Abstract Combination antiretroviral therapy (CART) has greatly reduced medical morbidity and mortality with HIV infection, but high rates of HIV-associated neurocognitive disorders (HAND) continue to be reported. Because large HIV-infected (HIV+) and uninfected (HIV-) groups have not been studied with similar methods in the pre-CART and CART eras, it is unclear whether CART has changed the prevalence, nature, and clinical correlates of HAND. We used comparable methods

of subject screening and assessments to classify neurocognitive impairment (NCI) in large groups of HIV + and HIV - participants from the pre-CART era (1988–1995; $N=857$) and CART era (2000–2007; $N=937$). Impairment rate increased with successive disease stages (CDC stages A, B, and C) in both eras: 25%, 42%, and 52% in pre-CART era and 36%, 40%, and 45% in CART era. In the medically asymptomatic stage (CDC-A), NCI was significantly more common in the

CART era. Low nadir CD4 predicted NCI in both eras, whereas degree of current immunosuppression, estimated duration of infection, and viral suppression in CSF (on treatment) were related to impairment only pre-CART. Pattern of NCI also differed: pre-CART had more impairment in motor skills, cognitive speed, and verbal fluency, whereas CART era involved more memory (learning) and executive function impairment. High rates of mild NCI persist at all stages of HIV infection, despite improved viral suppression and immune reconstitution with CART. The consistent association of NCI with nadir CD4 across eras suggests that earlier treatment to prevent severe immunosuppression may also help prevent HAND. Clinical trials targeting HAND prevention should specifically examine timing of ART initiation.

Keywords HIV · Combination antiretroviral therapy · HIV dementia

Introduction

Since the beginning of the HIV/AIDS epidemic, HIV-associated neurocognitive disorders (HAND) have been commonly observed in infected populations (American Academy of Neurology AIDS Task Force 1991; Antinori et al. 2007). These conditions, ranging from subtle neuropsychological impairments to profoundly disabling HIV-associated dementia, are more frequently seen in advanced stages of HIV disease (AIDS) but can occur even in individuals having medically asymptomatic HIV infection (CDC 1993 Stage A; Grant et al. 1987; Heaton et al. 1995; White et al. 1995). Moreover, HAND confers an increased risk for early mortality, independent of medical predictors (Ellis et al. 1997a; Mayeux et al. 1993), and often interferes significantly with cognitively demanding activities of daily living (e.g., employment, medication management, driving; Heaton et al. 2004b; Hinkin et al. 2004; Marcotte et al. 1999, 2004).

The availability of combination antiretroviral therapy (CART) since 1996 has successfully controlled HIV viremia and improved immune function in many treated, HIV-infected (HIV+) patients, leading to dramatic improvements in medical morbidity and life expectancy. Clear improvement in neurological outcomes in the era of CART also has been achieved, with a significant drop in the rate of frank HIV-associated dementia (Dore et al. 2003; Robertson et al. 2007; Sacktor et al. 2002). Pre-CART prevalence estimates were approximately 16% in AIDS cases (McArthur et al. 1993), whereas more recent estimates are less than 5% (Heaton et al. 2010). Further benefits of CART on the broader spectrum of HAND have been suggested by studies of neurocognitive change in HIV + groups initiating CART regimens. A recent review of 15 such studies indicated that 11 found some improvement in neurocognitive test performance after an average of

6 months on CART, although most studies had relatively small sample sizes and did not control for practice effects on repeated testing (Joska et al. 2010).

Unfortunately, however, beneficial effects of CART on neurologic manifestations of HIV infection, especially HAND, have been less than complete (McArthur and Brew. 2010). Neurocognitive responses to CART have been varied across individuals, and studies of HAND in treated patients have documented high persisting rates of mild-to-moderate neurocognitive impairment (NCI). For example, Robertson et al. (2007) assembled data on 1,160 HIV + patients involved in 14 different clinical trials involving CART. All participants completed a brief neurocognitive battery at least 20 weeks after randomization to treatment; 921 participants completed a follow-up exam 48 weeks later. Prevalence of NCI was 39% at baseline. Although 44% of those with NCI at baseline appeared to show CART-related improvement at follow-up (performed within the “normal” range, but with no apparent correction for practice effect), 21% of participants who were NC normal at baseline experienced incident impairment at follow-up. As a result, the total rate of NCI at follow-up was not very different from that at baseline (34% vs. 39%). In another study of persisting NCI on CART, Tozzi et al. (2007) followed 94 treated patients for a mean of 5 years (multiple assessments). All had NCI at baseline, and 63% showed persisting impairment; however, this could be an underestimate because, again, it is unclear whether or not they controlled for practice effects on the neurocognitive tests. A third recent study reported HAND in 69% of 200 HIV + patients who had maintained good virologic response (undetectable HIV RNA in plasma on CART) over a median of 48 months (Simioni et al. 2010).

Causes of continuing high rates of HAND in the CART era are uncertain, but multiple non-exclusive possibilities have been suggested: irreversible brain injury prior to initiating CART, incomplete viral suppression in the central nervous system (CNS) due to poor CNS penetration of some commonly used antiretroviral drugs and/or presence of drug-resistant viral strains, the possibility that even very low levels of viral replication in the CNS could result in neural injury or dysfunction due to prolonged exposure to inflammatory responses and neurotoxic viral proteins, possible neurotoxicity of antiretroviral therapy (ART) drugs, and exposure to other conditions that may affect cognition in long-term survivors, such as increased rates of metabolic abnormalities and associated vascular pathology or increased B-amyloid deposition in the brain.

In sum, although the most severe form of HAND, HIV-associated dementia, appears to be much less common in the era of CART, questions remain about any long-term benefit of CART with respect to milder forms of HAND. These abnormalities remain highly prevalent, and it is unclear whether their nature, pathophysiological mecha-

nisms, and clinical predictors have changed. Optimal comparison of HAND across time requires consistent definitions and testing, substantial representative cohorts, and sufficient knowledge of context including non-HIV (comorbid) conditions to achieve informative analysis.

This study compares baseline neuropsychological (NP) and neuromedical findings of two large cohorts of HIV + and HIV – participants who were recruited and assessed as part of a long-range program of research coordinated by the UCSD HIV Neurobehavioral Research Center (HNRC). Through collaborations with multiple institutions (listed in the acknowledgements), we performed comparable neuromedical and neurocognitive examinations on 857 participants from the pre-CART era and 936 from the CART era. Participants were recruited through advertisements and outreach to various communities and health care providers. It should be noted that these were not referral populations (i.e., not weighted to persons suspected or known to have neurologic disease). An almost identical NP test battery covering seven ability domains was used to classify HAND according to recently published international guidelines (Antinori et al. 2007). In order to provide comparable exclusions and minimize the effects of comorbid conditions on NP results, potential participants in both cohorts were carefully screened and excluded if they had any history of significant non-HIV-related risks for cognitive impairment. Rates of HAND were compared across eras in subgroups that were stratified by HIV serostatus and clinical stage of infection (HIV – controls vs. CDC 1993 stages A, B, and C). (Although the 2008 CDC classification system has de-emphasized the distinction between historic, asymptomatic, and mildly symptomatic HIV disease, we included all three stages in the current analyses to provide links with earlier studies of HAND and because most of our participants had been classified before the new guidelines were published (Centers for Disease Control 2008).) Immunological and virological predictors of HAND also were assessed and compared across eras. Finally, to explore possible qualitative differences in neurobehavioral outcomes, we compared severity and patterns of impairment across the seven ability domains for HIV + participants from the two eras.

Results

Demographic, psychiatric, and neuropsychological comparisons of treatment era subgroups

Table 1 displays the demographic characteristics, psychiatric history, and NP status of the treatment era participants, stratified by HIV serostatus and CDC-1993 disease stage. Consistent with CDC HIV/AIDS surveillance reports, demographic differences reflect changes in the US HIV/

AIDS epidemic over time, i.e., the infected population is somewhat older and contains higher proportions of females and ethnic minorities, as well as higher proportions of people reporting any history of injection drug use or who reported heterosexual contact as their only infection risk (Centers for Disease Control and Prevention 1992, 1994, 1996, 2000, 2004, 2008). CART era patients also tended to have slightly lower education levels than pre-CART era participants. Because classification of NCI was done using demographically corrected test norms, the demographic differences between treatment era groups did not bias the NCI prevalence estimates across time; i.e., there are no meaningful demographic differences between participant groups with and without NCI in either treatment era cohort (see Table 3).

As is typical of HIV + groups and HIV – controls with similar risk backgrounds, fairly high lifetime prevalence rates of major depressive disorder and substance use disorders are observed in both eras; however, fewer individuals met the criteria for current diagnoses at the time of testing (i.e., met diagnostic criteria for a DSM-defined disorder within the last 30 days). Higher rates of lifetime substance use disorders were seen in the CART era groups (Table 1), but these conditions were not related to NCI in the HIV + groups from that era (Table 3).

In both treatment eras, increased rates of NCI are seen when comparing seronegative controls and subgroups at successive CDC stages of (historic) HIV disease, in a stair-step pattern (Fig. 1). Although there are no treatment era differences in NCI rates among seronegative controls or infected individuals in CDC stages B and C, impairment rate among CART era participants in CDC stage A is higher than that in their pre-CART counterparts (36.2% vs. 25.2%, $p=0.001$). While in the pre-CART era rates of moderate to severe impairment (consistent with HIV-associated dementia) increased in subgroups with successively more advanced CDC stages of HIV disease (4%, 12%, and 17% for CDC stages A, B, and C), this pattern was not seen in the CART era subgroups (7–8% for all disease stages).

Characteristics of HIV infection and treatment in pre-CART and CART era HIV + participants

Table 2 shows HIV disease data for infected subgroups. The participants in both treatment eras who had more advanced CDC stage reported longer durations of known infection, but there was a significantly larger (threefold) difference in estimated disease duration between treatment era subgroups at each disease stage. Irrespective of disease stage, the CART era participants had been infected longer, reflecting improved survival. Patterns of nadir and current immunosuppression were also significantly different for the two treatment era cohorts: the CART era participants tended

to have much lower nadir CD4 cell counts, especially in participants with less advanced clinical disease histories (i.e., CDC stages A and B). On average, the CART era participants in all three disease stages were more likely to be receiving ART and had much greater immune improvement (difference between nadir and current CD4). Also, consistent with expected differences in treatment effects, being on ART was associated with a significantly higher (twofold) likelihood of achieving plasma viral suppression in the CART era (undetectable viral RNA), but not in the pre-CART era. Similar patterns are seen for suppression of HIV in cerebrospinal fluid (CSF) (see Table 2).

Pre-CART vs. CART era associations between NCI and demographics, psychiatric histories, HIV disease and treatment characteristics, and everyday functioning

Table 3 addresses possible treatment era differences in associations between NCI and other variables of interest. Impaired participants were very slightly older (not a clinically significant difference), and no other demographic characteristics (education, gender, or ethnicity), were associated with impairment. NCI is associated with unemployment, reports of cognitive difficulties in everyday life (Patient’s Assessment of Own Functioning Inventory), and

^c Cell counts shown as median (interquartile range)

current depressive symptoms (Beck Depression Inventory) in both eras.

Associations between NCI and infection risk categories and psychiatric history differed between the two treatment era cohorts (Table 3). In the pre-CART cohort, a history of lifetime (but not current) substance use disorders was associated with NCI. This association was not found in the CART era cohort even though those participants had

much higher rates of (mostly remote) alcohol and other substance use disorders. Indeed, those with NCI in the CART era were less likely to have prior substance use disorders (54.9% vs. 61.7% for NC normal; chi-squared=3.92, $p < 0.05$).

Turning to disease and treatment-related correlates of NCI, low nadir CD4 counts increased risk for NCI in both treatment eras. In contrast, impairment was also related to

^a Cell counts shown as median (interquartile range)

duration of infection and current degree of immunosuppression only in the pre-CART era. Also, although Table 1 indicates that higher rates of NCI were seen with more symptomatic disease histories (CDC-1993 stages A vs. B

vs. C) in both treatment eras, associations of NC outcomes with disease history are significant and independent of nadir CD4 only pre-CART; i.e., when nadir CD4 is covaried in the analyses, more symptomatic CDC-1993

disease stages were associated with worse NP Global Ratings in the pre-CART ($F(df=3, 669)=15.8, p<0.0001$; $A < B < C$) but not in the CART-era cohort ($F(df=3, 843)=1.8, p=0.14$). Antiretroviral (ARV) treatment itself was associated with NCI only in the CART era, but this “effect” is statistically significant only for CDC stage B. Immune improvement on treatment (current CD4 minus nadir CD4) was minimal in the pre-CART era and substantial in the CART era, but in neither era was this related to NCI. Treatment reduced HIV viremia only in the CART era, but successful viral suppression in plasma did not relate to lower risk of NCI in either era. Finally, in treated individuals, NCI was associated with failure to achieve viral suppression in the CSF in the pre-CART era, but not in the CART era.

Treatment era differences in pattern of impairment across ability domains

Figure 2 displays the rates of impairment across the seven major ability domains for the participants with NCI in each treatment era. NCI in the pre-CART era was more often characterized by deficits in motor speed/dexterity, speed of information processing, and verbal fluency, whereas the learning and executive function domains were more affected in the CART era.

Discussion

In one of the few prior direct comparisons of HAND in the pre-CART ($n=272$) and CART ($n=251$) eras, Sacktor et al. (2002) found no significant difference in prevalence rates of NCI in large but demographically very different cohorts of HIV + patients who were comparably screened for comorbidities. However, the high rates of observed impairment (74.3% vs. 76%) may have occurred because both cohorts were specifically selected for being at high risk for

NCI (low CD4 cell counts and/or clinical evidence of impairment).

A second previous direct comparison of pre-CART ($n=51$) and CART ($n=90$) era groups was conducted by Cysique et al. (2004) in Australia. These investigators studied demographically similar HIV + groups in the same university clinic, in which participants all had AIDS (i.e., CDC stage A3, B3, or C) and were carefully screened for comorbid conditions but were not selected based upon perceived risk for NCI. A slightly different test battery was used with the pre-CART and CART era participants, but the use of normative standards based upon demographically matched HIV-uninfected (HIV-) controls from each era helped assure comparability of impairment classifications. Rates of NCI in this study were much more typical of clinical populations selected only for having strict comorbidity exclusions and were similar for the pre-CART and CART groups (41% vs. 39%). Interestingly, NCI patterns differed between the two groups, suggesting that patterns of CNS pathology may have changed in the CART era (Joska et al. 2010).

The current study is most similar to that of Cysique et al. (2004) in that we assembled groups of participants who were not selected for being at high risk for NCI from the two treatment eras. The test batteries and methods for classifying NCI also were somewhat different in the two studies, and yet rates of NCI were quite similar for participants with comparable disease stage (all HIV-infected participants in the Cysique et al. study had AIDS): pre-CART rates were 41.1% for the Cysique et al. study versus 37.4% in the current study, and CART era rates were 38.8% in the Cysique et al. study versus 38.5% in this study.

The current study extended the findings of prior NCI comparisons in the two HIV treatment eras by providing data from large, well-characterized samples of HIV - controls and HIV + participants across the full spectrum

Fig. 2 NP Domain impairment in pre-CART and CART era HIV+ samples with NCI. *SIP* speed of information processing, *Learn* learning efficiency, *Recall* delayed recall, *Attn/WM* attention/working memory, *Exec* executive function; * $p<0.05$; ** $p<0.01$; *** $p<0.001$

of HIV disease. We found that CART era participants with medically asymptomatic or minimally symptomatic disease histories actually had a higher NCI rate than their pre-CART counterparts. This was true despite the facts that more CART-era participants who had remained medically asymptomatic were receiving antiretroviral therapy and that, as a group, they had comparably mild degrees of current immunosuppression and were much more likely to have viral suppression in both plasma and CSF. Although they had significantly higher rates of lifetime substance use disorders and longer durations of infection, treatment era differences in these factors were present at all disease stages and were unrelated to NCI in the CART era cohort. We suggest that the most important difference between CDC-A participants in the two eras that may have contributed to their different NCI rates is that participants in the CART era had much lower nadir CD4 cell counts. The era difference in nadir degree of immunosuppression (nadir CD4) is much larger for CDC-A than for the other disease stages, and low nadir CD4 was a robust predictor of NCI in both treatment eras. In fact, our finding regarding the importance of a low nadir CD4 as a risk for HAND has been reported now in multiple large studies in the USA (Heaton et al. 2009; Robertson et al. 2007) and other countries (Cysique et al. 2009; Munoz-Moreno et al. 2008; Tozzi et al. 2005).

The fact that NCI was associated with being on ART only in the CART era raises the question of whether some of the newer ARV medications may have toxic effects on the CNS. Although this possibility cannot be ruled out and deserves further study, it cannot be adequately evaluated in a cross-sectional study because clinical decisions about when to initiate treatment are based upon indicators of disease severity (nadir CD4 and medical symptoms) that themselves are risks for NCI. In any event, the increased rate of NCI among CART era (vs. Pre-CART) participants who were medically asymptomatic (CDC stage A) cannot be explained by neurotoxic effects of ARVs because NCI was not significantly related to treatment status in these individuals.

There were intriguing shifts between pre-CART and CART eras when we focus on more severe NCI (i.e., those meeting Frascati neurocognitive criteria for HAD; Antinori et al. 2007). Whereas in CDC stage C disease, the rate of HAD level NCI in the CART era was less than half that of the pre-CART era (6.9% vs. 16.7%, $p < 0.01$; Table 1), the rate of more severe NCI was actually higher in the CART era at CDC stage A (7.1% versus 3.6%, $p < 0.05$). It is possible that the fact that CART era CDC stage As had a greater likelihood of experiencing prior CD4 < 200, plus their longer survival with chronic immune stimulation might be playing a role in increasing their risk for evolving brain (neurological) complications.

Prior studies in both pre-CART and CART eras have demonstrated associations between NCI and HIV RNA levels

in the periphery (Childs et al. 1999; Ferrando et al. 1998; Nath et al. 2008) as well as in the CSF (Brew et al. 1997; Cysique et al. 2009; Ellis et al. 1997b; Letendre et al. 2004; McArthur et al. 1997). However, recent reports indicate that viral suppression on treatment is not sufficient to avoid development or persistence of NCI (Marra et al. 2009; Simioni et al. 2010). Prior analyses of data from the current CNS HIV Antiretroviral Therapy Effects Research (CHARTER) cohort (from which our CART era cases were drawn) suggested that the best neurocognitive outcomes may be associated with a combination of successful viral response to CART and absence of historical severe immunosuppression (nadir CD4 < 200; Heaton et al. 2010). In the present study, treated subgroups from neither era demonstrated an association between NCI and viral suppression in plasma; however, non-detectable virus in CSF was a positive indicator of normal cognitive function in the pre-CART subgroup only. Our findings support other observations that certain biomarkers of CNS disease that seemed promising in the pre-CART era (e.g., CSF viral load) are not so useful in the CART era (Cysique et al. 2005).

Both our study and the Cysique 2004 study found treatment era differences in pattern of NCI that might be consistent with a shift toward more cortical (vs. subcortical and white matter) involvement in the CART era. A problem with interpreting these differences as reflecting a shift toward greater cortical pathology is that the test battery is not specifically designed to detect such distinctions (e.g., more coverage of language and visuospatial functions would be desirable). Whether such differences in pattern of NCI are truly related to differences in type or distribution of HIV-related brain injury will require correlative work with studies that also employ neuroimaging or postmortem neuropathological analyses.

The limitations of this study include the fact that we cannot rule out cohort differences in this study that are unrelated to HIV or its treatment, especially given the demographic and HIV risk background differences in these samples, which mirror differences in the US epidemic over time (Centers for Disease Control and Prevention 1992, 1994, 1996, 2000, 2004, 2008). However, we attempted to adjust for demographic effects on neurocognitive test performances by using the same age-, education-, gender-, and ethnicity-corrected normative standards. Also, other than a trivial age difference between impaired and unimpaired participants (statistically significant only in pre-CART), none of these demographic variables related to NCI. Similarly, none of the lifetime or current psychiatric disorders assessed here (MDD and alcohol or other substance use disorders) were consistently related to NCI across treatment eras nor was the risk factor of “any IDU history” (per selection criteria, this was not current and not complicated by associated significant overdoses or traumatic brain injuries). Although HIV infection risk backgrounds also

differed between treatment era cohorts, these were unrelated to NCI in the pre-CART era; in the CART era cohort, having “only heterosexual contact” was the sole reported HIV risk factor associated with a higher rate of NCI.

NCI was classified and characterized in our two treatment era cohorts using a largely overlapping test battery (11 of 14 individual test measures were the same) covering the same seven ability constructs and using the same standardized methods consistent with recently published guidelines for diagnosing HAND (Antinori et al. 2007). However, three of the individual test measures did differ and helped to measure attention/working memory, processing speed, and executive functioning in somewhat different ways. On the other hand, each of these ability domains had at least one common test measure across eras. To keep the assessments as comprehensive as possible, we elected to include the three substitute tests in the main analyses reported here; however, when we excluded these measures, rates of NCI did not change significantly across HIV serostatus and disease stage subgroups.

HIV viral loads in plasma and CSF were neither available nor standard of care throughout much of the pre-CART era and were not assayed in our research program until the later part of that era. Also, the limit of detectability was higher in these earlier assays (400 vs. 50 copies per milliliter in the CART era studies). As a consequence, we had very limited viremia and CSF viral load data for the pre-CART HIV + cohort, and an “undetectable” finding did not necessarily mean the same thing across treatment eras. Nevertheless, the availability of these determinations for pre-CART participants was linked only to timing of the assessments (no other selection bias). Also, to permit at least preliminary treatment era comparisons involving viral suppression on treatment, we retrieved and analyzed all available stored samples on pre-CART participants to obtain total sample sizes of 110 (55 each for plasma and CSF) with NCI and 176 (85 for plasma and 91 for CSF) without NCI. Impairment rates were similar for the pre-CART participants with and without viral load determinations, suggesting that the subgroups with viral load data were fairly representative. The main finding of a pre-CART association between NCI and failure of CSF viral suppression on treatment was statistically significant despite the reduced sample size (total $N=138$) for this analysis.

In sum, we found high rates of NCI in large HIV + cohorts tested in the pre-CART and CART eras. The only significant treatment era difference was in the medically asymptomatic stage, in which a higher rate and severity of impairment was seen in the CART era participants. The latter CART era subgroup also had the largest discrepancy (relative to their pre-CART counterparts) in nadir CD4 cell counts. Due to the major degree of immune reconstitution and viral suppression seen with the CART-treated partic-

ipants, current CD4s and viral loads were no longer significant indicators of risk for NCI. The fact that low nadir CD4 was a similarly robust predictor of impairment in both eras is consistent with the view that early severe immunosuppression may initiate at least partially irreversible changes in the CNS and that earlier treatment aimed at protecting patients from these processes may improve CNS outcomes (Heaton et al. 2010). In view of the persisting high rates of NCI in the CART era, especially in HIV + individuals with a history of low nadir CD4s, clinical trials are needed to assess the value of initiating treatment in neurocognitively normal persons before they become markedly immunosuppressed. This type of longitudinal study, in which treatment is not linked to evidence of advancing disease, also may provide the most interpretable information about potentially neurotoxic effects of ARVs.

Materials and methods

Subjects

Pre-CART subjects were selected from the original cohort of the HNRC at the University of California San Diego. This subgroup consisted of 179 HIV-uninfected (HIV-) and 678 HIV-infected (HIV+) participants who had been enrolled into the HNRC study between December 1988 and December 1995. Exclusionary criteria for these subjects included any history of neurologic disorders and other conditions (e.g., psychiatric disorder with psychotic features, medications with CNS effects) known to affect neurocognitive performance

HIV seronegative cases for CART era comparisons ($n=94$) were selected from a larger group of HIV - subjects enrolled in the NIDA Program Project “Effects of Methamphetamine and HIV” at the HNRC. Subjects were enrolled between May 1999 and May 2004 and had the same exclusion criteria as the pre-CART cases.

The HIV + CART subjects ($n=843$) in this study were drawn from the six participating university centers of the CHARTER study: Johns Hopkins University (Baltimore, MD, $n=99$), Mt. Sinai School of Medicine (New York, NY, $n=152$), University of California San Diego (San Diego, CA, $n=179$), University of Texas Medical Branch (Galveston, TX, $n=142$), University of Washington (Seattle, WA, $n=137$), and Washington University (St. Louis, MO, $n=134$). Subject recruitment began in September 2003 and ended in August 2007.

While there were no formal exclusion criteria for participation in the CHARTER study, we utilized the online supplement to the Antinori et al. (2007) report which provided detailed guidelines for classifying the most commonly encountered comorbid conditions with respect to whether they should be considered incidental, contributing, or confounding. The comorbid conditions specifically

addressed in the guidelines include developmental disabilities, alcohol and other substance use disorders, traumatic brain injuries and other non-HIV-related neurologic conditions, systemic diseases including co-infection with hepatitis C virus, and HIV-related opportunistic CNS disease. Although it was recognized that it would be impossible to specify how to rate the full range of potential comorbid conditions and their combinations, the guidelines for the conditions just mentioned exemplified the following basic concepts: (1) incidental conditions are those that may affect neurocognitive performance to a minor degree but would be unlikely (by themselves) to cause an individual to be classified as significantly “impaired”; (2) contributing conditions could cause at least mild neurocognitive impairment, but the severity, nature, and/or timing of the impairment and associated disability make it likely that the currently observed impairment and functional decline also represent significant effects of HIV; and (3) confounding conditions are those that could fully explain significant neuropsychological impairment and currently observed problems with everyday functioning; HIV effects cannot be reliably inferred in these cases. For the purposes of this study, only those CHARTER participants deemed to have incidental comorbidity ($n=843$) were used for the CART era HIV + cases.

Procedures

Standard protocol approvals, registrations, and patient consents

These procedures were approved by the Human Subjects Protection Committees of each participating institution. Written informed consent was obtained from all study participants.

Neuromedical examination

Neuromedical examination procedures included medical history, structured neurological and medical examination, as well as collection of blood and urine samples. These procedures were performed by physicians, nurse practitioners, or trained nurses and research associates. The staff performing neuromedical and NP assessments was certified by the coordinating center (University of California, San Diego).

Laboratory assessment

HIV infection was diagnosed by enzyme-linked immunosorbent assay with Western blot confirmation. Routine clinical chemistry panels, complete blood counts, rapid plasma reagin, hepatitis C virus antibody, and CD4+ T cells (flow cytometry) were performed at each site’s Clinical Laboratory Improvement Amendments (CLIA)-certified, or CLIA equivalent, medical center laboratory. HIV RNA levels were measured

centrally in plasma and CSF by reverse transcriptase-polymerase chain reaction (Roche Amplicor, v. 1.5, lower limit of quantitation 50 copies per milliliter).

Neurobehavioral examination

All the participants completed a comprehensive neurocognitive test battery, covering seven cognitive domains known to be commonly affected by HIV-associated CNS dysfunction (administration time=2–2.5 h; see Table 4 for listing of

Table 4 Tests and Sources of Normative Data for the Neuropsychological Battery

Cognitive Domain and Test	Normative Data

specific tests). The best available normative standards were used, which correct for effects of age, education, sex, and ethnicity as appropriate. Test scores were automatically converted to demographically corrected standard scores (*T* scores) using available computer programs. To classify presence and severity of neurocognitive impairment, we applied a published objective algorithm that has been shown to yield excellent interrater reliability in previous multisite studies (Woods et al. 2004). This algorithm conforms to the Frascati criteria for diagnosing HAND (Antinori et al. 2007), which require presence of the least mild impairment in at least two of the seven ability domains.

Although the neurocognitive test batteries between the HNRC (pre-CART era) and CHARTER (CART era) studies were similar, there were some test substitutions in the neurocognitive test battery for the CART era subjects. The WAIS-III Symbol Search Test was used in place of the time (speed) component of the Digit Vigilance Test; the WAIS-III Letter Number Sequencing Test was used in place of the WAIS-R Digit Span Test; and the Wisconsin Card Sorting Test 64 Card Version was used in place of the Halstead Category Test. All test substitutions were determined to be tapping the same cognitive domain as the original test, and secondary analyses were performed to ensure similar patterns of findings with respect to NCI rates in treatment era and CDC stage group comparisons.

Psychiatric examination

Psychiatric diagnoses were assessed using the Structured Clinical Interview for DSM-IV (SCID; First et al. 1994) for the pre-CART subjects or the computer-assisted Composite International Diagnostic Interview (CIDI) (World Health Organization 1997) for the CART subjects. Both are structured instruments widely used in psychiatric research. The SCID and CIDI classify current (within the last 30 days) and lifetime diagnoses of mood disorders and substance use disorders, as well as other mental disorders. Current mood was assessed with the Beck Depression Inventory (BDI) or the Beck Depression Inventory-II (BDI-II; Beck et al. 1961, 1996).

Functional impairment in everyday life

Reports of cognitive difficulties in everyday life were assessed using the Patient's Assessment of Own Functioning Inventory (PAOFI; Chelune et al. 1986). The PAOFI includes 33 items on which participants rate themselves as having neurobehavioral difficulties in their everyday lives. Domains of memory, language and communication, sensory-perceptual and motor skills, and higher-level cognitive functions are assessed. A total summed score is derived, with higher scores indicating more difficulty.
