BACKGROUND. Recurrence and/or metastasis occurs in more than half of patients with head and neck squamous cell carcinoma (HNSCC), and these events pose the greatest threats to long-term survival. We set out to identify genetic alterations that underlie recurrent/metastatic HNSCC.

METHODS. Whole-exome sequencing (WES) was performed on genomic DNA extracted from fresh-frozen whole blood and patient-matched tumor pairs from 13 HNSCC patients with synchronous lymph node metastases and 10 patients with metachronous recurrent tumors. Mutational concordance within and between tumor pairs was used to analyze the spatiotemporal evolution of HNSCC in individual patients and to identify potential therapeutic targets for functional evaluation.

RESULTS. Approximately 86% and 60% of single somatic nucleotide variants (SSNVs) identified in synchronous nodal metastases and metachronous recurrent tumors, respectively, were transmitted from the primary index tumor. Genes that were mutated in more than one metastatic or recurrent tumor, but not in the respective primary tumors, include *C17orf104*, inositol 1,4,5-trisphosphate receptor, type 3 (*ITPR3*), and discoidin domain receptor tyrosine kinase 2 (*DDR2*). Select *DDR2* mutations have been shown to confer enhanced sensitivity to SRC-family kinase (SFK) inhibitors in other malignancies. Similarly, HNSCC cell lines harboring endogenous and engineered *DDR2* mutations were more sensitive to the SFK inhibitor dasatinib than those with WT *DDR2*.

CONCLUSION. In this WES study of patient-matched tumor pairs in HNSCC, we found synchronous lymph node metastases to be genetically more similar to their paired index primary tumors than metachronous recurrent tumors. This study outlines a compendium of somatic mutations in primary, metastatic, and/or recurrent HNSCC cancers, with potential implications for precision medicine approaches.

Introduction

Head and neck squamous cell carcinoma (HNSCC) is the seventh most common incident cancer worldwide, with more than 600,000 new cases each year (1). The major risk factors for HNSCC are tobacco use, alcohol consumption, and/or infection with oncogenic strains of HPV, primarily HPV 16 (2). Despite advances in multimodality treatment, including surgery, radiation, and chemotherapy, 5-year overall survival has improved modestly

over 3 decades, and this persistent mortality is largely due to high rates of regional metastasis and locoregional recurrence (3).

HNSCC metastases almost always arise first in the cervical lymph nodes (4). Most patients are diagnosed with locally advanced disease, and more than half have cervical lymph node metastases present at initial diagnosis (5). Clinically, this is classified as synchronous nodal metastasis and is an indicator of a poor prognosis. Five-year adjusted survival rates range from approximately 30% to 60% for patients with synchronous nodal metastasis compared with approximately 85% for patients whose cancer has not metastasized (6). Patients with synchronous nodal metastasis are also more likely to develop locoregional or distant metastatic recurrence of HNSCC after completing curative-intent therapy (7).

Authorship note: Matthew L. Hedberg and Gerald Goh contributed equally to this work.

All index primary tumors and synchronous nodal metastases were surgically resected. Dx, diagnosis; site, anatomic location of primary tumor; path, pathological; OC, oral cavity; P, pharynx; L, larynx, LN, lymph node (cervical).

Rates of recurrence following treatment of an index HNSCC tumor range from approximately 25% to 50%, depending on the anatomical location of the primary tumor, stage at diagnosis, and HPV status (8). Relapse after initial curative-intent treatment is known as metachronous recurrence. In patients who experience recurrence, approximately 25% to 50% will do so more than once (8). Recurrent tumors are more likely to be locoregional than distant (9). Median survival following metachronous recurrence is less than 22 months in patients who are eligible for salvage surgery or reirradiation and less than 12 months for those receiving palliative chemotherapy alone (8). Recurrence in HNSCC is often resistant to standard therapy and is generally considered incurable (8, 10).

The genetic alterations underlying nodal metastasis and recurrence are incompletely understood and present a fundamental challenge to the development of more effective therapies. Next-generation sequencing of several cancers has greatly expanded our appreciation of the genetic heterogeneity that exists in a variety of malignancies. Cumulative evidence implicates a complex, nonlinear, branched evolution model of subclonal populations within tumors that defines dynamic processes that likely mediate the expansion of minor subclones under the selective pressure of therapy, culminating in metachronous recurrences that are often treatment resistant (11, 12). In hematological malignancies, distinct patterns of clonal evolution in the development of therapeutic resistance and relapse have been reported (13, 14). In melanoma treated with MEK inhibitors, sequencing of recurrent tumors has identified activating mutations in *MEK2* that confer resistance to targeted therapy (15). Whole-exome sequencing (WES) studies have revealed mutational signatures induced by temozolomide in recurrent glioma, demonstrated inherent functional variability in recurrent clones that affect response to chemotherapy in colorectal cancer, and shown that treatment can be

guided by the sequencing of metastases or circulating tumor cells in breast cancer (16–19).

Next-generation sequencing studies have not yet characterized synchronous nodal metastasis or metachronous recurrence in HNSCC. Microarray-based expression profiling of unmatched normal mucosa, primary tumors, lymph node metastases, and recurrent HNSCC lesions identified mRNA expression signatures predictive of metastasis and recurrence, but the clinical impact of these observations remains unrealized (20–23). Only one study included analysis of patient-matched index primary tumors and synchronous nodal metastases; this found that the expression profiles of primary tumors were largely preserved in their respective metastatic lymph nodes (23). To date, WES studies in HNSCC have been conducted almost entirely in newly diagnosed primary tumors; these studies have enriched our understanding of the genetic alterations underlying the pathophysiology of primary HNSCC and identified novel therapeutic targets (24–31). Mutational compendiums in the setting of metastasis and/or recurrence may contribute to similar advances for these HNSCC patients with especially poor prognoses. In an effort to define and target the genetic alterations underlying metastasis and recurrence in HNSCC, we performed WES of patient-matched tumor pairs in the setting of synchronous nodal metastasis or metachronous recurrence.

Results

Patient characteristics and WES. The cohorts analyzed in this study were 2 groups of patients with HNSCC from the University of Pittsburgh: the synchronous nodal metastasis group and the metachronous recurrence group (Supplemental Figure 1; supplemental material available online with this article; doi:10.1172/JCI82066DS1). The synchronous nodal metastasis group consisted of 13 patients contributing blood, primary tumor, and synchronous nodal metastases. The metachronous recurrence group consisted of 10 patients contributing blood, primary tumor, and recurrent tumor. All patients were treated with curative intent for the index tumor, and all metachronous recurrences underwent salvage therapy.

Clinical and pathologic characteristics were typical of a surgically treated HNSCC population and are summarized in Tables 1 and 2. Briefly, all patients were of mixed European descent, 83% of the patients were male (19/23), mean age at diagnosis was 61.9 ± 11.2 years (range: 44–79), 87% (20/23) had a history of substantial tobacco exposure (generally > 20 pack years), 74% (17/23) had documented alcohol use, and only 1 patient had HPV+ disease. Of the 5 patients in the metachronous recurrence group with nodal disease at the time of initial diagnosis, all had evidence of extracapsular spread as did 10 of the 13 patients in the synchronous nodal metastasis group.

The majority of the index primary tumors were located in the oral cavity (61%; *n* = 14), with the remainder distributed between the larynx (22%; *n* = 5) and pharynx (17%; *n* = 4). As is commonly seen in HNSCC, most patients presented with advanced disease. Of the newly diagnosed index primary tumors, 25% and 70% were American Joint Committee on Cancer (AJCC) stage III or

All index primary tumors and metachronous recurrences were surgically resected. IMRT, intensity-modulated radiation therapy; RT, radiation therapy. Index primary tumors for patients PY-6, PY-8, and PY-10 were recurrences, which are not staged.

IVA, respectively; metachronous recurrent tumors are not staged (Table 2 and ref. 32). All metachronous recurrences sequenced in this study were locoregional and, compared with their paired index primary tumors, 7/10 were located in different anatomic subsites of the head and neck (Table 2). Median time to recurrence in the metachronous recurrence group was 5.5 months (range, 2.2–33.9) (Table 2). Of 10 patients in the metachronous recurrence group, 2 received adjuvant radiation therapy and 3 received adjuvant chemotherapy in combination with radiation after resection of the index primary tumor (Table 2).

Genomic DNA from patient-matched tumor pairs and peripheral blood mononuclear cells (PBMCs) was subjected to exome sequencing as described in Methods. By design, tumors were sequenced to higher depth of coverage than normal samples (PBMCs). Normal samples were sequenced to a mean depth of 123 independent reads per targeted base and tumors to a mean of 202 independent reads (Supplemental Table 1). Single somatic nucleotide variants (SSNVs) and somatic copy number variants (SCNVs) were called (see Methods), and tumor purity was estimated from deviation in minor allele frequency of heterozygous SSNVs in segments showing loss of heterozygosity (LOH) (Supplemental Table 2). In 1 primary tumor, 2 synchronous metastases, and 1 metachronous recurrence, estimated tumor purity was too low to yield high-quality sequencing data (Supplemental Table 2). These patients were not included in the analysis of genetic concordance between matched tumor pairs, but the tumors obtained from them that did yield high-quality sequencing data were included when reporting overall mutation rates in each tumor type (11 total synchronous metastases and 9 total metachronous recurrences). All SSNVs identified by exome sequencing are enumerated in Supplemental Table 10, and sequencing files were deposited in the NCBI's database of Genotypes and Phenotypes (dbGaP phs0001007.v1.p1).

Genetic profiles of index primary tumors. Among 22 primary tumors, 1,961 SSNVs were identified in 1,666 genes (Supplemental Table 10). Tumors averaged 89.1 SSNVs (range 3–413), and the ratio of nonsynonymous/synonymous variants in coding

regions was 3.14:1. Analysis of mutation burden with MutSigCV (<http://www.broadinstitute.org/cancer/software/genepattern/modules/docs/MutSigCV>) revealed a single gene, tumor protein p53 (*TP53*), with a significant excess of SSNVs (mutated in 13 tumors, $q = 2.66 \times 10^{-6}$) (33). We utilized the findings of Vogelstein et al. ($n = 124$), the The Cancer Genome Atlas (TCGA) Pan-Cancer effort ($n = 127$), and the TCGA HNSCC cohort ($n = 11$) to generate a composite list of 191 genes, which have either been established as cancer driver genes and/or as genes that are commonly mutated in HNSCC (cancer driver genes) (Supplemental Table 3 and refs. 30, 34, 35). Forty-seven nonsynonymous SSNVs were identified in 28/191 cancer driver genes, which is significantly greater than expected by chance ($P = 5.2 \times 10^{-5}$, Monte Carlo) (Supplemental Table 4).

GISTIC2 analysis of SCNVs in the primary tumors of our cohort identified 8 significantly amplified regions, including portions of 3q and 8q that were amplified in a majority of tumors in the TCGA HNSCC cohort as well as 3q26.32 ($q = 4.95 \times 10^{-6}$), 7p11.2 ($q = 2.62 \times 10^{-3}$), and 11q13.3 ($q = 1.14 \times 10^{-3}$), which were also significantly amplified in the TCGA HNSCC cohort and overlap well-known cancer driver genes phosphatidylinositol-4,5-bisphosphate 3-kinase, catalytic subunit alpha (*PIK3CA*), *EGFR*, and cyclin D1 (*CCND1*), respectively (Supplemental Figure 2 and refs. 30, 36). We also observed 8 segments with significant recurrent somatic deletions, including portions of 3p and 8p that were lost in a majority of tumors in the TCGA HNSCC cohort as well as 9p21.3 ($q = 0.15$), which was also significantly deleted in the TCGA HNSCC cohort and overlaps cyclin-dependent kinase inhibitor 2A (*CDKN2A*) and *CDKN2B* (Supplemental Figure 2 and refs. 30, 36). Overall, the genetic profiles of the index primary tumors in this cohort are similar to those reported in other WES studies of primary HNSCC (24–31).

Index primary tumors from patients in the synchronous nodal metastasis group had a significantly greater mutational burden than those from patients in the metachronous recurrence group (125.9 ± 103.2 versus 36.0 ± 31.6 SSNVs, $P = 9.94 \times 10^{-3}$, 2-tailed

Figure 1. SSNVs in HNSCC tumors. (A) Top panel: distribution of SSNVs in each tumor pair; synchronous nodal metastases on the left, metachronous recurrences on the right. Lower panel: panels describing presence of SSNVs in select cancer driver genes in each tumor pair. SSNVs were identified as unique to primary tumor (dark blue), shared between paired tumors (light blue), or unique to metastasis or recurrent tumor (gold). (B) Differences in subclonal architecture in the primary and synchronous nodal metastatic tumors from patient PY-16. 44% of SSNVs were private to the metastatic tumor (clusters 4 and 5) and 25% private to the primary tumor (cluster 1). (C) SSNVs in the samples from patient PY-8 are unique to the primary tumor (cluster 1) or the recurrent tumor (cluster 2); shared SSNVs (clusters 3 and 4) are germline. VAF, variant allele frequency.

t test). Even after excluding PY-15 (413 SSNVs) as an outlier, there was a significant difference in the number of SSNVs between the 2 groups (102.0 ± 59.2 versus 36.0 ± 31.6 , $P = 4.21 \times 10^{-3}$, 2-tailed *t* test). Similarly, SCN burden in the index primary tumors differed significantly, with a higher fraction of the genome in index primary tumors from the synchronous nodal metastasis group harboring SCNVs than those in the metachronous recurrence group (Supplemental Table 5, 0.36 ± 0.13 versus 0.19 ± 0.13 , $n = 13$ and $n = 9$, $P = 0.017$, Mann-Whitney *U* test).

Genetic profiles of synchronous nodal metastases. In the synchronous nodal metastasis group, we obtained high-quality sequencing data from the matched PBMCs, primary tumor, and synchronous nodal metastases of 11 patients, allowing for the analysis of genetic concordance within matched tumor pairs in these patients (Figure 1A and Supplemental Table 2). The nodal metastases in these patients harbored 1,499 SSNVs in 1,310 genes (Figure 1A and Supplemental Table 10). Thirty-three nonsynonymous SSNVs in the metastases were found in 23/191 cancer driver genes, which is significantly greater than expected by chance ($P = 0.0013$, Monte Carlo) (Supplemental Table 6 and refs. 30, 34, 35). In the primary tumors of these 11 patients, 84.8% (979/1154) of nonsynonymous SSNVs and 94.1% (32/34) of nonsynonymous SSNVs in cancer driver genes were transmitted to the nodal metas-

tases (not a significantly different rate of transmission, $P = 0.15$, Fisher test) (Figure 1A and Supplemental Table 10). In the nodal metastases of these 11 patients, 13.9% (208/1499) of the SSNVs were identified as newly arisen, i.e., absent in the primary tumor (see Methods), including 1 new mutation in a cancer driver gene, *MLL4*, in PY-15 (Figure 1A, Supplemental Table 10, and Supplemental Table 6).

The PyClone algorithm was used to identify and quantify clonal populations in the primary and metastatic tumors (37). In 10 of 11 patients, 80% or more of the SSNVs identified in the nodal metastases were transmitted from the primary tumor (Supplemental Table 10). In those 10 patients, PyClone analysis revealed that the majority of SSNVs were transmitted in a stable fashion, with the primary clone (containing > 50% of SSNVs) being present at similar cellular prevalence in both the primary and metastatic tumors (Supplemental Table 7). In the 11th patient, PY-16, 44% of SSNVs were unique to the metastatic tumor (clusters 4 and 5 in Figure 1B), which had lost 25.2% of the SSNVs found in the primary tumor (cluster 1 in Figure 1B).

GISTIC2 analysis of SCNVs in the synchronous nodal metastases revealed 4 regions of significant focal amplification and 4 regions of significant focal deletion, with copy number gains encompassing *EGFR*, and *CCND1* and copy number losses encom-

Figure 2. Somatic CNVs in HNSCC tumors. (A) Overview of CNVs and (B) GISTIC significant peaks across 11 primary tumors and paired synchronous nodal metastases. (C) Overview of CNVs and (D) GISTIC significant peaks across 8 primary tumors and paired metachronous recurrences. Red, amplifications; blue, deletions; shades of red and blue, unique to primary or metastatic/recurrent tumor or transmitted between tumors; green line, $q = -.25$, signifying threshold for significance.

passing *CDKN2A* and *CDKN2B* (Supplemental Figure 3 and ref. 36). The copy number profiles between matched primary tumors and synchronous nodal metastases were not significantly different (fraction of genome-harboring SCNVs, 0.38 ± 0.14 versus 0.32 ± 0.14 , $n = 11$, $P = 0.48$, Mann-Whitney U test, Supplemental Table 5 and Figure 2A). Many of the significant SCNv peaks identified in the nodal metastases of these patients arose in the primary tumor; 3/4 regions of significant focal amplification identified in the

nodal metastases were also significantly amplified in the primary tumors (3q26.32, 7p11.2, and 11q13.3) (Figure 2B).

Among these 11 patients, 60 genes harbored nonsynonymous mutations in 2 or more patients (Figure 1A and Supplemental Table 10). Three of those 60 genes, *TP53*, *FAT1*, and *MLL2*, are cancer driver genes. Two genes were newly mutated in the synchronous metastases of 2 patients, *C17orf104* and inositol 1,4,5-trisphosphate receptor, type 3 (*ITPR3*) ($P = 0.37$, Monte Carlo)

Table 3. Genes that are exclusively mutated in 2 synchronous nodal metastases

Gene	Patient	aa change	Index primary			Synchronous nodal metastasis		
			Ref	Nonref	MAF	Ref	Nonref	MAF

	PY-21	Q145 ^A	234	0	0	215	34	0.137
<i>ITPR3</i>	PY-15	R149L	44	0	0	55	32	0.368
	PY-16	R64H	164	0	0	137	31	0.185

Ref, number of reference sequence reads; nonref, number of nonreference sequence reads; MAF, minor allele frequency (adjusted for estimated tumor purity). ^ANonsense mutation.

(Table 3). The precise function or functions of *C17orf104* have not been described, whereas *ITPR3* encodes a calcium channel receptor that binds inositol 1,4,5-trisphosphate, mediates intracellular calcium levels, and is important to exocrine functions that influence metabolism and growth (38, 39). *ITPR3* has been implicated in breast cancer proliferation, and elevated expression levels correlate with increased invasion and metastasis and decreased survival in colorectal cancer as well as dissemination of gastric cancers (40–42).

Genetic profiles of metachronous recurrent tumors. In the metachronous recurrence group, we obtained high-quality sequencing data from the matched PBMCs, primary tumor, and metachronous recurrent tumors of 8 patients, allowing for the analysis of genetic concordance in matched tumor pairs from these patients (Figure 1A and Supplemental Table 2). The metachronous recurrent tumors in these 8 patients harbored 457 SSNVs in 441 genes. Nine nonsynonymous SSNVs were found in 6/191 cancer driver genes, this number being significantly greater than expected by chance ($P = 0.019$, Monte Carlo) (Supplemental Table 9 and refs. 30, 34, 35). In the primary tumors from these 8 patients, 90.1% (274/304) of SSNVs overall and 100% (5/5) of SSNVs in cancer driver genes were transmitted to the metachronous recurrent tumors (Figure 1A). In the metachronous recurrences of these 8 patients, 40.0% (183/457) of SSNVs were identified as newly arisen (Figure 1A). The copy number profiles between matched primary tumors and metachronous recurrent tumors were not significantly different (fraction of genome harboring SCNVs, 0.21 ± 0.13 versus 0.34 ± 0.12 , $P = 0.05$, $n = 8$, Mann-Whitney U test, Supplemental Table 5 and Figure 2C). GISTIC2 analysis of these 8 primary tumor-metachronous recurrence pairs identified no regions of significant focal amplification or deletion in the primary tumors, whereas 4

and 6 regions of significant focal amplification and deletion were observed in the recurrent tumors, respectively, with copy number gains overlapping *PIK3CA*, *NFIB*, and *CCND1* and copy number losses overlapping *TATDN2* and *FAT1* (Figure 2D, Supplemental Figure 5, and ref. 36).

The PyClone algorithm was used to determine whether the metachronous recurrent tumors were largely clonal, as was observed in the synchronous nodal metastases (37). The total mutation load in the tumor pairs from patients PY-3, PY-6, PY-7, and PY-10 was too low (<30 SSNVs per pair) for analysis with this technique. In the metachronous recurrent tumors from patients PY-1, PY-5, and PY-11, 90% or more of the SSNVs identified were transmitted from the primary index tumor and present at similar cellular prevalence (Supplemental Table 7). In the metachronous recurrent tumor from patient PY-4, 60.2% of the SSNVs identified were transmitted from the primary index tumor, and the recurrence was composed of a set of SSNVs seeded from the primary tumor, present at high cellular prevalence (0.9–1.0), and a set of SSNVs unique to the metachronous recurrent tumor (40%), present at a moderate cellular frequency (a subclonal population) (Supplemental Table 10 and Supplemental Figure 4). In patient PY-8, the metachronous recurrent tumor was genetically distinct from the index primary tumor, with 110 and 26 SSNVs unique to the metachronous recurrent and index primary tumors, respectively (clusters 1 and 2); only 3 SNVs, all of which were also detected at trace levels in the matched normal tissue, were shared between the 2 tumors (clusters 3 and 4), demonstrating that this is a true “second primary” or “second field” tumor (SPT) (Supplemental Table 10 and Figure 1C). Also, newly arisen mutations were identified in 4 cancer driver genes of this SPT: *KDM5C*, *POLQ*, *SF3B1*, and *TP53* (Supplemental Table 8).

Table 4. *DDR2* is exclusively mutated in 2 metachronous HNSCC recurrences

^ANonsense mutation.

Figure 3. *DDR2* mutations in HNSCC. The genetic alterations in *DDR2* identified in our cohort and the previously reported, transcript-altering *DDR2* mutations identified in other sequencing studies of primary HNSCC tumors are displayed. 2/9 (22.2%) metachronous recurrent tumors sequenced in this study had newly arisen *DDR2* mutations vs. 12/658 (1.8%) newly diagnosed primary HNSCC tumors in other studies.

Among the 8 patients with high-quality sequencing data from all 3 tissue samples, 4 genes, discoidin domain receptor tyrosine kinase 2 (*DDR2*), *OR7A5*, *SYNE1*, and *TP53*, harbored nonsynonymous mutations in 2 or more patients (Supplemental Table 10). *DDR2* was the only gene with newly acquired mutations in the metachronous tumors of 2 patients, PY-3 and PY-8 (Table 4 and Figures 3 and 4). *DDR2* encodes the discoidin domain receptor 2, which is a collagen-stimulated receptor tyrosine kinase implicated in a wide range of processes including regulation of epithelial-to-mesenchymal transition (EMT) and osteogenic/chondrogenic differentiation (43, 44). Although the functional mechanisms of *DDR2* expression and/or mutation in disease are incompletely understood, alterations in *DDR2* have been implicated in cellular adhesion, migration, invasion, and metastasis in prostate cancer,

breast cancer, and recently, HNSCC (45–48). In total, *DDR2* mutations were observed in 3 of the 19 patients whose tumor pairs had reliable WES data (Table 4). A *DDR2*(I724M) mutation was identified in both the index primary tumor and synchronous nodal metastasis of patient PY-22.

Patients PY-3 and PY-8 both developed metachronous recurrences within the field of radiation therapy following resection of their index primary tumors. *DDR2*(R709*) and *DDR2*(I474M) mutations were identified in their metachronous recurrent tumors, respectively, and appeared to be newly arisen, as they were not identified in the paired index primary tumors from these patients. However, the depth of sequencing achieved in this study was not sufficient to rule out the possibility that these mutations were present in rare subclones in the primary tumors. The spec-

Figure 4. Spatial and temporal evolution of disease in patients harboring newly arisen *DDR2* mutations in their recurrent tumors. The clinical histories of patient PY-3 (A) and patient PY-8 (B) are shown. Index primary and metachronous recurrent tumors assessed via WES are outlined and presented with CT imaging of the respective tumors. Treatments between cancer events are illustrated on the time line, and the time to recurrence between sequenced tumors is indicated in months. Below each time line is the mutational burden of each sequenced tumor for PY-3 and PY-8, respectively. SSNVs are defined as germline/unknown (black), unique to index primary tumor (dark blue), shared between paired tumors (light blue), or unique to metachronous recurrent tumor (gold). XRT, radiation therapy; chemo, chemotherapy.

Figure 5. HNSCC cells harboring an endogenous *DDR2*(D590G) mutation are sensitive to dasatinib. 6.5×10^3 BICR 18 (*DDR2* mutant), PE/CA-PJ34, and UPCI 15B (both *DDR2* WT) cells were plated in triplicate in a 48-well plate, treated with half-log doses of dasatinib from 10 nM to 30 μ M for 48 hours, and assessed by MTT. Pooled data from 3 replicate experiments are shown (A) and demonstrate exquisite sensitivity to dasatinib in the case of BICR 18. PE/CA-PJ34 and UPCI 15B cells are 1 and 2 orders of magnitude less sensitive, respectively, to treatment with dasatinib. 2.0×10^4 BICR 18 cells were placed in migration (uncoated) chambers or invasion (Matrigel coated) chambers and treated in duplicate with DMSO or in triplicate with the indicated doses of dasatinib for 24 hours. Cells were counted and averaged from 4 photomicrographs ($\times 20$) of each membrane, and the invasion/migration ratios were calculated. Pooled data from 3 replicate experiments are shown (B) along with representative images of the membranes (C). The invasion of BICR 18 cells in Matrigel invasion assays is inhibited by dasatinib in a dose-dependent manner. Growth curves and statistics (extra sum of the squares F test and unpaired, 2-tailed *t* test with Welch's correction) are described in Methods.

trum of *DDR2* mutations in human HNSCC, including the new mutations reported here, is shown in Figure 3 and refs. 24–31. Figure 4 summarizes the clinical history of the 2 patients (PY-3 and PY-8) whose recurrent tumors were found to harbor new *DDR2* mutations. Several *DDR2* mutations, identified in squamous cell carcinoma of the lung, have been shown to be oncogenic and/or to confer high sensitivity to SRC-family kinase (SFK) inhibitors both in vitro and in vivo (49, 50). *DDR2* mutations in recurrent/metastatic HNSCC could have important clinical implications, as significant clinical response to the SFK inhibitor, dasatinib, has been reported in 2 patients with squamous cell carcinoma of the lung harboring *DDR2*(S768R) mutations (49, 51).

HNSCC cell lines with *DDR2* mutations are sensitive to dasatinib.

To investigate whether *DDR2* mutations might serve as predictive biomarkers of dasatinib sensitivity in HNSCC, we treated a panel of HNSCC cell lines with dasatinib. BICR 18 harbors an endogenous *DDR2*(D590G) mutation, whereas PE/CA-PJ34 (clone C12) is known to have WT *DDR2*, and UPCI 15B also has WT *DDR2*, by Sanger sequencing (data not shown).⁽⁵²⁾ By MTT assay, following 48 hours of dasatinib treatment, these 3 cell lines were found to have IC₅₀ values of 5.608×10^{-8} M, 5.426×10^{-7} M, and 2.211×10^{-6} M, respectively (Figure 5A). In addition to its potent cytotoxic

effect on BICR 18 cells at 48 hours, administration of dasatinib in the setting of 24-hour Matrigel invasion assays significantly inhibited the invasion of BICR 18 cells in a dose-dependent fashion (Figure 5, B and C). The sensitivity of BICR 18 cells to dasatinib was attenuated to a statistically significant degree in the setting of *DDR2* knockdown, implicating *DDR2* in the marked sensitivity of this mutant HNSCC cell line to dasatinib (Supplemental Figure 6). Similarly, when the most dasatinib-resistant HNSCC cell line from our panel, UPCI 15B, was engineered to express the *DDR2*(R709*) mutation, identified in the metachronous recurrent tumor of patient PY-3, statistically significant sensitization to dasatinib treatment compared with *EGFP* control and WT *DDR2* was observed (Supplemental Figure 7). Taken together, these data suggest that *DDR2* status may serve as a biomarker for response to SFK inhibitors in HNSCC.

Discussion

WES of patient-matched tumor pairs from 23 individuals with HNSCC demonstrates the intertumor genetic heterogeneity of this cancer. To our knowledge, this is the first study of HNSCC to examine intertumor genetic heterogeneity in synchronous nodal metastases and metachronous recurrence across multiple

patients; it provides a model to determine patterns of mutation and clonal evolution that may be targetable for the treatment of recurrent/metastatic disease.

Primary tumors in our study averaged 67.6 nonsynonymous SSNVs per tumor, including mutations in tumor suppressor genes, oncogenes, and genes that have previously been found to be significantly mutated in HNSCC, such as *AJUBA*, *CASP8*, *FAT1*, *FBXW7*, *NFE2L2*, and *TP53* (Supplemental Table 10 and Supplemental Table 4). Interestingly, primary tumors were not found to harbor mutations in several tumor suppressor genes and oncogenes previously implicated in HNSCC, including *CCND1*, *PIK3CA*, *NOTCH1*, *PTEN*, *CDKN2A*, *HRAS*, and *EGFR*. However, copy number alterations, consistent with previously published reports, were seen in several of these genes, and the overall genetic profiles of primary tumors in our study appear similar to those reported in other WES studies of primary HNSCC tumors (Supplemental Figure 2 and refs. 24–31).

Approximately 86% (1290/1499) of the SSNVs identified in synchronous nodal metastases from 11 patient-matched tumor pairs were transmitted from their respective index primary tumors. This high degree of mutational similarity between primary tumors and synchronous nodal metastases in individual patients was also seen in the only other published sequencing report of patient-matched HNSCC tumors to date, in which whole genome sequencing was performed on 3 regions of a primary HPV⁺ HNSCC tumor and 2 regions of a single synchronous cervical lymph node metastasis from 1 patient (53). In that study, Zhang et al. used multiple samples of the same tumor to study intratumor genetic heterogeneity and approximated the phylogenetic evolution and time line of cancer development in that patient. They estimated that the clones making up the nodal metastasis evolved at a significantly later point in time than the clones of the index primary tumor (53). We are unable to estimate the time line of clonal evolution, as our study design does not allow for the analysis of intratumor genetic heterogeneity. However, if metastatic potential is acquired in later stages of HNSCC progression, as posited by Zhang et al., then mutated genes identified in multiple nodal metastases, but not in the primary tumors, may confer metastatic ability. Newly arisen mutations in *C17orf104* and *ITPR3* were seen in the nodal metastases of 2 patients in the synchronous nodal metastases group; these represent plausible targets for investigation in future studies (Table 3). Alternatively, if the ability to metastasize is developed early in HNSCC development, as is the commonly held clinical belief and may be suggested by the observation that in 8/11 patient-matched tumor pairs in the synchronous metastasis group, fewer SSNVs were identified in the metastases than in their paired primary tumors, then commonly transmitted mutations may confer metastatic ability (Supplemental Table 10).

Approximately 60% (274/457) of the SSNVs identified in metachronous recurrences from 8 patient-matched tumor pairs were transmitted from their respective index primary tumors. This finding suggests a greater degree of intertumor genetic heterogeneity in the setting of metachronous recurrence versus synchronous nodal metastasis in HNSCC. This was largely expected given that, compared with their matched index primary tumors, metachronous recurrent tumors sequenced in this study were malig-

nancies that arose in different anatomical microenvironments at later points in time, often following genotoxic therapy, including radiation and/or chemotherapy.

The field cancerization theory suggests that there are numerous malignant and premalignant fields present in the mucosa of HNSCC patients (54). This can lead to a high degree of intertumor genetic heterogeneity in the setting of recurrent disease, as metachronous tumors can be recurrences that evolved from cells in the initial primary tumor that survived treatment or they may arise from malignant clones that developed in a field unrelated to the initial cancer event, known as an SPT (3). To date, the differentiation of recurrence and SPT have been based on histologic appearance, anatomic location, and kinetics of tumor formation, with earlier events (<24 months) generally considered to represent recurrences. Molecular diagnostic studies using mutated *TP53* and patterns of genetic changes as markers suggest that as many as 50% of recurrent HNSCC tumors that arise within 3 years of initial treatment and occur within 2 cm of the original index tumor location may in fact be SPTs (9). In patient PY-8, we conclusively demonstrate an instance in which the metachronous tumor represents a true SPT. The metachronous tumor was found to harbor newly arisen mutations in multiple cancer driver genes and shared no SSNVs with the index primary tumor studied from that patient, apart from 3 SNVs of uncertain, potentially germline, origin. Identification of the unique mutational profiles in recurrences and SPTs will be vital to the rational design of personalized therapy that appropriately targets the newly aberrant cellular processes contributing to the formation of metachronous head and neck tumors.

Although this cohort is small, it is striking that 2/9 metachronous recurrent tumors, including one true SPT, harbored *DDR2* mutations that were not identified in their matched primary tumors. Sequencing data, utilizing platforms sufficient for detection of *DDR2* mutations, are available for at least 658 newly diagnosed primary HNSCC tumors to date, and only 12 have been found to harbor transcript-altering *DDR2* mutations (Figure 3 and refs. 24–31, 53, 55). The HNSCC cell line BICR 18, which harbors an endogenous *DDR2* mutation, HNSCC cells engineered to express the *DDR2* mutations identified in metachronous recurrent HNSCC tumors, and *DDR2* mutant tumors in 2 lung cancer case reports, demonstrated increased sensitivity to dasatinib (Figure 5, Supplemental Figure 7, and refs. 49, 50). While the precise mechanism or mechanisms underlying dasatinib sensitivity are beyond the scope of this report, the general mechanisms and consequences of discoidin domain receptor signaling in cancer are areas of ongoing research (47–50, 56). The *DDR2*(R709*) mutation identified in the metachronous recurrent tumor of patient PY-3, which conferred the greatest degree of sensitization to dasatinib in the present study, has also been reported in gastric and endometrial cancers. It is among the most common recurrent mutations and is the only recurrent truncation mutation, identified in *DDR2* across all cancers in the TCGA and COSMIC databases (57–60). Patient PY-3 was HPV negative, had no history of smoking or significant alcohol use, and had a low mutational burden, further implicating *DDR2* as a potential driver in the metachronous recurrence.

If validated in larger cohorts, our observation that *DDR2* mutations may be enriched in metachronous recurrences and may confer enhanced sensitivity to SFK inhibitors has important implica-

tions for the treatment of recurrent disease, especially in light of the exceptional clinical response to dasatinib reported in 2 patients with lung squamous cell carcinoma harboring *DDR2*(S768R) mutations. As such, further mechanistic investigations to define the role of *DDR2* mutations as predictive biomarkers in HNSCC are warranted. While SFK inhibitors are FDA approved in several hematological malignancies, their role has not been defined in solid tumors and is the subject of ongoing preclinical and clinical investigations (61). A 12-patient, single-arm, phase II study of dasatinib in unselected patients with recurrent/metastatic HNSCC failed to demonstrate significant activity; however, the *DDR2* status of patients' tumors was unknown (62). A biomarker-guided trial in which patients with *DDR2*-mutated tumors are selected to receive a SFK inhibitor has not been performed. A variety of sequencing platforms in common clinical use are capable of rapidly assessing the mutational status of *DDR2* and other genes in HNSCC tumor samples (63). The implementation of such techniques will be required to determine to what degree, if any, *DDR2* mutations are enriched in metastatic/recurrent disease overall and to correlate mutational status with treatment response and outcomes.

Limitations of the present study include the relatively small sample size, the use of a cohort of convenience where adequate biologic material was available for sequencing, a lack of distant metastases, variations in tumor sample purity, and the assessment of a single sample per tumor, thereby precluding assessment of intratumor heterogeneity. While these findings will require validation in future, larger sequencing studies, we believe this is the first mutational analysis of patient-matched tumor pairs in the setting of synchronous nodal metastasis and metachronous recurrence in HNSCC. The findings provide an opportunity to guide future investigations.

Methods

Patient selection and DNA extraction. Fresh-frozen tumor pairs and matched normal tissue were banked in the University of Pittsburgh head and neck tissue bank and made available for sequencing in this project under the auspices of an observational research study funded by the Specialized Program of Research Excellence (SPORE) as previously described (29). Genomic DNA for WES was extracted from whole blood and fresh-frozen tumor tissue using the DNeasy Blood & Tissue Kit (QIAGEN) according to the manufacturer's instructions.

WES and analysis. Targeted capture was performed using the NimbleGen 2.1 Exome reagent, followed by sequencing on the Illumina platform, and downstream processing was performed as previously described (64, 65). Briefly, sequences were aligned to NCBI Build 37 of the human genome using the ELAND program (Illumina). Somatic mutations were called based on the significance of differences in reference and nonreference read distributions between tumor and matched normal samples. Under the assumption that few if any clonal somatic changes should occur in blood DNA, as a control the same test was applied to germline DNA using tumor DNA as reference, which, as previously shown, yields high validation rates of putative somatic mutations (66). If a mutation was called in either tumor of a patient-matched pair, it was considered present in the second tumor if there were at least 5 independent reads supporting the variant call. Calls were further evaluated by manual inspection of read alignments. Sequencing data were deposited in the NCBI's database of Genotypes and Phenotypes (dbGaP phs0001007.v1.p1).

Additional tissue samples from 6 tumors (the primary tumors of patients PY-1, PY-7, PY-13, PY-19, PY-24, and the recurrent tumor from patient PY-3) underwent WES under the auspices of other studies (29, 30). The alternative informatics pipeline and sequencing methods are described in the published reports. In these 6 tumors, 78% of the mutations detected by the sequencing and bioinformatics pipeline in this study were also identified in the other studies (Supplemental Table 9). A lack of hotspot mutations in *PIK3CA* (AAs 542, 545, and 1047) was confirmed by Sanger sequencing of the tumor samples used in this study (data not shown).

MutSigCV (v1.3.01) was used to determine whether genes were mutated more often than expected by chance (33). CNVs were identified by comparing coverage depth ratios of tumor and matched normal samples after normalizing for mean coverage depth of each exon and changes in minor allele frequency at informative SNPs. GISTIC2.0 was used to assess the significance of recurrent CNVs, and the PyClone algorithm was used to assess clonality, as described previously (36, 37).

Cell cultures. The HNSCC cell lines BICR 18 and PE/CA-PJ34 (clone C12) were obtained from Sigma-Aldrich; UPCI 15B was a gift from Theresa Whiteside (University of Pittsburgh Cancer Institute). The HNSCC cell lines were grown in the following culture mediums, each containing 10% fetal calf serum and 1× penicillin/streptomycin solution (Invitrogen): UPCI 15B in DMEM, BICR 18 in DMEM with 2 mM glutamine (Mediatech Inc.) and 0.4 µg/ml hydrocortisone, and the PE/CA-PJ34 (clone C12) cells in Iscove's Modified Dulbecco Minimum Essential Medium with 2 mM glutamine (Mediatech Inc.). All cell lines were maintained in a humidified cell incubator at 37°C, 5% CO₂.

Drug treatment and survival assays. HNSCC cells were plated at the indicated concentrations in 48-well culture plates overnight and treated with the indicated concentrations of dasatinib (Bristol-Myers Squibb) for 48 hours, at which point MTT (Sigma-Aldrich) was performed according to the manufacturer's instructions, as previously described (26). Growth curves were generated using GraphPad Prism 6 software as outlined in *Statistics*.

Invasion assays. Invasion of BICR 18 cells in the presence or absence of dasatinib was tested using BioCoat migration and Matrigel-coated invasion chambers (BD Biosciences) according to the manufacturer's instructions. Briefly, 2.0 × 10⁴ BICR 18 cells were placed in migration (uncoated) chambers or invasion (Matrigel coated) chambers. They were treated with DMSO (*n* = 2) or the indicated doses of dasatinib (*n* = 3) for 24 hours. The experiment was repeated 3 times, and cells were counted and averaged from 4 photomicrographs from each membrane. Bar graphs and statistical analysis generated in GraphPad Prism 6 are outlined in *Statistics*.

***DDR2* knockdown.** BICR 18 cells were plated at 10% confluence in 96-well plates overnight, treated with 8 µl polybrene, and infected with 15 µl of MISSION pLKO.1-puro lentiviral particles containing control or α -*DDR2* shRNA constructs (α -EGFP control, 121117 5'-CCGGCCCATGCCTATGCCACTCCATCTCGAGATGGAGTGGCATAGGCATGGGTTTTGTG-3', or 195105 5'-CCGGCGAACTGTTTAGTGGGTAAGCTCGAGCTTACCCACTAAACAGTTTCGTTT-TTTG-3') (Sigma-Aldrich). Seventy-two hours later, cells were split into 96-well plates and cultured for 2 weeks in media containing puromycin to derive subclones expressing the shRNA constructs. Cells were then cultured in full medium without puromycin until sufficient volumes were obtained for phenotypic analyses (3–6 weeks).

Cloning and mutagenesis. WT *EGFP* was cloned into the retroviral vector pMXs-puro (Cell Biolabs Inc.). WT *DDR2* cloned into a pWZL-Blast vector was a gift from Peter Hammerman (Dana-Farber/Harvard Cancer Center, Boston, Massachusetts, USA) and was used as a template for site-directed mutagenesis using the QuikChange Site-Directed Mutagenesis Kit (Stratagene) (49). Mutagenesis of the *DDR2* WT gene was performed according to the manufacturer's instructions and confirmed by Sanger sequencing.

Mutant *DDR2* expression. Retroviruses were generated using the Platinum Retrovirus Expression Systems (Cell Biolabs), Eugene HD (Promega), and retroviral vectors carrying the gene of interest (pMXs-puro-*EGFP* as control, pWZL-Blast-*DDR2* [WT], pWZL-Blast-*DDR2* [mutants]) according to the manufacturers' instructions, as previously published (26).

Western blotting. Standard Western blotting was performed as previously described (67). Primary antibodies were as follows: α -*DDR2* (catalog 12133, Cell Signaling Technology Inc.), α - β -tubulin (ab6046, Abcam), goat anti-rabbit IgG (H+L)-HRP-conjugated secondary antibodies (catalog 170-6515, Bio-Rad), and Luminol reagent (sc-2048, Santa Cruz Biotechnology Inc.).

Statistics. Mean values with SEM from replicate experiments plotted as indicated in figure legends were plotted as mean values $\pm$ SEM in Graphpad Prism 6. A sigmoidal dose-response curve with automatic outlier elimination was applied to generate optimized data sets. The finalized data sets, with outliers removed, were used to generate growth curves using the least squares fit log (inhibitor) versus normalized response-variable slope equation. The log IC_{50} values were compared using an extra sum of the squares F test (null hypothesis indicates the log IC_{50} values are identical; the null hypothesis was rejected in cases where $P < 0.05$). For bar graphs, mean values with SEM were calculated and plotted as above and compared using an unpaired, 2-tailed *t* test with Welch's correction.

Study approval. The patient cohort consisted of HNSCC patients treated at the University of Pittsburgh Medical Center otolaryngol-

ogy clinics who were enrolled in an observational research study supported by the University of Pittsburgh's SPORE in head and neck cancer. All participants provided written informed consent, and the study was approved by the University of Pittsburgh Institutional Review Board.

Author contributions

Conception and design were by MLH, JRG, SIC, and RPL. Development of methodology was performed by MLH. Acquisition of data was performed by MLH, GG, BBD, YZ, MLF, VWYL, SIC, and LW. Analysis and interpretation of data were performed by MLH, GG, JEB, BBD, WEG, JRG, VWYL, RPL, and RSH. Writing, review, and/or revision of the manuscript were done by MLH, GG, JEB, BBD, JRG, RPL, and RSH. Administrative, technical, or material support was provided by MLH, JRG, SIC, and LW.

Acknowledgments

We would like to thank Theresa Whiteside for graciously providing the UPCI 15B cell line and Peter Hammerman for graciously providing the *DDR2* retroviral expression construct. This work was supported by grants from the NCI (1F30CA180235-01A1 to M.L. Hedberg, and P50CA097190 to J.R. Grandis), the Agency for Science, Technology and Research of Singapore (fellowship to G. Goh), the American Cancer Society (CRP-08-229-01 to J.R. Grandis), and Gilead Sciences Inc. (research support to R.P. Lifton and R.S. Herbst).
