope scores.<sup>5</sup> Transfusion volume greater than 60 ml/kg was associated with an increased risk of major adverse events. While a large prospective noninferiority trial in stable critically ill pediatric intensive care unit (ICU) patients<sup>11</sup> showed no significant outcome differences with a restrictive transfusion strategy, subgroup analysis of post-cardiac surgery patients showed an upward trend toward more organ dysfunction.<sup>12</sup> A unique concern for transplant recipients is the risk of allosensitization following transfusion.<sup>13,14</sup>

The International Society for Heart and Lung Transplantation Registry reports that approximately 25% of pediatric heart transplant recipients are infants under 1 year of age.<sup>15</sup> Many physiologic changes occur during the first 12 months of life, distinguishing infants from the general pediatric population. Infant heart transplant recipients may have a relative physiologic immunodeficiency<sup>16-18</sup> which could affect their response to RBC transfusion. They

1  
2  
3  
4 are also more likely to undergo cardiac transplant for cyanotic heart disease and clinically need  
5  
6  
7 higher baseline hemoglobin levels. In light of these differences, this study aims to evaluate the  
8  
9  
10 outcome impact of intraoperative RBC transfusion to infant heart transplant surgery recipients on  
11  
12 postoperative length of stay, morbidity and mortality in this unique pediatric subgroup.

## Methods

After Institutional Review Board approval and waiver of consent, charts of all pediatric patients less than one year of age undergoing heart transplantation at Loma Linda University Medical Center from 1985 to 2012 were reviewed, with data collection and preliminary analysis completed in 2013. At this institution, cardiopulmonary bypass perfusion protocols and transfusion strategies for infant heart transplant recipients have remained fairly stable over the past three decades, with important changes as noted. The perfusion protocol included active surface cooling during line placement and surgical dissection, hemodilution on initiation of CPB, deep hypothermia during low flow states or **circulatory** arrest,<sup>19</sup> and alpha-STAT management to maintain capillary microcirculation integrity,<sup>20</sup> while relying on dissolved oxygen to supply the cerebral metabolic demands.<sup>21</sup> The CPB prime included calcium-free crystalloid prime and 100 ml of albumin 25% added to maintain osmolality for a total volume of approximately 550 ml. The circuit included a DeBakey roller pump, arterial filter, and in-line hemoconcentrator. After appropriate heparinization and cannulation, CPB was initiated with rapid cooling (over approximately 15 minutes) to 18 degrees C. Initially longer deep hypothermic **circulatory** arrest (DHCA) times were utilized; however, with increased experience the DHCA times decreased. More recent cases were done with selective cerebral perfusion. Upon rewarming, continuous ultrafiltration was initiated (reversing hemodilution by removing approximately 500-800 mL ultra-filtrate). Washed irradiated RBCs were transfused per institutional protocol during and after CPB, providing further hemodilution correction during rewarming and replacing ongoing blood loss with the goal hematocrit between 30% and 35%. To eliminate the confounding effect of significant blood product exposure prior to surgery, exclusion criteria included prior heart

transplant, preoperative extracorporeal membrane oxygenation and preoperative exchange transfusions.

Total intraoperative RBC transfusion volumes (ml/kg) were extracted from medical records, blood bank records, and the Loma Linda University International Heart Institute database. Preoperative, intraoperative, and postoperative patient characteristics were recorded. Vasoactive support included use of either inotrope or vasopressor infusions. Postoperative duration of mechanical ventilation was defined from end of surgery to the first successful tracheal extubation lasting at least 24 hours.

Statistical Analysis: The primary outcome measure chosen for this study was the relationship between RBC transfusion and post-transplant LOS as this summates postoperative morbidity. We did not use 30 day mortality as our primary outcome because the number who died within 30 days after transplant was 25. This limits our ability to adjust for potential confounding variables and other significant predictors of 30 day mortality. LOS was defined as the time from postoperative ICU admission until discharge home. It is standard practice at this institution to discharge patients home directly from the pediatric cardiac ICU. Histograms and Kolmogorov-Smirnov test statistics were examined to determine whether the distribution of LOS was reasonably modeled by a normal distribution on the original or log scale. The log transformation of LOS better approximated normality than the untransformed LOS. Year of transplant was dichotomized based on implementation of selective cerebral perfusion in 1995. Transfused volume was converted to 100 ml/kg to facilitate data analysis and comparison to clinical transfusion practices.

Secondary outcomes examined included postoperative major adverse events defined as cardiac arrest, primary open chest (open sternum at conclusion of primary operation), reoperation

(additional postoperative surgical intervention), new dialysis, or new onset of seizures. Other secondary outcomes were duration of postoperative vasoactive support, postoperative ventilator days, and 30 day mortality. Categorical data are given as number (%) and differences were compared using the Wald test for proportions. Continuous data were analyzed for normal distribution by the Shapiro Wilk test with  $p < 0.05$  indicating the data were not normally distributed. Continuous data are given as mean or median and 95% confidence interval (CI) as appropriate to the data. Differences between categorical variables for continuous data that were not normally distributed were compared by the Hodges Lehman method assuming data symmetry and given as difference and 95% CI.

Initial univariate analysis was conducted to evaluate the relationships between RBC transfusion volume, logLOS and the secondary outcomes. Identified significant confounding variables were subjected to multiple regression analysis to evaluate the effects of confounding factors on LOS. Variables were included in the model if they were independent predictors of LOS or if they were associated with a  $\geq 10\%$  change in the beta estimate for RBC effect. All regression assumptions were checked by visually investigating residual plots. Linearity was additionally assessed via partial regression plots between the predictors and the log transformed LOS. Results are presented as beta coefficients and their standard error. Significance was set at 0.05. The analysis was performed using SAS/STAT software, Version 9.4 of the SAS System for Windows, SAS Institute Inc, Cary, NC, USA.

## Results

A total of 313 infants who underwent primary cardiac transplant were identified. Six were excluded for missing data yielding 307 study patients. Characteristics of those who survived >30 days after transplant (n=282) are compared to those who died within 30 days of transplant (n=25) in Table 1. Median age at transplant was 50 days and weight 3.95 kg. Most infants had single ventricle physiology (66.8%); cardiomyopathy and other complex congenital cardiac defects accounted for most of the remaining patients. Preoperative prostaglandin infusion was common and about one-third required ventilator support prior to transplantation. The mean preoperative hemoglobin was 13.1 g/dl (range 7.8 to 19.5 g/dl). Median postoperative LOS was 18.2 days. Two patients were discharged home with continued mechanical ventilation (one had a 222 day LOS but required ventilator support for 423 days).

Transfusion volume was inversely related to age and weight (Figure 1). The median volume of RBCs transfused during surgery was 109 ml/kg (range 28-328 ml/kg). All patients were transfused during CPB, with the majority receiving 1-2 units; 275 patients required additional transfusion after separation from CPB, while 32 patients did not. As shown in Figure 2, the majority of RBC transfusion occurred during CPB. The first postoperative hemoglobin recorded averaged 12.0 g/dl (range 7.4-18.1). Postoperative LOS was evaluated and found to be heavily right skewed (KS: 0.1960; p-value < 0.010; mean = 24.21 versus median = 18). LOS was log transformed to better approximate normality. Univariate analysis showed no relationship of logLOS to RBC transfusion volume (Figure 3). Univariate analyses of preoperative and postoperative characteristics compared to RBC transfusion are summarized in Table 2, and to logLOS in Table 3.

Following univariate and bivariate analyses, multiple regression analysis was performed in a stepwise manner. Model development steps for all transplant recipients and for only those who survived >30 days post-transplant are shown in Supplemental Digital Material Tables 1 and 2. Multiple regression analysis (Table 4) revealed age, year of transplant group, preoperative ventilator support, and prolonged postoperative ventilatory or vasoactive support to be significant confounding variables for logLOS. Multiple regression analysis showed occurrence of one or more postoperative major adverse event was not a significant predictor of LOS in the presence of the other covariates so major adverse events was excluded from the final model (Supplemental Digital Material). Age and weight had a direct linear correlation ( $r = 0.8157$ ;  $p < 0.0001$ ) and therefore only age was used. After adjusting for all identified confounding variables, volume of RBC transfusion was not significantly associated with log transformed LOS ( $-0.126$ ;  $-0.274$  to  $0.022$ ;  $p = 0.098$ ). Increased age at transplant was associated with a reduction in LOS ( $-0.093$ ;  $-0.157$  to  $0.0289$ ;  $p = 0.0053$ ) while increased duration of postoperative ventilation was associated with longer LOS ( $0.261$ ;  $0.184$  to  $0.338$ ;  $p < 0.0001$ ). Similarly, multiple regression analysis of only those who survived > 30 days after transplant showed that RBC transfusion volume had no effect on LOS when confounding variables are considered (Table 5). The 30-day postoperative mortality was 8.87% (25 cases), thus limiting logistic regression analyses to univariate and bivariate models. Univariate and bivariate logistic regression modelling of variables related to 30-day mortality are shown in Tables 6 and 7.

## Discussion

RBC transfusion is a medical intervention in which the risks and benefits must be carefully weighed. Non-infectious risks account for the majority of fatal transfusion complications; the majority of pediatric reports are associated with human errors such as overtransfusion and misunderstanding neonatal requirements.<sup>22</sup> Withholding transfusion may be equally dangerous as a significant portion of intraoperative pediatric cardiac arrests are associated with inadequate resuscitation of surgical bleeding.<sup>23</sup> We found no positive correlation between intraoperative RBC transfusion volume and increased LOS by univariate analysis or multiple regression analysis (-0.126; -0.274 to 0.022; p = 0.098). Univariate analysis showed that infants with delayed chest closure or reoperation for other surgical reasons had larger intraoperative RBC transfusion volumes at the time of transplant, but we did not find significant intraoperative RBC transfusion volume differences in infants who required prolonged postoperative ventilator or vasopressor support, nor in those who who developed postoperative new seizures, new need for dialysis, cardiac arrest or death within 30 days of transplant (Table 2). Further, multiple regression analysis showed postoperative major adverse events were not a significant predictor of LOS in the presence of the other covariates (Supplemental Digital Material). Our findings differ from a previous report.<sup>5</sup> Several factors may have contributed to this difference.

Infants  $\leq$  30 days of age are at greatest risk for blood loss during pediatric cardiac surgery, with blood loss varying inversely with age and notable differences between age groups.<sup>24</sup> While the CPB perfusion strategy in this study was different (hemodilution with large volume acellular prime, followed by hemoconcentration during rewarming though continuous ultrafiltration and concurrent RBC transfusion), the median transfusion volume we found (109

1  
2  
3  
4 ml/kg) was not significantly greater than that reported in infants <12 months of age in a prior  
5  
6 report (95±53 ml/kg).<sup>5</sup> That group reported RBC transfusion volume, but not age, to be  
7  
8 independently associated with the studied outcomes. They also found that major adverse events  
9  
10 (new dialysis, sepsis, graft failure, ECMO and open chest) were associated with larger  
11  
12 transfusion volumes. In contrast we found that patient age and weight were directly linked and  
13  
14 were independent predictors of LOS while RBC transfusion volume was not. Younger, smaller  
15  
16 infants had longer LOS and prolonged vasoactive and ventilator support, possibly reflecting  
17  
18 organ system maturation during the first year of life. The outcome differences between studies  
19  
20 may highlight a sampling bias: our analysis was restricted to infants up to 12 months of age  
21  
22 (median age 50 days), while the prior report<sup>5</sup> included pediatric cardiac transplant recipients ≤ 18  
23  
24 years of age (median age 11.7 years). Not surprisingly, infants in that report received the largest  
25  
26 blood transfusion volume in ml/kg; only those weighing >30kg averaged transfusion volumes  
27  
28 <15ml/kg, placing the majority of transplant recipients <30kg in the high exposure group.

Though age was not shown to be statistically significant in that report, it has obvious clinical significance; this discrepancy is likely due to age differences, with only a small number of infants and small children included in that report. Further, we did not find relationships between transfused volume and several postoperative major adverse events, prolonged postoperative ventilatory or vasoactive support, or death within 30 days of transplant. We postulate that the infant's immature immune system<sup>16-18</sup> and transfusion of washed irradiated RBCs may not elicit the same inflammatory and immunomodulatory effects seen with transfusions to older children and adults, but this will require further investigation.

Previous investigators found that increased transfusion during CPB was associated with excessive postoperative bleeding and worsened outcomes following pediatric cardiac surgery.<sup>25</sup>

1  
2  
3  
4 Those investigators reported notable risk factors for excessive postoperative bleeding included  
5 age and weight. Those with excessive bleeding averaged 138 days age and 5.3 kg weight  
6  
7 compared to 657 days and 10.3 kg weight in those without excessive bleeding.<sup>25</sup> Similarly,  
8  
9 infants that required intraoperative and postoperative transfusions despite undergoing a blood-  
10 sparing approach to pediatric cardiac surgery had worsened outcomes (increased ventilator days  
11 and ICU LOS) compared with non-transfused infants.<sup>26,27</sup> However, considering the uniform  
12  
13 intraoperative transfusion protocol and maximal blood-sparing approach (including miniaturized  
14 CPB circuit down to 95 ml priming volume), it is possible that the need for RBC transfusion is a  
15  
16 marker for rather than the cause of patient morbidity. Another retrospective study of infants  
17  
18 undergoing heart surgery reported that a comprehensive blood conservation strategy, including  
19  
20 reduction of circuit priming volume from 600 to 300 ml, was associated with significant  
21  
22 decreases in intraoperative and postoperative blood transfusion, inotropic scores, ventilator  
23  
24 duration, and hospital LOS (despite lower hemoglobin values after implementation).<sup>28</sup> However,  
25  
26 it is possible that the other improvements in CPB and patient management implemented in this  
27  
28 study contributed favorably to those outcome differences.

38  
39  
40

41 Many retrospective studies have linked increased blood transfusions with worsened  
42  
43 outcomes. Perhaps the underlying association is the severity of surgical bleeding and  
44  
45 preoperative morbidity rather than the amount of blood transfused,<sup>29</sup> as one study found the  
46  
47 volume of chest tube drainage at 24 hours to be the strongest independent predictor of  
48  
49 mortality.<sup>30</sup> Underlying confounders are difficult to tease out in these retrospective studies. All-  
50  
51 cause mortality and secondary outcomes (stroke, MI, acute renal failure, infections, arrhythmias,  
52  
53 bleeding, ICU and hospital LOS) were evaluated in a meta-analysis of 21 prospective  
54  
55 randomized controlled trials involving transfusion protocols during cardiac or vascular surgery  
56  
57  
58  
59

2  
3  
4 which randomized to either a restrictive or liberal transfusion study arm (including studies using  
5 acute normovolemic hemodilution as a restrictive approach). Four of the studies involved  
6 pediatric patients.<sup>31</sup> Pediatric patients in the restrictive study arms had significantly less blood  
7 utilization, but there were no statistically significant differences in mortality or secondary  
8 outcomes. Of note, both ICU and hospital LOS were increased by one day in the pediatric  
9 patients randomized to a restrictive approach. This meta-analysis also reported numerically more  
10 adverse events (death, stroke, infections) in the restrictive group.<sup>31</sup> A review of the literature  
11 searching for prospective studies involving RBC transfusion management during surgery for  
12 repair of congenital heart disease in the pediatric population found only a small number of  
13 heterogeneous trials with insufficient evidence to assess the outcome impact of RBC transfusions  
14 in this subgroup.<sup>32</sup>

30  
31 The lowest “safe” hematocrit during CPB has yet to be determined, and there is some  
32 evidence that intraoperative anemia may be associated with negative outcomes. A randomized  
33 trial in infants < 9 months age to assess the effect of hemodilution (goal hematocrit 20% vs 30%)  
34 prior to low flow CPB during cardiac surgery found that during the postoperative period the low  
35 hematocrit group had decreased cardiac index, higher serum lactate levels, and increased total  
36 body water, with no difference in total blood product exposure. At 1 year of age, those evaluated  
37 in the low hematocrit group demonstrated >0.5 standard deviation lower Psychomotor  
38 Development Index scores.<sup>33</sup> The same group of investigators combined these results with a  
39 similar study evaluating the difference between hematocrit of 25% versus 35% which  
40 demonstrated that decreased hematocrit prior to low flow CPB was associated with increased  
41 intraoperative fluid balance and slight increase in lactate levels 60 minutes after CPB. More  
42 importantly there was a significant nonlinear increase in Psychomotor Development Index scores

3  
4 at 1 year of age with increasing hematocrit (plateauing at hematocrit of 23.5%), raising concern  
5  
6 regarding the practice of extreme hemodilution to minimize blood transfusion in infant cardiac  
7  
8 surgery.<sup>34,35</sup>  
9  
10

11 Our analysis showed age and weight to significantly correlate with LOS. This  
12  
13 demonstrates the importance of comparing the outcome impact of RBC transfusion within  
14  
15 specific age groups to minimize sampling bias. Additional studies are needed to address the  
16  
17 effects of blood transfusion strategies in varied pediatric subgroups, as age and size are linked to  
18  
19 estimated blood volume, the resultant dilutional effect of CPB circuit prime, and the amount of  
20  
21 physiologic reserve. Infants are more likely to have cyanotic heart disease, require more complex  
22  
23 repairs, and have longer duration of CPB and cross clamp times, which results in increased  
24  
25 nonhemostatic thrombin generation, fibrin degradation, and subsequent increased bleeding.<sup>36</sup>  
26  
27  
28  
29  
30

31 Weaknesses of this study include its retrospective design over an extended time period  
32  
33 during which changes have occurred in the approach to infant heart transplantation, blood  
34  
35 product storage, and hospital discharge criteria. We have addressed this by evaluating outcomes  
36  
37 based on year of transplant and before and after implementation of selective cerebral perfusion  
38  
39 during CPB. However, it is possible that other confounding variables remain not accounted for in  
40  
41 this study. There were transfusion guidelines that specified a target postoperative hemoglobin,  
42  
43 and postoperative hemoglobin was within the target range on average. However, this target range  
44  
45 was not met in all patients. Washed irradiated RBCs were utilized per protocol, so there was no  
46  
47 control group to evaluate whether or not this practice impacted outcomes. Both lactate and  
48  
49 potassium levels rise during blood storage and the standard protocol for RBC transfusion in  
50  
51 transplant recipients involves irradiation, which further weakens the RBC membrane increasing  
52  
53 potassium leakage. Washing irradiated RBCs can reduce potassium and lactate loads, prevent  
54  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 hyperkalemia in infants during CPB and remove pre-storage additives (which may have an  
5  
6  
7 unknown effect on the neonate).<sup>37-39</sup> This is also an area in need of further research.  
8

9  
10 There are other limitations to generalizing our findings. Tranexamic acid was not part of  
11  
12 the perioperative protocol for infant cardiac transplant as the risk-benefit ratio in pediatric  
13  
14 cardiac surgery had not been adequately established.<sup>40</sup> Our study design did not include RBC  
15  
16 transfusion or chest tube output during the first 48 hours postoperatively, which could have  
17  
18 provided additional pertinent information. The Index for Mortality Prediction After Cardiac  
19  
20 Transplantation (IMPACT) score<sup>41</sup> was not utilized as it was not suitable to distinguish  
21  
22 differences within our specific patient population.  
23  
24

25  
26 Pediatric transfusion medicine is a developing field with large gaps in evidence-based  
27  
28 practice.<sup>42</sup> Whether increased blood transfusion is the cause of increased morbidity or simply a  
29  
30 marker of it remains unclear. Neonates and infants are an important subgroup within the  
31  
32 pediatric population requiring unique consideration to account for their maturing organ systems,  
33  
34 decreased physiologic reserve, and increased surgical blood loss and RBC transfusion  
35  
36 requirement (in ml/kg) compared to their larger counterparts. This retrospective study of RBC  
37  
38 transfusion to infants undergoing heart transplantation failed to show a positive correlation  
39  
40 between intraoperative RBC transfusion volume and postoperative LOS, while decreased age  
41  
42 (which directly correlated with weight) was an independent predictor of increased LOS. The  
43  
44 difference in outcomes between this and a prior report<sup>5</sup> highlight the possibility of sampling bias  
45  
46 in pediatric studies covering a large developmental time period including patients from the first  
47  
48 day of life to 18 years of age. Additional prospective studies are needed to determine the  
49  
50 outcome impact of RBC transfusion strategies to infants as a unique pediatric subgroup.

*Table Legends*

**Table 1:** Comparison of characteristics in infants <1 year of age who survived >30 days (Survivors) compared to those who died within 30 days (Non-survivors) after heart transplant.

Data were tested for normal distribution using the Shapiro Wilk test, with  $p < 0.05$  indicating data were not normally distributed. Normally distributed data are given as mean; 95% confidence interval (CI) and differences were tested using the t-test. Data that were not normally distributed are given as median; smoothed empirical quantiles and differences were compared using the Hodges Lehman method assuming data symmetry. Categorical data are given as number (%) and differences were compared using the Wald test for proportions. Year of transplant was grouped based on implementation of selective cerebral perfusion during bypass starting in 1995.

**Table 2:** Intraoperative red blood cell transfusion (100 ml/kg) compared to patient and perioperative characteristics. Continuous data were compared by linear regression. Differences in continuous data between categorical variables were compared by the Hodges Lehman method assuming data symmetry.

**Table 3:** Length of stay (LOS) compared to patient and perioperative characteristics. The log transformation of LOS better approximated normality than the untransformed LOS. Continuous data were compared to Log LOS by linear regression and differences in continuous data between categorical variables were compared by Hodges Lehman assuming data symmetry.

**Table 4:** Final multiple regression model of factors influencing Log length of stay (LOS) for 307 infants <1 year undergoing cardiac transplantation included in the study. The model indicates that RBC transfusion has no impact on LOS. Year of transplant group had an effect on LOS for all patients, but not when those who died within 30 days of transplant were excluded (Table 5). For every 10% increase in age one would expect an 8.9% reduction in LOS ( $\exp(-0.093) =$

0.911). Those intubated prior to transplantation had a 15.82% increase in LOS over those who were not intubated ( $\exp(0.1469) = 1.158$ ). There was a 63% decrease in LOS for those who died within 30 days ( $\exp(-1.0038) = 0.366$ ). For each 10% increase in days on postoperative ventilator support, one would expect a 2.52% increase in the LOS ( $1.1^{(0.2612)}=1.025$ ) and for each 10% increase in days on postoperative vasoactive support one would expect a 15.82% increase in the LOS ( $1.1^{(0.1468)}=1.1582$ ).

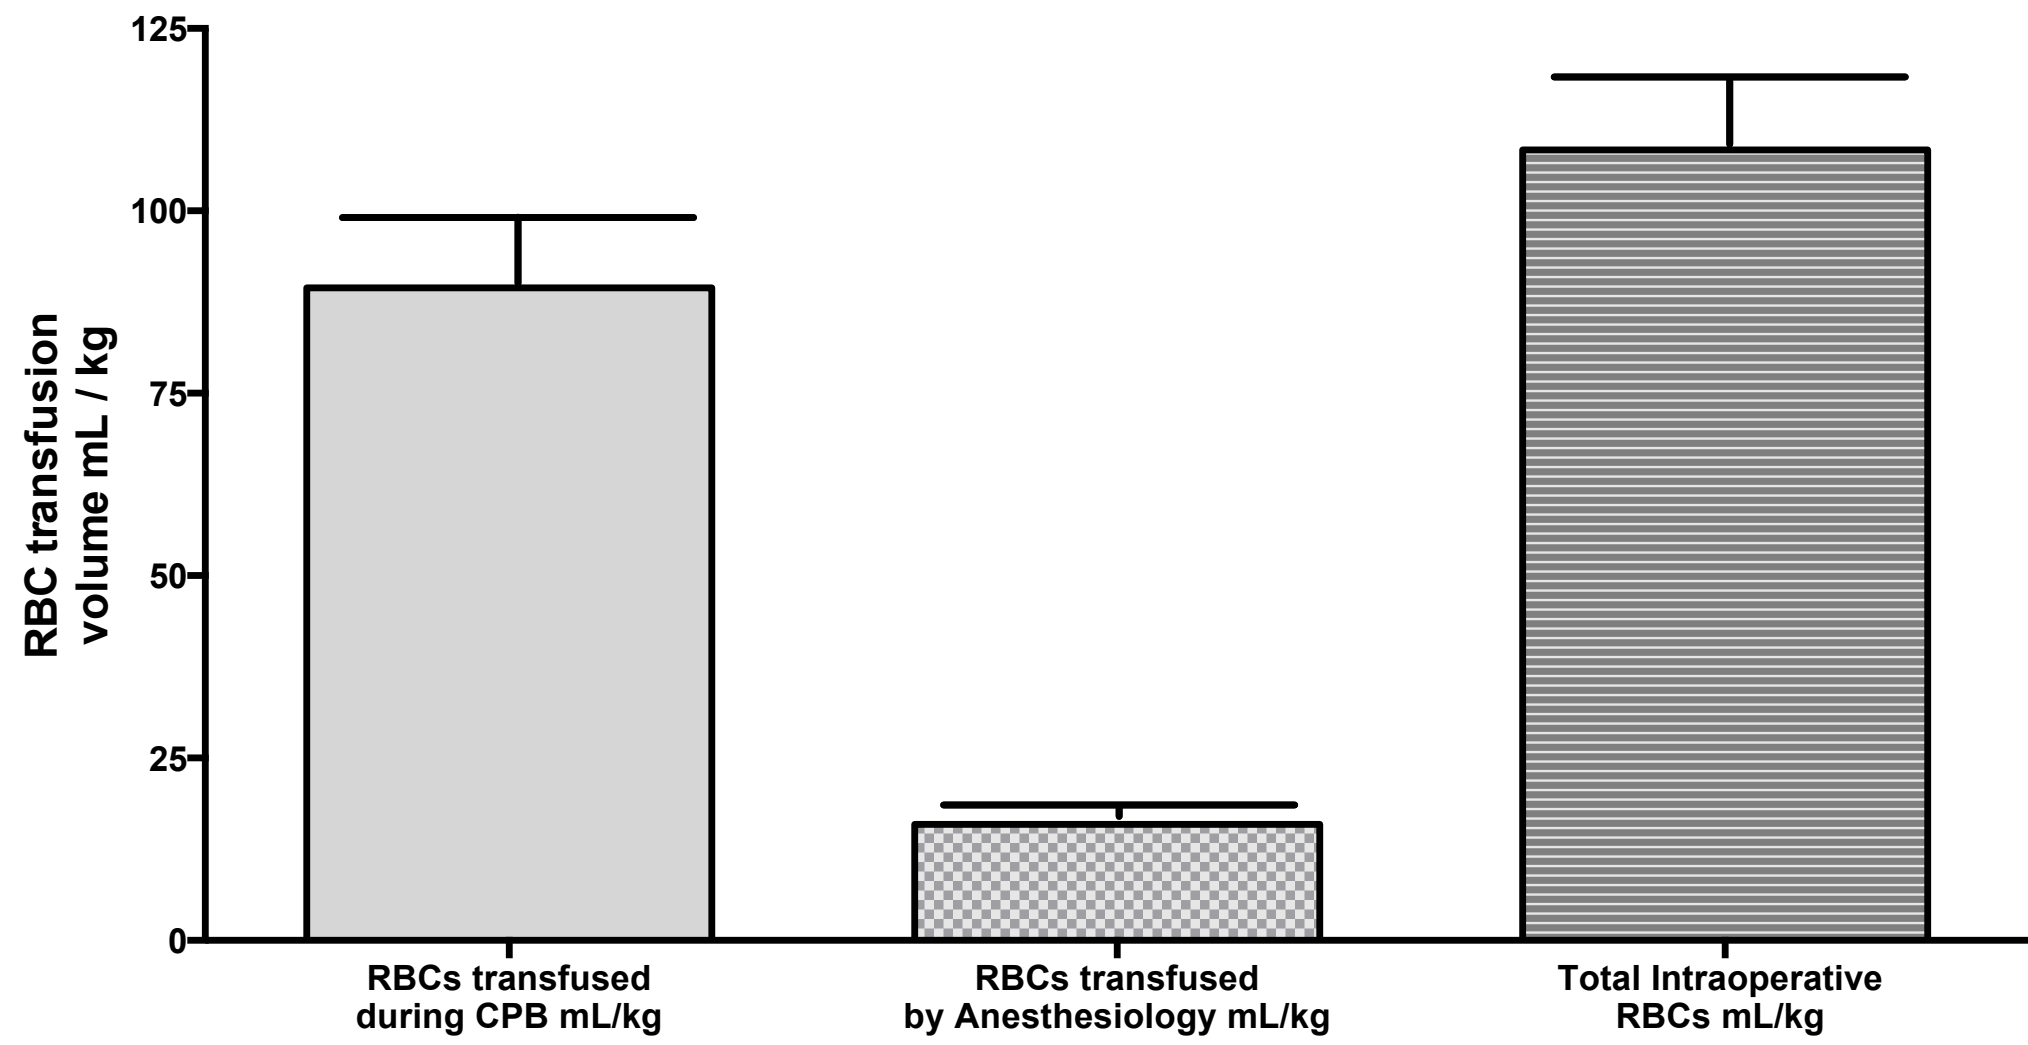

**Table 5:** Final multiple regression model of factors influencing Log length of stay (LOS) for 282 infants <1 year of age undergoing cardiac transplantation who survived >30 days postoperatively. The model indicates that there is no impact of intraoperative red blood cell transfusion (RBC) on LOS. For every 10% increase in age one would expect a 0.91% decrease in LOS. Those intubated prior to transplantation had a 17.70% increase in LOS compared to those who were not intubated ( $\exp(0.16268) = 1.1767$ ). For each 10% increase in days on postoperative ventilator support, one would expect a 3.44% increase in the LOS ( $1.1^{(0.29615)}=1.344$ ).

**Table 6:** Univariate Logistic Regression modeling odds of 30-day mortality in 25 heart transplant recipient infants <1 year of age who died within 30 days of transplant compared to 282 who survived >30 days after transplant. One patient has missing data for time on CPB, so the analysis of CPB time contains one fewer. **Bold** indicates significance; *italic* indicates variables that do not hold well in the logistic regression analysis because of the small sample size. Log of odds was linear with the continuous independent variables. H-L Chi Square p-value: Hosmer and Lemeshow Goodness-of-fit test. Odds ratios were calculated as the odds of the outcome for the first listed categorical variable compared to the odds of the outcome for the second listed categorical variable.

1  
2  
3  
4 **Table 7:** Bivariate logistic regression modeling of variables related to 30-day mortality in 25  
5 heart transplant recipient infants <1 year of age who died within 30 days of transplant compared  
6 to 282 who survived >30 days after transplant. One patient has missing data for time on CPB, so  
7 the analysis of CPB time contains one fewer. **Bold** indicates significance; *italic* indicates  
8 variables that do not hold well in the logistic regression analysis because of the small sample  
9 size. Log of odds was linear with the continuous independent variables. H-L Chi Square p-  
10 value: Hosmer and Lemeshow Goodness-of-fit test. Odds ratios were calculated as the odds of  
11 the outcome for the first listed categorical variable compared to the odds of the outcome for the  
12 second listed categorical variable.

**Table 6:** Univariate Logistic Regression modeling odds of 30-day mortality in 25 heart transplant recipient infants <1 year of age who died within 30 days of transplant compared to 282 who survived >30 days after transplant. One patient has missing data for time on CPB, so the analysis of CPB time contains one fewer. **Bold** indicates significance; *italic* indicates variables that do not hold well in the logistic regression analysis because of the small sample size. Log of odds was linear with the continuous independent variables. H-L Chi Square p-value: Hosmer and Lemeshow Goodness-of-fit test. Odds ratios were calculated as the odds of the outcome for the first listed categorical variable compared to the odds of the outcome for the second listed categorical variable.

**Table 7:** Bivariate logistic regression modeling of variables related to 30-day mortality
