SIMULATED PERFORMANCE OF CIEE'S "ALTERNATIVES TO COMPRESSIVE COOLING" PROTOTYPE HOUSE UNDER DESIGN CONDITIONS IN VARIOUS CALIFORNIA CLIMATES

Yu Joe Huang

Simulation Research Group Building Technologies Department Environmental Energy Technologies Division Lawrence Berkeley National Laboratory

ABSTRACT

To support the design development of a "compressorless" house that does not rely on mechanical air-conditioning, the author carried out detailed computer analysis of a prototypical house design to determine the indoor thermal conditions during peak cooling periods for over 170 California locations. The peak cooling periods are five-day sequences at 2% frequency determined through statistical analysis of long-term historical weather data. The DOE-2 program was used to simulate the indoor temperatures of the house under four operating options: windows closed, with mechanical ventilation, evaporatively-cooled mechanical ventilation, or a conventional 11/2ton air conditioner. The study found that with a 1500 CFM mechanical ventilation system, the house design would maintain comfort under peak conditions in the San Francisco Bay Area out to Walnut Creek, but not beyond. In southern California, the same system and house design would maintain adequate comfort only along the coast. With the evaporatively-cooled ventilation system, the applicability of the house design can be extended to Fairfield and Livermore in northern California, but in southern California a larger 3000 CFM system would be needed to maintain comfort conditions over half of the greater Los Angeles area, the southern half of the Inland Empire, and most of San Diego county. With the 11/2-ton air conditioner, the proposed house design would perform satisfactorily through most of the state, except in the upper areas of the Central Valley and the hot desert areas in southern California. In terms of energy savings, the simulations showed that the prototypical house design would save from 0.20 to 0.43 in northern California, 0.20 to 0.53 in southern California, and 0.16 to 0.35 in the Central Valley, the energy used by the same house design built to Title-24 requirements.

SIMULATED PERFORMANCE OF CIEE'S "ALTERNATIVES TO COMPRESSIVE COOLING" PROTOTYPE HOUSE UNDER DESIGN CONDITIONS IN VARIOUS CALIFORNIA CLIMATES

1.0 INTRODUCTION

Since 1993, the author has been involved with a team of researchers, engineers, and architects in the "Alternatives to Compressive Cooling" project sponsored by the California Institute for Energy Efficiency (CIEE) with the goal to design and construct a house for California Transition Climates that would not require mechanical air-conditioning. There is no rigorous definition of the Transition Climates, but they can be roughly delineated as the area between the coast and the Central Valley or Southern desert where the climates are alternately affected by cooler marine or warmer inland influences. The rationale for the project is that as urbanization expands into the Transition Climates, new housing is being constructed with central air-conditioning systems that operate for a limited number of days and add an extremely disadvantageous electricity load to the utility district on hot summer afternoons. The project aims to provide a counter-example by demonstrating that it is possible to build a relatively conventional house in such locations that does not require, or at least minimizes, the use of air-conditioning.

In July 1995, the project team held a design charette in San Francisco with invited architects and builders that resulted in four concept house plans of varying degrees of conventionality. The project designer, George Loisos, selected one of the house plans with the most immediate market appeal and buildability, refined it into working drawings, and gave it the title of the "Summer Comfort House". At the same time, other members of the team, especially the Davis Energy Group, worked with consultant engineers to design possible alternative cooling systems such as a mechanical ventilation system, an indirect evaporatively-cooled ventilation system, or a small air-conditioner should that prove necessary. More detailed descriptions of the "Summer Comfort House" and cooling system can be found in other project reports (Loisos and Ubbelohde 1996, Bourne et al. 1998).

To support the design development and evaluate the performance of the "Summer Comfort House" and the proposed cooling systems, the author carried out the DOE-2 (Winkelman et al. 1993) computer analysis described in this report. This analysis differs from standard building energy simulations in two ways : (1) the focus is on the building performance during peak design periods rather than over an average year, and (2) the performance evaluation is measured in terms of indoor thermal conditions rather than building energy use. The reason for this perspective is that public acceptability of the house will depend much more on whether it can provide satisfactory comfort on the hottest days, rather than on its energy performance. Therefore, the key issue being addressed by the DOE-2 analysis is to determine how the "Summer Comfort House" performs under design conditions in various California Transition Climates. Only after this analysis was completed was a secondary task added to simulate the building's annual energy performance in the 16 climate zones designated by the California Energy Commission for Title-24 compliance. This use of DOE-2 to analyze design performance opens up the issue of how to define appropriate outdoor design conditions. Since the "Summer Comfort House" is designed to use thermal mass and/or night venting to moderate daytime temperatures, the simulations need to be done not for a single design day, but for a heat wave of several days duration. Such design climatic data are not readily available. Typical engineering references such as the ASHRAE *Handbook of Fundamentals* provide only single peak design temperatures with no information about the preceding or subsequent temperature history (ASHRAE 1997). A recently completed ASHRAE Research Project compiled 5-day design sequences for 216 U.S. locations, of which only five were located in California, too sparse to distinguish between coastal, transition, and inland climates (Colliver et al. 1996). The 16 California Energy Commission Title 24 hourly weather tapes (California Energy Commission 1980, 1992) have a similar problem in geographical coverage. Furthermore, all such "typical year" weather data are suspect because by design they omit extreme climatic conditions.

Because of the clear need for better weather data for this and similar projects, the author obtained funding from the University of California Energy Institute (UCEI) in 1996 to develop 5-day sequences at various design frequencies for 171 California locations based on 10 to 30 years of historical weather data for each location. Each design sequence consists of the maximum and minimum dry-bulb and coincident wet-bulb temperatures for each day of the 5-day design sequence (Zhang and Huang 1999).

2.0 METHODOLOGY

2.1 Design Climate Sequences

The UCEI Weather Project produced design weather sequences for 171 California locations at 4 design criteria of 0.4%, 1%, 2%, and 10% annual frequency. 15 stations have hourly drybulb and wet-bulb temperatures. The remaining 156 have only max/min dry-bulb temperatures. The same search method was used on both sets of data to identify 5-day sequences with average temperatures corresponding to the four design criteria mentioned. For the stations with only max/min dry-bulb temperatures, the coincident wet-bulb temperatures at the daily maxima were interpolated based on the relationship between the peak dry-bulb and coincident wet-bulb design temperatures given in the ASHRAE Region X weather data for the same locations (ASHRAE 1982). The coincident wet-bulb temperatures at the daily minima were estimated using the average wet-bulb depressions during peak cooling periods in the 16 California Energy Commission Title 24 weather tapes. The 156 stations were then grouped into the 16 climate zones according to the Title 24 climate zone boundaries, with some adjustments to avoid large discontinuities when crossing climate zone boundaries (Zhang and Huang 1999).

Correlating the design frequencies for the 5-day sequences to conventional design temperatures is more complex than meets the eye. We found that the peak temperature during a 5-day design sequence was significantly higher than the design temperature of the same design frequency, e.g., 0.4%, 1%, etc. This is not unexpected since the peak temperature within a 5-day sequence introduces a further frequency probability, but relating the combined frequency to conventional hourly frequencies is difficult. Empirical comparisons to ASHRAE design temperatures indicate that the maximum temperature during a 2% design sequence corresponded closest to 0.1% summer/0.4% annual temperatures. Since these design temperatures are the most stringent design criteria, we selected the 2% design sequence for use in this analysis. One interpretation of this design frequency is that it would occur once every 250 days, or slightly more than once in a typical year. The average and peak temperatures of the 2% design sequences for the 2% design sequences for the 2% design sequences for the 2% design sequence to the set average and peak temperatures of the 2% design sequences for the 171 California

locations are listed in Appendix B. The maximum and minimum daily temperatures for each of the 5 days are listed on the first line for each city in Table 1, preceded by the temperatures for the warm-up period.

The warm-up period refers to the days before each five-day design sequence. Since DOE-2 initializes the house conditions for 7 days or 168 hours before each simulation period, the assumed weather conditions of the warm-up period can have a significant impact on the thermal conditions of the building during the design sequence. For this analysis, the temperatures for the warm-up period are taken as the average of the five-day sequence at the 10% design frequency. This criteria corresponds roughly to using the average maximum and minimum temperatures from the hottest month of the year.

The design sequences are incorporated into the DOE-2 simulations by a procedure that creates a pseudo-yearly weather file with the 5-day design sequence repeated twice, once beginning on July 1 and the other on September 15, and filling the remaining 355 days each with a repetition of the warm-up day.

2.2 DOE-2 Model of Prototype House

A general description and architectural drawings of the "Summer Comfort House" are available in other project reports (Loisos et al. 1997). The house is a Mediterrean-style 2story building of conventional wood-frame construction with a floor area of 2190 ft². Following an earlier DOE-2 analysis effort, the insulation levels of the building were selected as R-40 roof, R-33 walls, and R-5 slab edge. The building window area (glazing only) is 293 ft² (13.8% of floor area), all consisting of double-pane low-E windows with a Ufactor of 0.31 and a Solar Heat Gain Factor of 0.37 (Shading Coefficient 0.43). A shading multiplier of 0.60 on solar heat gain is added to account for drapes or blinds half closed during the cooling season.

The building is modeled with the front facing west and the courtyard opening to the south. For solar protection, the building has 3 ft. roof overhangs on all sides. Additional shading is provided to the front of the building by a large entry porch, and by identical neighboring buildings located 10 ft. away on both the north and south sides of the house.

To enhance the building's thermal mass, the insides of the exterior walls are finished with $\frac{3}{4}$ in. gypsum board, the interior walls are made of $\frac{3}{4}$ in. of solid gypsum, and the floor slab is assumed to be 50% exposed tile and 50% carpeted. The infiltration rate of the building is modeled with an Effective-Leakage-Fraction of 0.0006, reflecting a relatively tight construction given this building's large surface-to-volume ratio. Both the roof and walls are modeled with albedos of 0.65 indicating off-white to light colors.

Although DOE-2 cannot model inter-zone air flows, the building was modeled as eight thermal zones (main space, 1st floor bedroom, 2nd floor master bedroom, 2nd floor master bathroom, and 2nd floor bedroom, 1st floor attic, main attic, and garage) to model, partially at least, temperature variations between the first and second floors.

The modeling of the floor slab is particularly problematic because of DOE-2's limited ability to model ground heat flows, and the large thermal lag of the soil. While the design simulations are done for two 5-day design sequences, the heat flows through the slab core should still reflect long-term average seasonal conditions, with only the slab edge affected by the transient increase in air temperatures. For this analysis, a specialized method was developed that uses results from two-dimensional analysis of foundation heat flows for California climates, and models the floor slab so that both the temporary heat gain through the perimeter as well as the heat sink effect of the slab core are taken into account. This modeling detail can have a significant impact on the thermal behavior of the house, and is discussed in more detail in Appendix C of this report.

2.3 DOE-2 Model of Cooling Systems

This study considered five different modes of operation of the "Summer Comfort House": (1) none, i.e., the house is closed and has no ventilation of any kind (although there remains stack and wind-driven infiltration), (2) natural ventilation through windows, (3) mechanical ventilation with a ducted 1500 CFM fan system operating in an economizer mode, (4) indirect evaporatively-cooled ventilation, i.e., same as 3 but with the intake air passing first through an indirect evaporative cooler, and (5) small $1\frac{1}{2}$ ton air-conditioner with a 1500 CFM fan operating in an economizer mode. The first mode represents a worst case scenario that would virtually guarantee overheating in almost all climates. The second mode is also not considered seriously because of its dependence on occupant action. Moreover, the simulation results are not credible since there are no available data on wind conditions during the 5-day design sequences. This leaves the last three modes as the cooling system options under contention. Lastly, additional parametric studies were done: with increased fan capacity for the third option, and an improved evaporative cooling control system for the fourth option.

The mechanical ventilation and indirect evaporatively-cooled ventilation systems were both modeled in DOE-2 using user-defined Input Functions. Both systems required two functions, one to add ventilation air to the space depending on indoor and outdoor air conditions, and another to record the zone temperature. For the mechanical ventilation system, a fixed amount of ventilation air (1500 CFM) is added to the house if the previous hour's indoor temperature is above 68°F and higher than the outdoor air temperature. When the previous hour's indoor temperature is below 68°F, but still higher than outdoor air temperature, the fan

CFM is reduced proportionally to zero at 62°F, at which point ventilation is stopped. The intent of this control logic is to model ventilative cooling down to 65°F and eliminate the oscillation seen with a simpler 65°F cut-off.* The DOE-2 results show that the Function produces minimum zone temperatures slightly below 65°F.

The Input Function for indirect evaporatively-cooled ventilation is similar, except that the temperature of the ventilation air is reduced by 60% of the wet-bulb depression (the difference between the dry- and wet-bulb temperatures), assuming an effectiveness of 0.60 for the indirect evaporative cooler. Although the ideal control for such a cooling system would be to ventilate whenever the temperature of the evaporatively-cooled air is below the indoor air temperature, but practically this would be difficult because this temperature can only be detected after the system has been turned on. For the "standard" 1500-CFM system, a simpler control system was used where the dry-bulb temperature minus 10°F is used as an approximate indicator of the evaporatively-cooled air temperature. This temperature offset was derived by trial and error and resulted in slight overcooling in Northern California climates (down to 62-63°F), but in Southern California climates such as Pasadena, it shut down the system when the evaporatively-cooled air temperature was still lower than that of the indoor air.

^{*} The oscillations result because the User Function uses the previous hour's zone temperature to determine whether ventilative cooling is done. With a simple 65°F cutoff, the zone would alternate between venting and no venting with a 2-3°F oscillation.

To study the practical maximum cooling capacity of the ventilation systems, the simulations were repeated with a 3000 CFM fan, and for the indirect evaporatively-cooled system, with an improved control based on the actual evaporatively-cooled air temperature.

The $1\frac{1}{2}$ ton air-conditioner system was modeled using the standard DOE-2 RESYS (Residential) system with the cooling setpoint held at 78°F. The fan capacity was kept at 1500 CFM, and mechanical ventilation down to 65°F mimicked by modeling natural ventilation using a fixed air-change rate. The air-conditioner was given a cooling capacity of 18,000 Btu/hour, and modeled with part-load performance curves for a high-efficiency air conditioner and a COP of 2.70.

For the annual simulations, the building was modeled with a $1\frac{1}{2}$ ton air-conditioner with a COP of 2.70 and a 50,000 Btu pulse-combustion furnace with a steady-state efficiency of 0.74. Attempts to simulate the building with the ventilative cooling systems described earlier was unsuccessful due to the lack of a control algorithm to prevent overcooling on mild days or during the heating season. As a result, these runs showed unreasonably high heating energy consumption and have been omitted from this study.

3.0 RESULTS

3.1 Maximum indoor temperatures

The DOE-2 calculated maximum and minimum indoor temperatures from the two design periods in the five conditioned zones for the "Summer Comfort House" in 171 California climates are shown in Table 1. For each city, the first line gives its geographical coordinates, followed by the max/min temperatures for the warm-up period and the five days of the design sequence. The following four lines give the maximum and minimum temperatures by zone for the following control options: Closed (Option 1), Vent (Option 3), IEC (Option 4), and A/C (Option 5). For the A/C line, the last column gives the peak A/C electricity demand over the two design sequences. A blank in that column indicates for that location the air-conditioner never came on. The results for some representative cities are also plotted in Figures 3 through 16, and discussed in greater detail in the following section.

Those cities identified by an "S" or "EI" are those for which there were detailed hourly dryand wet-bulb temperature data. For the other cities, the design sequences are based on maxmin dry-bulb temperatures only, with extrapolated wet-bulb temperatures.

Since Table 1 does not indicate how often the maximum and minimum temperatures were reached, it tends to accentuate the range of temperatures. For example, Table 1 shows the maximum indoor temperatures with mechanical ventilation in Los Angeles (LAX) to be from 78.1 to 78.9°F depending on the location in the house. However, Figure 7 shows that this temperature was reached 78°F only two of the ten days, and that the average peak indoor temperature was actually 76°F or less.

Figure 17 plots the maximum indoor temperature against the average outdoor temperature over the 5-day design sequence for the four control options. Except for the last air conditioner option, the maximum indoor temperatures for the other three options correlate quite well to the average outdoor temperature over the 5-day design sequence, with a secondary effect when the average temperature on the hottest day is significantly higher than that for the entire 5-day period. When the windows are closed, the maximum indoor temperature is roughly 8° higher than the average outdoor air temperature, with another 2° increase if one of the five days is particularly hotter than the other four. Of the 171 climates, only a handful of coastal locations have maximum indoor temperatures falling within the Comfort Line at 78°F. With mechanical ventilation, the maximum indoor temperatures are now 6°F higher than the average outdoor temperature in the cooler locations, and 2° higher in the hotter locations, with roughly a third of the locations falling within the Comfort Line. With indirect evaporatively-cooled ventilation, the maximum indoor temperatures are now roughly the same as the average outdoor temperature in the hotter locations, so that nearly half of the 171 locations have maximum indoor temperatures below the Comfort Line. With a $1\frac{1}{2}$ ton air-conditioner, the maximum indoor temperatures are held within a degree of 78°F until the average outdoor temperature over the 5-day period exceeds 86°, at which point the air-conditioner cannot meet the cooling load.

3.2 Hourly temperature profiles

Figures 3 through 14 show 12 representative hourly temperature plots for selected California locations: four extending inland from the Bay Area, four for the Los Angeles area, and four for the San Diego area. The format is identical on the twelve plots, with the outdoor drybulb shown as a thin solid line, the outdoor wet-bulb as a thin dashed line, and the indoor temperatures for 1500 CFM mechanical ventilation (Vent), indirect evaporatively-cooled ventilation (IEC), and a 1½ ton air-conditioner (AC) shown as thick solid, dashed, and dotted lines, respectively. A thick horizontal line at 78°F indicates the upper limit of the comfort zone.

Figures 3 and 4 show that mechanical ventilation is adequate in Northern California locations in the vicinity of the Bay Area. Although the daytime peak temperatures in Martinez and Walnut Creek are quite high, they are offset by large diurnal swings and low nighttime temperatures that facilitate night cooling. Because ventilative cooling is stopped when the indoor temperature drops to 65°F, there is little difference between the Vent and IEC options.

Figures 5 and 6 show that as one proceeds further inland, the extremely high daytime outdoor peaks cause maximum indoor temperatures to rise to nearly 80°F in Fairfield and Davis, although an indirect evaporatively-cooled ventilation system will still keep them below the Comfort line (78°F).

Figures 7 and 8 for Los Angeles (LAX) and Pasadena show striking differences in design temperature conditions and cooling performance as compared to in Northern California. At LAX, the peak temperatures are low but the temperature swings are also small, due to the marine influence at the coast. The house performs satisfactorily under all three modes, but the nighttime cooling potentials are minimal. In Pasadena, the daytime peak outdoor temperatures are now in the 90's, while the nighttime outdoor lows are near 70°F, greatly reducing night cooling potentials as compared to in Northern California. Consequently, both the mechanical venting and indirect evaporatively-cooled systems result in maximum indoor temperatures from the mid to low 80's. The improvement in indoor temperatures with the indirect evaporatively-cooled system, however, is significantly more than in Northern California due to its ability to capture some night cooling potential. Figure 15 shows that this performance is constrained by the 1500 CFM fan size and control strategy. Figures 9 and 10 show the cooling performance further inland in Pomona and Riverside to be similar to that in Pasadena.

Figures 11 and 12 are for San Diego airport and Bonita. In San Diego, the nighttime outdoor minima are so high and the diurnal outdoor temperature swings so minimal that the

mechanical venting system could not provide any night cooling, resulting in indoor temperatures that exceed 80°F on the fourth day. In Bonita, however, the system performed quite satisfactorily.

Figure 13 and 14 show that further inland, the indirect evaporatively-cooled system seems to be sufficient in La Mesa. However, the $1\frac{1}{2}$ ton air-conditioner is needed in El Cajon. In both locations, mechanical ventilation alone will result in peak temperatures in the low 80's in La Mesa and in the mid 80's in El Cajon.

Figures 15 and 16 show the results in Pasadena and La Mesa when the fan size is doubled from 1500 to 3000 CFM, and the indirect evaporative cooling control is improved to check the actual evaporatively-cooled supply air temperature. In both cities, the performance of the mechanical venting is not improved because the air temperatures are too high to permit much use. However, the increased air flow rate clearly increased the cooling capacity of the indirect evaporatively-cooled system, so that the house in Pasadena overheated by 1°F or so on three of the five days, a level of performance similar to that achieved using the $1\frac{1}{2}$ ton air-conditioner.

3.3 Mapping of indoor temperatures

The simulated performance of the "Summer Comfort House" in 171 California locations is entered into the commercial *DISSPLA* mapping software to produce contour maps of the state that show the geographical distribution of applicability for the various cooling options. The contour maps for four cooling options (1500 CFM mechanical ventilation, 1500 CFM indirect evaporatively-cooled ventilation, 1½ ton air conditioner, and 3000 CFM indirect evaporatively-cooled ventilation) are shown in Appendix A.1 through A.8. The average outdoor temperatures over the 5-day design sequence are mapped in Appendix A.9 and A.10, while the names of the 171 locations are mapped in Appendix A.11 and A.12. Some words of caution are needed about these contour maps. Only a few of the 171 locations are located in the mountainous areas, which show up on the contour maps as odd bull-eyes. The contour mapping routine also is not aware of coastal conditions, resulting in concentric contours around each station rather than parallel to the coast as common sense would indicate. Despite these shortcomings, the maps are useful in turning a large amount of numbers into coherent pictures that quickly reveals the geographical applicability for each cooling option.

On Figures 18 and 19, the 79°F contours for each cooling option are combined to show the regions for which each is appropriate for the prototypical house. These are labeled as

Vent for 1500 CFM mechanical ventilation

IEC for 1500 CFM indirect evaporatively-cooled ventilation

IEC+ for 3000 CFM indirect evaporatively-cooled ventilation with improved controls

AC for $1\frac{1}{2}$ air-conditioner with a 1500 CFM fan

AC+ for conventional sized air-conditioner

The reason for using 79° instead of the 78°F comfort line (and cooling setpoint for the air conditioner) is to make allowances for a small 1°F "deadband" that occurs even with mechanical air conditioning.

3.4 Annual heating and cooling performance

Although the primary criteria for the acceptability of the Summer Comfort House are the maximum indoor temperatures reached during peak cooling conditions, there was a secondary concern about the building's energy use over the entire year. The building's annual energy performance was calculated by repeating the DOE-2 simulations using the California Energy Commission's weather tapes for the 16 climate zones defined for Title-24 calculations (California Energy Commission 1980, 1992). Because the building model and operating assumptions used in this study differed from those used for Title-24 compliance calculations, the annual simulations were done in three ways -(1) with the original building conditions and operating assumptions, i.e., low internal loads level due to the use of energyefficient appliances and shading from neighboring buildings to the north and south, (2) with Title-24 building conditions and operating assumptions, i.e., Title-24 level of internal loads and no shading from neighboring buildings. and (3) with Title-24 building conditions, operating assumptions, and conservation levels, i.e., the house had it been built to Title-24 requirements for wall and roof insulation, window type, and medium gray color on the roof and walls.

The results from the three sets of runs are shown on Table 2, and plotted in Figures 20 and 21. The use of Title-24 operating conditions resulted in a 10-20% reduction in the calculated heating energy use, and up to a 15% increase in the calculated cooling energy use. This is the offset due to the DOE-2 modeling of shading and internal gain conditions beyond those considered in Title-24 conditions. Using the Title-24 operating conditions as a neutral benchmark for comparison, Table 2 shows that the prototypical design uses 40% less heating fuel in Northern California, 50% less in Southern California, and 25% less in the Central Valley, than the same house built to Title-24 requirements. In cooling and fan electricity, the prototypical design saves from 50% up to 70% compared to the same house built to Title-24 requirements. In Figure 22, the annual fuel and electricity usages have been converted to costs at \$0.60/Therm and \$0.10/kWh, and summed to derive total annual energy costs. These show the annual energy costs of the prototypical design to be roughly 30-40% lower than the same house built to Title-24 requirements.

Table 3 gives further information about the impact from each of these parameters on the calculated building performance – Title-24 internal loads, insulation levels, and glass type, wall and roof color, carpeted floor, and shading from neighboring houses. The most important parameter that increased the prototypical building's heating loads is its low internal loads, with shading from neighboring buildings, partially exposed floor space, and light-colored walls and roofs all of similar impact. These heating penalties are, however, more than offset by the savings due to the higher wall and roof insulation levels, and improved glazing.

4.0 CONCLUSIONS

With the 1500 CFM mechanical ventilation system, the building is comfortable during the 5day design sequences in the San Francisco Bay Area out to Walnut Creek, but not beyond, i.e., Livermore, Fairfield. It's also adequately comfortable for San Luis Obispo and the inland areas of Santa Barbara, but starting from Los Angeles, indoor comfort would be maintained only at the coast, with the exception of San Diego.

With the 1¹/₂ ton air conditioner, the house will not maintain adequate indoor comfort in the upper areas of the Central Valley (Red Bluff), the deserts east of Los Angeles and San Diego counties, and is marginally adequate in the Fresno area.

With the 1500 CFM indirect evaporatively-cooled ventilation system and a crude dry-bulb temperature minus 10°F control logic, the building is comfortable in Northern California to Fairfield and Livermore, but in Southern California only 10 miles inland. With the 3000 CFM system and a better indicator for the cooled air temperature, the building would work in half of greater Los Angeles, the southern half of the Inland Empire, and most of San Diego county. In Northern California, the building would be comfortable from the San Francisco Bay Area out to Davis and Sacramento.

In terms of energy use, the prototypical house requires substantially less than the same building built to Title-24 requirements, with annual cost savings ranging from 0.20 to 0.43 in northern California, 0.20 to 0.53 in southern California, and 0.16 to 0.35 in the Central Valley. The energy performance of the prototypical house compared to other houses in general, however, is difficult to evaluate due to differences in house size, surface-to-volume ratio, solar gain, and other architectural details.

5.0 ACKNOWLEDGEMENTS

The author wishes to express his thanks to Zhou Lei, a visiting scholar from China, for his help in the DOE-2 simulations and recreating the plots and maps for this final report, Zhang Hui for extracting the design sequence temperature data for the UCEI project, and to George Loisos, David Springer, Leo Rainer, and other members of the Alternatives to Compressive Cooling project for their support and patience.

California Energy Commission 1980. "Assumptions Used with Eenergy Performance Computer Programs", 1980 Residential Building Standards Development Project Report No. 7, P400-80-026, Building and Appliance Standards Office, California Energy Commission, Sacramento CA.

California Energy Commission 1992. 'Climate Zone Weather Data Analysis and Revision Project', Final Report, prepared for the Energy Efficiency and Local Assistance Division and the Building and Appliance Office, by Augustyn + Company, Albany CA, under contract No. 400-88-010, Sacramento CA.

Colliver, D. G., H. Zhang, R. S. Gates, and K. T. Priddy 1996. "Determination of the 1, 2¹/₂ and 5% occurences of extreme dew-point temperatures and mean coincident dry-bulb temperatures. *ASHRAE Transactions*, American Society of Heating, Refrigerating, and Air-Conditioning Engineers, Atlanta GA.

Loisos, G. and S. Ubbelohde 1996. "Summer comfort house Lorimer Team schematic design", report to the California Institute for Energy Efficiency, Berkeley CA.

Winkelmann, F.C, B.E. Birdsall, W.F. Buhl, K.L. Ellington, A.E. Erdem, J.J. Hirsch and S. Gates 1993. "DOE-2 BDL Summary, Version 2.1E", LBL-34946, Lawrence Berkeley National Laboratory, Berkeley CA.

Zhang, Hui and Y.J. Huang 1999. "Climatic data for the assessment of alternative cooling technologies in California", final report to the University of California Energy Institute, Center for Environmental Design Research, University of California, Berkeley CA, also LBNL Report 42965, Lawrence Berkeley National Laboratory, Berkeley CA.

Appendix C. Modeling of Foundation Heat Flows in Design Simulations with DOE-2.1E

This section describes the general approach used to model foundation heat flows for the design simulations of the prototype "Alternatives to Compressive Cooling" house. This modeling issue has been studied with some detail because 1) the thermal storage effects of the floor slab can have a significant impact in moderating indoor temperatures during peak cooling periods, and 2) the standard modeling method in DOE-2 for underground heat transfer is extremely simplified and provides very little guidance for even a first-order approximation of heat flows.

The approach used in this analysis is to separate the floor slab into two surfaces – a "perimeter" section assumed to respond in a delayed fashion to outdoor air temperature, and a "core" section assumed to respond only to long-term ground temperatures. These sections should be considered less as physical sections, but as modeling abstractions, since the heat flows of the "perimeter" also include the long-term heat flows of the "core" region. In the design sequence simulations, the "perimeter" heat flows would respond with a 2-3 day delay to the increased outdoor air temperatures, but the "core" heat flows are assumed to be unaffected by such transient effects. This is done by modeling the "core" in DOE-2 as an UNDERGROUND-FLOOR with an annual sinusoidal monthly GROUND-TEMPERATURE profile.

The foundation heat flows were calculated for a one-ft cross-section for the following foundation conditions in three transitional climates using a two-dimensional finite-difference program, *hdbk.c*, originally developed by the University of Minnesota's now-defunct Underground Space Center (Labs et al. 1988) :

Cover	Insulation condition	<u>Climate zones</u>
rug	uninsulated and insulated	CTZ04, 09, 13
wood	uninsulated and insulated	CTZ04, 09, 13
dirt	uninsulated and insulated	CTZ04, 09, 13

Another utility program, *fdnreg.f*, was then used to calculate average heat fluxes per ft² for the perimeter and core regions of the foundation. The annulus method was used to extrapolate to a typical 28x55 building foundation. The discrepancy between this footprint and the "Alternatives" prototype should be insignificant. *fdnreg.f* outputs give the indoor/outdoor temperature difference, perimeter heat flow, and core heat flow per ft² of area.

For the "perimeter" region, linear regressions were done between the heat flows and the indoor/outdoor temperature difference, and the resulting slope used as the U-value for a DOE-2 EXTERIOR-WALL. The residuals from this regression are added to the heat flows for the "core" section. These heat fluxes were then reduced to a sine curve, and used to calculate DOE-2 GROUND-TEMPERATUREs which would produce the same heat flows given the appropriate indoor zone temperature and floor slab U-value.

Table C.1 gives the results for the linear regressions for the "perimeter", and sine curve regressions for the "core" region heat flows.

C.1 'Perimeter' Section

The averaged regression slopes from CTZ04 and CTZ09 are used since these two are most representative of Transition Climates. Furthermore, interpolated Slopes are developed for the half carpet/half wood and half carpet/half tile cases. These U-values are listed in Table C.2. To dampen air temperature fluctuations, 2 ft. of dirt are included in the foundation layer. In addition, a resistance layer is added to produce the desired conductivity from Table C.2. The layer-by-layer R-values are listed in Table C.3.

* note : Rugn'Pad R = 2.08; 5/16'' Wood R = $1/(.02604' \times .0667) = 0.3904$; 3/16'' Tile R = $1/(.015625' \times .800) = 0.01953$

"Core" Section

Long-term climatic data from the UCEI project was used to define the annual monthly maximum and minimum ground temperatures. These are :

Location	2% Summer	0.6% Winter	Range	Average	74°F - Average
Fresno_SAN	97	30	67	63.5	10.5
Pasadena	88	40	48	64.0	10.0
Sunnyvale	80	36	44	58.0	16.0

1. Since UNDERGROUND-FLOOR heat flows in DOE-2 are calculated as UA x (T_{gnd} - T_{in}), T_{gnd} and U can be adjusted to produce the desired Q. Since the regressions were done per ft² of floor area, A drops out :

 $Qc = U * (T_{gnd} - T_{in}) = amp * cos((im - phase)*0.5236) + inter2$

 $T_{gnd} = T_{in} + (amp * \cos((im - phase)*0.5236) + inter2)/U$

For the core areas, I modeled the same floor layers as defined for the perimeter section. The U-values are given in Table 1.

• AMP is estimated using the annual Range from the UCI climate data defined as the difference between the winter 0.6% and summer 2.0% design temperatures. Linear regressions for the 3 locations give good results, granted that the number of data points is very small. Values for the half carpet cases are averaged from the uniform covering cases :

	Insul	ated	Uninsu	ulated
	Amplitude	Range	Amplitude	Range
Carpet	0.00810	0.19634	0.01040	0.24213
Wood floor	0.00905	0.21813	0.01179	0.27038
Tile	0.00999	0.23838	0.01294	0.28726
1/2 carpet, 1/2 wood	0.00858	0.20723	0.01110	0.25625
¹ / ₂ carpet, ¹ / ₂ tile	0.00905	0.21736	0.01167	0.26470
Dirt			0.01033	0.23164

INTER2 is estimated from the average annual temperature difference from the UCI Project defined as T_{in} - (sum20pct + win6pct)/2. For the slab cases, this is 74°F - (sum20pct + win6pct)/2. Values for the half carpet cases are averaged from the uniform covering cases :

Foundation Type	Intercept for Insulated cases	Intercept for Uninsulated cases
Carpet	03883 * (Tin - AvgT) - 0.26053	04589 * (Tin - AvgT) - 0.24299
Wood Floor	04236 * (Tin - AvgT) - 0.27767	05138 * (Tin - AvgT) - 0.25496
Tile	04602 * (Tin - AvgT) - 0.28993	05711 * (Tin - AvgT) - 0.26064
¹ / ₂ Carpet, ¹ / ₂ Wood	04060 * (Tin - AvgT) - 0.26910	04863 * (Tin - AvgT) - 0.24898
¹ / ₂ Carpet, ¹ / ₂ Tile	04243 * (Tin - AvgT) - 0.27523	05150 * (Tin - AvgT) - 0.25182
Dirt		03403 * (Tin - AvgT) - 0.12223

• PHASE values seem not to correlate to easily identifiable temperatures. They also do not vary that much between locations. Therefore, average phase lags are calculated from the three locations. Values for the half carpet cases are averaged from the uniform covering cases :

	Phase values						
Foundation type	Insulated	Uninsulated					
Carpet	-2.496	-3.238					
Wood Floor	-2.796	-3.308					
Tile	-2.871	-3.370					
¹ /2 Carpet, ¹ /2 Wood	-2.646	-3.273					
¹ / ₂ Carpet, ¹ / ₂ Tile	-2.683	-3.304					
Dirt		-2.990					

T_{in} is set to 74°F for slab and 60°F for crawl space foundations.
